We present the detailed result for this scenario in Table 5, which includes the number of configurations considered as the current configuration (the second column) and three metrics to measure the performance of `LearnPerf`. To simplify our discussion below, we refer to a configuration and all its neighbors as a *region*. Each region includes at least 100 neighbors or includes all neighbors that add types to up to seven parameters. The first metric (column three in the table) is the accuracy. For any given configuration, if the most performant neighbor identified by `LearnPerf` is among the three neighbors with least execution times, then we classify this as a correct identification. We consider top three neighbors because it is common for many neighbors to have very small difference in execution times. The accuracy is calculated by dividing the number of correct identifications over all regions considered for that benchmark. For example, for Scimark, we considered 500 regions, and for 408 regions `LearnPerf` made correct identifications. As a result, the accuracy is 81.6%.

The second metric (column four in the table) is the average differences between the execution times of the real and the identified most performant neighbors. For example, if the real most performant neighbor for a region has an execution time of 4.73s and the identified neighbor has an execution time of 4.75s, then the time difference is 0.02s. This column records the average of differences of all regions for that benchmark. The third metric (column five in the table) calculates the time difference in percentage.

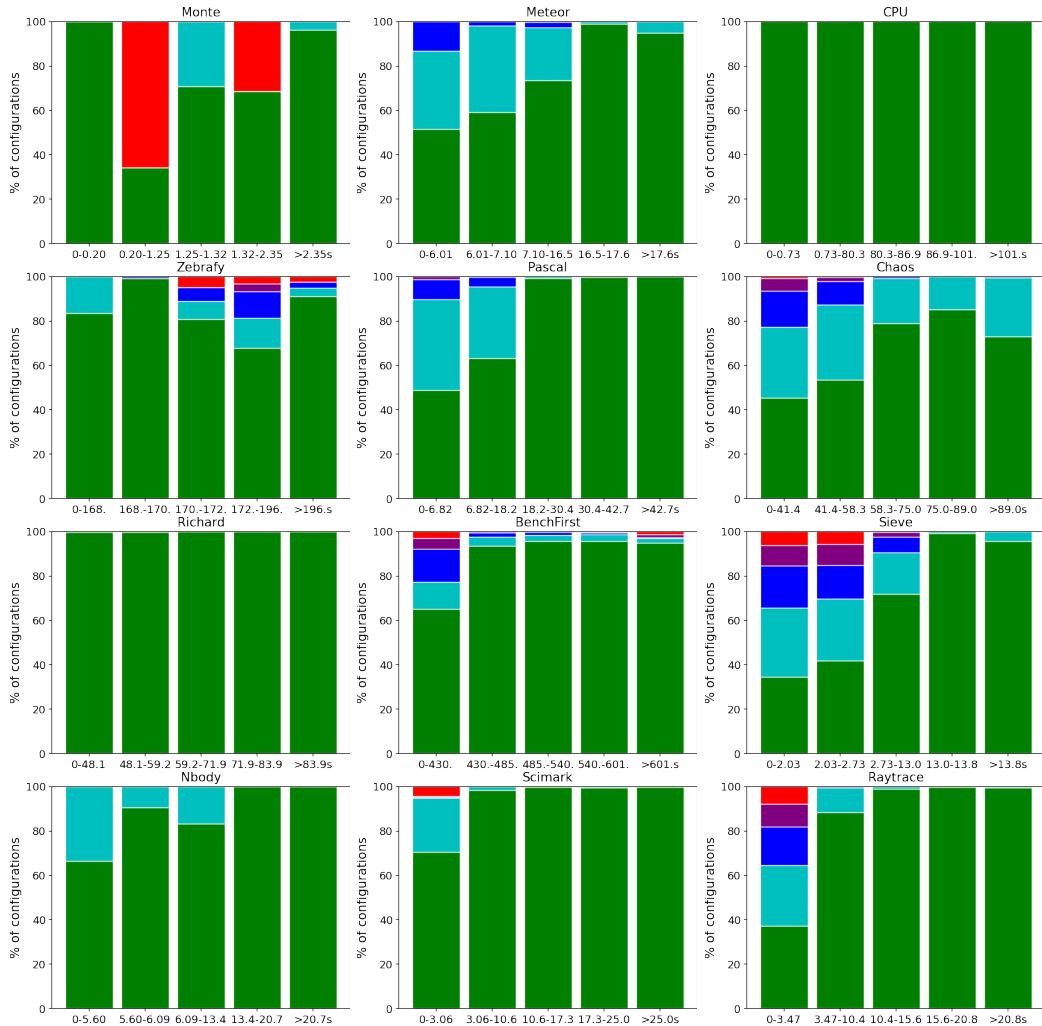

Figure 8 LearnPerf detailed benchmark's performance based on different measured run time groups.

Again, the table shows that our approach is very accurate in identifying the most performant neighbors, with the difference ratio always below 1% except for Pascal that has a 2.4% DR.

5.4 Training and Prediction Times

Table 6 presents times needed for generating and measuring 40 configurations for training the model, the time for training the model once these 40 configurations are ready, and the average feature extraction time for each program. We do not present the prediction time because that is less than 1ms for each configuration. From the table, we can see that the most time in our approach is spent on measuring the running times for training the model.

For some benchmarks, measuring the times is relatively fast, such as for Monte Carlo, Meteor, Sieve, Nbody, Scimark, and Raytrace. However, it takes significantly longer to measure the times for some benchmarks, including CPU, Zebrafy, Chaos, Richard, and BenchFirst. The reason is that each configuration from these benchmarks takes a long time to complete. Usually, this large amount of measuring time will lead to a long response time. Also, it looks like this long waiting time is hard to avoid.

21:20 Learning Gradual Typing Performance

Table 5 LearnPerf's performance on finding the most performant neighbor to migrate for each benchmark.

Benchmark	# of regions	Accuracy	Average difference(s)	difference ratio
Monte Carlo	42	100%	0.0	0%
Meteor	500	77.0%	0.032	0.338%
CPU	38	94.74%	0.004	0.998%
Zebrafy	89	98.88%	0.007	0.087%
Pascal	500	44.80%	0.171	2.388%
chaos	297	83.16%	0.059	0.88%
Richard	98	100%	0	0%
BenchFirst	113	93.81%	0.004	0.058%
Sieve	500	63.6%	0.020	0.685%
Nbody	500	34.60%	0.116	1.246%
Scimark	500	81.6%	0.021	0.344%
Raytrace	385	96.88%	0.007	0.034%

Table 6 Training and Prediction time of Each benchmark.

Benchmark	Measuring 40 configurations (s)	Training(s)	Feature extraction (ms)
Monte Carlo	53.27	1.00	10.98
Meteor	490.06	0.99	23.38
CPU	2997.87	3.3	1001.96
Zebrafy	7394.38	4.75	1012.30
Pascal	580.05	1.01	40.89
Chaos	2654.87	1.03	29.15
Richard	2462.77	1.99	1013.33
BenchFirst	21816.94	3.89	1112.32
Sieve	373.33	1.02	19.67
Nbody	488.94	0.99	25.86
Scimark	555.68	0.99	27.73
Raytrace	623.55	2.98	26.17

Fortunately, with the help of type migration tools, we can significantly shorten the response time. The idea is that we start to measure the runtimes way before the user needs the migration support. We tested this idea by automating the process of generating type information for parameters with HiTyper, merging the generated type information into the original program, randomly generating configurations for training, running all generated configurations to measure their runtime duration, extracting features for these configurations, and training a time prediction model based on the collected times and extracted features. We tested this idea on three large benchmarks, including CPU, Zebrafy, and BenchFirst.

Once the model has been trained, predicting the running time is very fast. Since feature generation is also very efficient, we can quickly provide migration support with the model. For example, for any given configuration, LearnPerf is able to find the most performant neighbor within a few seconds.

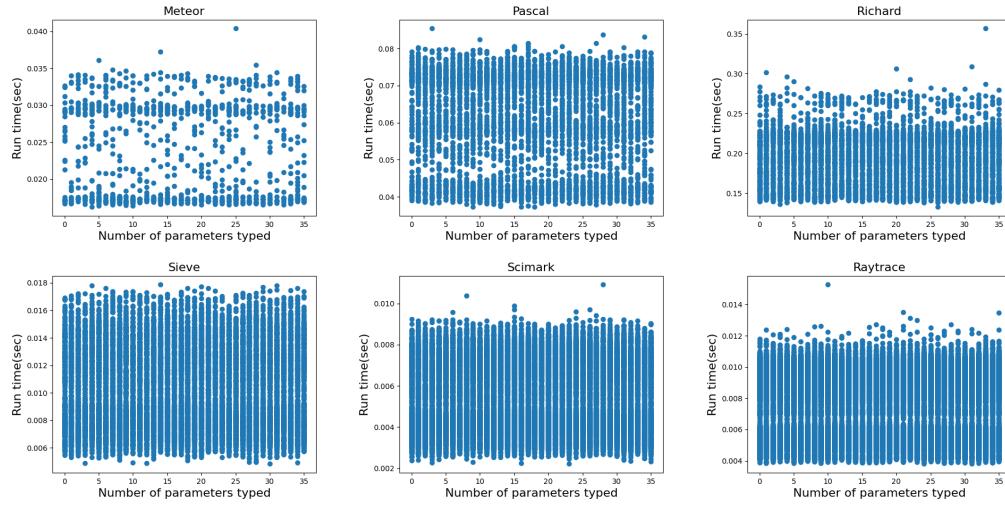

Figure 9 The relation between run times and the number of parameters that have type annotations for six benchmarks for transient semantics.

5.5 Different Machine Learning Methods

We used linear regression to train our model. During the development of `LearnPerf`, we also explored other machine learning algorithms, including random forest regression, decision tree regression, and AdaBoost regression. We decided to use linear regression for the following reasons. First, linear regression usually does not need too many training instances. In our case, 40 training instances yield good performance. Second, training and prediction with linear regression is very fast than other models. Third, linear regression yields good performance across all benchmarks. For example, while random forest achieves 1.38% and 1.19% *DRs* for Monte and Sieve, respectively, the *DRs* for Raytrace and Scimark are above 13%.

We also tried some other famous Machine learning models, such as support vector machine regression and MLP regression, but they either need more training instance or take more times for training and prediction. Also, they do not outperform linear regression for our problem.

5.6 Evaluation of Transient Semantics

In addition to evaluating the performance of `LearnPerf` on the guarded semantics, we have also evaluated it on the transient semantics (Vitousek et al. [47]) using the same benchmarks. In our feature extraction code for transient semantics, we set all the return values of *callOH*(\cdot) in Figure 5 to 0 because transient casts do not introduce proxies.

Figure 9 presents the runtime distributions for six benchmarks under transient semantics. We omit the other six because their distributions are similar. Comparing this figure to Figure 7 we observe that the runtimes in transient semantics are several magnitudes smaller than in guarded semantics. Also, the runtimes have smaller variations across different configurations.

Table 7 presents the performance of `LearnPerf` for the transient semantics. We can observe that the *DR* is much higher than that for guarded semantics. Meanwhile, we observe that the *MAE* and *MSE* are close to 0. This indicates that a possible reason that *DR* is relatively high because the runtime of each configuration is very smaller, usually below 0.1 seconds. A small randomness in measured time can lead to a high *DR* in this case.

 **Table 7** Overall performance of `LearnPerf` for the transient semantics.

Benchmark	# training	# testing	MAE	MSE	DR
Monte Carlo	40	344	0.002 ± 0.0	0.004 ± 0.0	31.43%
Meteor	40	984	0.005 ± 0.01	0.006 ± 0.0	25.09 %
CPU	40	2857	0.01 ± 0.0	0.02 ± 0.08	18.91%
Zebrafy	40	3960	0.001 ± 0.0	0.003 ± 0.0	27.77%
Pascal	40	5144	0.01 ± 0.0	0.013 ± 0.0	18.549%
Chaos	40	5960	0.02 ± 0.0	0.06 ± 0.0	34.38%
Richard	40	5960	0.027 ± 0.0	0.033 ± 0.0	24.93%
BenchFirst	40	5960	0.033 ± 0.0	0.087 ± 0.0	25.88%
Sieve	40	15321	0.002 ± 0.0	0.001 ± 0.0	29.07%
Nbody	40	16344	0.003 ± 0.0	0.005 ± 0.01	21.78%
Scimark	40	25048	0.001 ± 0.0	0.001 ± 0.0	27.129%
Raytrace	40	33864	0.001 ± 0.0	0.002 ± 0.0	25.497%

Overall, our approach works pretty well for transient semantics also. The main insight is that the algorithm in Figure 5 derives coefficients of cast overheads rather than the real runtime overhead of casts. The overhead of a transient cast (checking type tags) can also be estimated using coefficients.

5.7 Threats to Validity

It may be possible that the results observed in our evaluation do not transfer to other Python programs. We have done the following to reduce this possibility. (1) We chose the benchmarks that are commonly used in the literature for evaluating gradual typing performance as well as three large Python programs (details in Section 5.1). (2) The evaluated programs cover most commonly used language features in Python, including control structures such as conditionals and loops, functions, classes with inheritance, tuples, dictionaries, nested lists, etc. (3) The amount of typed parameters can have a big impact on the results. As shown in Table 5, the percentages that parameters have types are quite diverse, ranging from about 50% (Meteor and Zebrafy) to about 100% (Monte Carlo, Sieve, and Nbody). (4) The kinds of casts in translated programs could also affect the performance of `LearnPerf`. After checking the translated programs, we observed the presence of simple casts (about 63% of all casts) between basic types as well as higher-order casts (about 37% of all casts) between function types, list types, and object types. (5) Each time is an average of 10 runs and each machine learning experiment is averaged over 5 trials.

6 Related Work

Understanding performance changes during migration. While a lot of work has been done to automatically migrate dynamic programs toward more static, little work has been done to aid the performance aspect during program migration except for a few efforts.

Our work is closely related to the work by Campora et al. [8]. They developed HERDER to help navigate the performance landscape during migration. However, there are many differences between `LearnPerf` and HERDER. First, `LearnPerf` is able to precisely predict a time for any configuration while HERDER is able to find only a symbolic overhead for each configuration. There is no direct mapping from these symbolic values to real runtimes

and so the relation between two symbolic values often does not carry over to the real runtimes. For example, two configurations from a single benchmark have symbolic values $2 * \ell_3 * \ell_4$ and $67 * \ell_3 * \ell_4$, respectively, while their corresponding runtimes are 24.79 and 37.38 seconds, respectively. As a result, several migration supports are possible with `LearnPerf` but not `HERDER`, such as classifying neighbors of a certain configuration based on their speedup/slowdown ratios.

Another difference is that, since our approach is based on machine learning, we only need to extract approximate values for features. `HERDER`, however, is based on static analysis and needs to be very accurate. For example, in `LearnPerf`, the overhead for a function cast is a simple addition of creation overhead and invocation overhead. In `HERDER`, a function cast needs to be transformed to an intermediate language to simulate the creation of proxies. As a result, it is easier to support more language features in `LearnPerf` than in `HERDER`. For example, we support object and class types, but they were missing in `HERDER`.

Greenman et al. [15] also investigated the performance problem during program migration but from a very different perspective. Through a large-scale empirical study, the authors studied how outputs from profilers may be exploited for proving migration supports. They considered seventeen strategies for how to avoid configurations with unacceptable performance and navigate to configurations to acceptable performance. Through the study, they generated three useful lessons for developers and one lesson for language designers for how to deal with the performance problem. Their focus is very different from our work in that we aim to predict the runtime for each configuration, and provide other migration supports, such as finding the best performing configuration among the neighbors, on top of that.

Assessing and Optimizing Gradual Typing Performance. Takikawa et al. [41] evaluated the performance of Typed Racket, focusing on the areas mixing untyped and typed code. The evaluation revealed significant runtime overhead in sound gradual typing. In evaluating the performance of a gradual type system, Greenman et al. [16] conducted a thorough analysis by fully annotating a series of benchmarks in Typed Racket. Absolute performance calculations were derived by generating a significant subset of configurations from the complete lattice of possible configurations. Performance ratios for each configuration were then compared against base configurations to identify K-step and D-deliverable configurations.

Since the report of the performance problem in gradual typing, a lot of work has been done to solve this problem, ranging from designing new type systems or new languages, inferring more types to reduce casts, to developing more efficient cast languages.

Rastogi et al. [34] introduced a type inference algorithm for existing gradually typed code, especially focusing on the inflow and outflow of types. Their approach supports open-world soundness to enable sound interactions with unseen code. Instead, Nguyen et al. [27] used static analysis to remove casts that always succeed without considering open-world soundness.

The idea of developing new languages to avoid expensive interactions has been explored by Muehlboeck et al. Muehlboeck and Tate [26]. Several approaches have been developed to exploit compilers or JITs to improve gradual typing performance Rastogi et al. [35], Richards et al. [36], Bauman et al. [5]. Another important line of improving gradual typing performance is through the design of new or change cast constructs Feltey et al. [12], Kuhlenschmidt et al. [20]. The work by Allende et al. [4] designed confined gradual typing, allowing users to control the flowing of type information through type annotations for reducing expensive boundary crossings.

Our approach is complementary to these approaches in that they do not try to compare the performance of different configurations and identify performant configurations. Also, while these approaches optimize the performance of gradual programs, they often do not

fully reduce the overheads due to runtime type checks. This paper shows that our approach works well for both the guarded and transient semantics. It looks promising in applying our idea to the translated programs from these approaches to predict the performance of these optimized programs.

Machine Learning for Programming. Many machine learning based approaches have been developed for solving programming language and software engineering problems Wan et al. [49], Allamanis et al. [2]. A main trend is using deep models, such as large language models, to automatically extract code features. Interestingly, our exploration shows that deep learning approach does not produce a good model for performance prediction for our problem. Vo and Nguyen [48] observed a similar phenomenon for vulnerability detection.

7 Conclusion

With gradual typing, developers enjoy the benefits of both static and dynamic typing. A major obstacle of adopting gradual typing is that the runtime overhead when going from less typed regions to more typed regions is often high and unpredictable. To address this issue, we developed a machine learning-based solution named `LearnPerf` that approximates runtime overheads due to inserted casts. We have evaluated our approach on 12 Python benchmarks, with each of the three large benchmarks having more than 1000 LOC. The evaluation results demonstrated that `LearnPerf` is able to precisely predict the execution time of each configuration. On top of that, we can develop further migration supports, such as finding the most performant neighbor of a configuration when it has poor performance. Our approach works well for both guarded and transient semantics. In the future, we would like to extend our approach to support a more macro level gradually-typed language, such as Typed Racket. It is also interesting to investigate if our approach can be employed to predict the performance of optimized gradual programs.

Abstract

Many object-oriented applications in algorithm design rely on objects never changing during their lifetime. This is often tackled by marking object references as read-only, e.g., using the `const` keyword in C++. In other languages like Python or Java where such a concept does not exist, programmers rely on best practices that are entirely unenforced. While reliance on best practices is obviously too permissive, const-checking is too restrictive: it is possible for a method to mutate the *internal state* while still satisfying the property we expect from an “immutable” object in this setting. We would therefore like to enforce the immutability of an object’s *abstract state*.

We check an object’s immutability through a *view* of its abstract state: for instances of an immutable class, the view does not change when running any of the class’s methods, even if some of the internal state does change. If all methods of a class are verified as non-mutating, we can deem the entire class view-immutable. We present an SMT-based algorithm to check view-immutability, and implement it in our linter/verifier, CONSTRCTOR.

We evaluate CONSTRCTOR on 51 examples of immutability-related design violations. Our evaluation shows that CONSTRCTOR is effective at catching a variety of prototypical design violations, and does so in seconds. We also explore CONSTRCTOR with two real-world case studies.

1 Introduction

Object-oriented code routinely manipulates objects and passes around references to them, some of which are stored in other objects. Parts of the code often rely on some object not being changed during its lifetime. This may be in order to uphold some properties as thread safety [30], security [50] and the stability of invariants [31], allow the use of features like interning [11], or improve the readability of the code [24]. Other considerations include information leakage [50] and concurrency [30]. For these reasons, client code may be written under the assumption that objects on which it relies do not change.

22.2 Constrictor: Immutability as a Design Concept

In each of these use cases, the term *immutability* denotes some set of specific assumptions about the object that the use case requires: when used from multiple threads, an object's fields must be available to read without data races; to be safe to pass into an API, the client programmer wants to know foreign code is not going to break the API's relied-upon invariants; when used as a key in a hash table, the library assumes that the hash value of the object is going to remain constant. Despite different needs relying on different assumptions, programming practices rely on one of two solutions: (i) documentation-based agreements at the project or language level [44] that delegate all responsibility to human users, or (ii) annotations that can be checked by the compiler or some external tool.

The first option is extremely expressive – as expressive as humans are – but has the obvious downside of the risk of human error. In the scope of checked annotations, some language features provide some steps in this direction: C++'s `const` keyword and Java's `final` that designate fields and variables as read-only. However, neither of these is a good match for the cases described above: `final` only blocks assignment to a field or variable, but the referenced object can still be mutated via function calls, and `final` does not provide guarantees about object fields unless those happen to be `final` as well.

C++'s `const` is seemingly a better fit, but is still not expressive enough. First, a similar problem to `final` still exists, where a pointer/reference being `const` and its content being immutable are still managed separately (e.g., `const A* const`), and that decision is still left to the programmer. In addition to that, `const` can be used on a specific method, indicating that the method cannot mutate any fields. This does not allow declaring an entire interface as immutable, only certain method; and other methods, particularly ones introduced via inheritance, can mutate any field, including those accessed by `const` methods. The semantics of `const` cannot be used to enforce the property that an interface and all its implementing hierarchy be immutable. In addition to this, for some use-cases it is too restrictive not to be able to assign to *any* field, so C++ also allows marking fields as `mutable` (can be changed even from `const` methods). It is then, again, the user's responsibility to use this annotation responsibly, and no formal guarantees are provided by the compiler.

Immutability in class hierarchies. When provided with an interface or class that is supposed to be immutable, a programmer would like to take advantage of this immutability for purposes of design simplicity or for various optimizations. However, implementing classes and subclasses can introduce unwanted mutations. Languages like Java and C# handle this by marking key library classes (e.g., strings) as `final` or `sealed`. This still does not protect the user from contract mismatches within the library implementation; and, moreover, it precludes legitimate extensions of classes in ways that do not violate the immutability guarantees. This is one of the instances for which the Liskov Substitution Principle (LSP) [39] applies; inheritance as a language mechanism cannot enforce the preservation of properties, and lack of mutations is one such property. The LSP is a *principle*, rather than a *mechanism*, because it is not always possible to distinguish implementations that preserve the properties and ones that do not; and because the properties themselves are often implicit.

Kotlin collections are an interesting example – Figure 1 shows a truncated version of two interfaces, `List` and `MutableList`, from the Kotlin standard library. As summed up by a Google developer [37]:

MutableList, as the name implies, is a list that has operations to mutate, or change, its contents: add, remove, and replace items. It's easy to come to the conclusion that the List type must therefore be immutable. That's not the case. Lists are "read-only", but they may or may not be mutable. [...] The MutableList interface extends the List interface, so it's very easy to create a list that you can change, but pass it around to other code so that code can only read it, even as you're still making changes.

```

interface List<E> {
    operator fun get(index: Int): E
    fun indexOf(element: E): Int
    operator fun contains(element: E): Boolean
    // truncated
}

interface MutableList<E> : List<E> {
    fun add(element: E): Boolean
    fun remove(element: E): Boolean
    fun clear()
    // truncated
}

class Foo(val someList: List<Int>) {
    init { // called during object construction
        assert(0 in someList)
    }
    fun doStuff() {
        // some stuff
        val idx = someList.indexOf(0) // implicit assumption:
                                       // init assert still holds!
        // some more stuff
    }
}

```

 **Figure 1** List and MutableList from Kotlin and client code.

In other words, since `MutableList` instances are also `List` instances, the best we can say is that `List` does not allow mutation and does not forbid mutation. An understandably-confused programmer may create an instance of the `Foo` class (line 17 of Figure 1) using a `MutableList`, which will be allowed by the type-checker. The list might at first satisfy the initial assertion, but the programmer may then clear it before calling `doStuff`. `doStuff` relies on the assertion in the constructor and dereferences a now-empty list, due to the mistaken assumption that `List` objects cannot change. Kotlin’s list hierarchy keeps us from taking advantage of the type checker to enforce our design decisions.

This shows how immutability-related violations of the LSP are particularly insidious. For this reason, the Scala standard collections library and the Guava libraries for Java fully separate their mutable collections from the immutable ones [5, 7, 21].

Object state: concrete vs. abstract. One possible solution is to “freeze” the memory: create a copy of an object that disallows mutation of all fields. This “freeze” could be shallow (as C++’s `const` would create) or deep (essentially an expensive clone). Such a shallow “freeze” operation exists in languages such as JavaScript [8] and Ruby [4]. Both approaches have significant disadvantages as mentioned, and are not widespread. Moreover, object fields are sometimes used for internal bookkeeping in ways that permits – and requires – to update their values in situations where the object’s content is not conceptually changed. An example of this can be seen in `ImmutableLookupList` (Figure 2), where the field `lookupCache` is used for memoizing calls to `indexOf`. While the class indeed mutates this field, it does so in a way that is non-observable to the user. In such cases, memory freeze is too strong, as it would disallow these updates. This requires the same kind of escape hatch that `mutable` provided for `const`, which yet again puts the burden on the programmer to decide which fields present part of the visible state. In some cases, the distinction is not even possible, because a field may produce a visible effect for some, but not all, of the ways in which it can be mutated.

22:4 Constrictor: Immutability as a Design Concept

```

class ImmutableList<E> : List<E> {
    private var lookupCache: CacheEntry<E, Int>?
    val backingArray: Array<E>
    override fun indexOf(elem: E): Int {
        if(this.cache != null && this.cache!!.first == elem)
            return this.cache!!.second

        var ret = -1
        for(i in backingArray.indices())
            if(backingArray[i] == elem) {
                ret = i
                break
            }

        this.cache = CacheEntry(elem, ret)
        return ret
    }
    // truncated
}

```

Figure 2 A class that mutates fields but not in an observable way.

For example, in the standard implementation of the union-find data structure [33], some mutations to the pointer structure may cause visible mutation while others are just different ways of expressing the same data.

The problem with `ImmutableLookupList` is actually a problem with considering `lookupCache` to be part of the state. It is, of course, part of the *concrete state* of an `ImmutableLookupList` object, i.e., it is part of the memory allocated for the object. However, let us consider how `ImmutableLookupList` looks to an external observer: `lookupCache` is used in the implementation of the method `indexOf`, and mutated by it, but this mutation is not observable – through `indexOf` or any other method of `ImmutableLookupList`. It is, in other words, an “implementation detail”, never exposed to any client code. It does not impact the *abstract state* of the object [54]. What we need, therefore, is immutability of the *abstract state* of the object.

1.1 Our approach: views and view immutability

In order to separate the abstract state from the fields pertaining to internal implementation, we define an object’s *view*: the set of methods that expose the abstract state to the rest of the system. The guarantee we want, then, is that if the view of an object is immutable, and this property is enforced down the inheritance tree, the immutable hierarchy can safely accommodate mutations of internal state. An enforcement mechanism less rigid than `const` or frozen objects can allow optimizations like memoization and caching, while disallowing the introduction of visible mutation into the hierarchy.

We define for each object two sets of methods, the set of immutable methods I , annotated by the programmer as `@immutable`, which are methods that do not mutate the abstract state of the object, and the set of view methods V , annotated as `@viewmethod`, whose return values define the object’s abstract state. In the common case, $V \subseteq I$, and so `@viewmethod` also indicates `@immutable` (this is not theoretically required, but conserves user effort). Marking the class as `@immutable` has the same effect as marking each of the class’s methods as `@immutable`, with one notable distinction: the class annotation is inherited, and applies to *all* methods of the inherited class, including new methods that were not inherited from its parent class.

We then define the notion of *view-immutability* with regards to the view V such that when calling any method from I , the object’s internal state may change, but the abstract state exposed by V does not. While checking this property is not tractable, we show a relaxed property that can be checked, that implies the stronger property under certain conditions.

The notion of view-immutability is meant to be checked in a modular way – there is no need to verify anything regarding the client code, only the data structures themselves. We expect that common data structures in libraries be annotated with `@immutable` as needed, and client code can use these data structures with the desired guarantees.

Our theory is flexible enough to support weaker notions of immutability, e.g., temporary mutability during an init phase [51], or temporary *immutability*, e.g., immutable references in the type system guaranteeing that referenced objects do not change, as in Rust [40].

We implement our approach in a linter/verifier for Python programs named CONSTRUCTOR. We translate each class to an SMT encoding using our translating compiler, Py2SMT, then check whether each of the methods in I are indeed non-mutating.

Lightweight verification. CONSTRUCTOR does not verify the code for correctness; rather, it checks for adherence to design decisions, which is an easier problem. However, it can still fail: CONSTRUCTOR’s analysis is bounded, and its reliance on SMT inherits the solver’s limitations. Even with these limitations, CONSTRUCTOR can still act as a contract-checker. This hinges on the fact that immutability violations are usually not bugs but rather unintended violations of conscious design decisions made by different programmers, and as such, they rarely hide from the programmer – or from CONSTRUCTOR. Empirically, the immutability property depends *mostly* on the program’s dataflow and not on complex relationships between values. Sometimes there are some correlations that need to be tracked, e.g., in Figure 2 the cache variable’s value is returned to client code, and so needs to be consistent with a real value/index in the list. When the SMT solver returns *unknown*, there are two options: if CONSTRUCTOR is run as a verifier, these unknowns will be treated as violations, whereas if it is run as a linter, only violations for which the solver has returned an answer will be displayed to the user.

We evaluate CONSTRUCTOR on 51 examples of immutability-related design violations. Our evaluation shows that CONSTRUCTOR is effective at catching a variety of prototypical design violations, and does so in seconds. We also explore CONSTRUCTOR with two real world case studies, one fixing a design problem in a collections module, and the other introducing memoization into an immutable design pattern. Moreover, we explore human errors that could be made when providing CONSTRUCTOR with annotations.

Contributions. The contributions of this paper are:

- A definition of *view immutability*, and a relaxed definition that can be statically checked.
- An SMT-based algorithm for checking view immutability.
- Py2SMT, a compiler that encodes Python functions for SMT solvers.
- CONSTRUCTOR, a verifier/linter that implements our algorithm for Python programs.
- An empirical evaluation of CONSTRUCTOR and detailed analysis of the results.²

2 Overview

CONSTRUCTOR is a linter/verifier for Python, so, from now on, the examples will be written in Python. The general concepts are identical and we will be using full type annotations.

We continue our running example that consists of a list library that includes the interface `LookupList` in Figure 3. This interface only contains methods that allow for the *inspection* of instances of its implementors. The programmer’s intent was that instances of `LookupList` should not be mutated (visibly) through their methods. Users of the library rely on this assumption, which until now was only enforced by comments and naming conventions.

² Our replication package is available as a DARTS artifact [36].

22:6 Constrictor: Immutability as a Design Concept

```
@immutable
class LookupList[E]:
    @viewmethod
    def __getitem__(self, idx: int) -> E:
        pass

    def index_of(self, element: E) -> int:
        pass

    @viewmethod
    def get_size(self) -> int:
        pass
```

Figure 3 A Python interface for a list class with an `index_of` method.

The programmer seeks to formalize this assumption: they add the `@immutable` annotation `LookupList`. Because `LookupList` functions as an interface, the substitution principle [39] dictates that the `@immutable` annotation should hold for inheriting classes as well.

Consider two implementors of `LookupList` (Figure 4). One of them, `UpdatingLookupList`, violates this assumption by adding methods that mutate the state in a visible way. The other, `MemoizingLookupList`, also mutates an object field, but does not change the abstract state of the object as observed through the `LookupList` interface: the field `cached` is used for memoization: storing `index_of`'s most recent input/output. Since both classes update data in object fields, the distinction between them is not a simple semantic check.

Our goal is for CONSTRICTOR to warn the user about the `@immutable` annotation's violation in `UpdatingLookupList`, and not generate a spurious warning for `MemoizingLookupList`.

Immutable abstract state. The sense in which we would like `LookupList` to be immutable is that the return values of “getter” methods, such as `__getitem__`, do not change after calling any of `LookupList`'s methods. In this sense, their *abstract* state is represented by their “observing” methods, whose return values should not change if we wish to consider `LookupList` an immutable interface.

We call the set of methods representing the abstract state the class's *view*: if two objects can be viewed differently through these methods, they definitely do not represent the same conceptual object. Notice that defining the view as just `__getitem__` and `get_size` would be equivalent to defining it to be all three methods of `LookupList`, because for any implementation upholding the class contract, two instances agreeing on the return values of `__getitem__` and `get_size` for all parameters would also agree on the return values of the other two methods.

The choice of view is akin to defining the abstract object: `index_of` only exposes the first instance of every value, and different lists that share the locations of duplicate elements – it does not matter which elements as long as they are duplicates – would be equivalent under a view made up of only `index_of`. Moreover, if `LookupList` had a `contains` method returning whether an element is in the list *somewhere*, then a view comprising only `contains` would essentially define the abstract object to be equivalent to a set.

It is therefore important to choose a view that represents the intended abstract state for the class. Modeling a list essentially means modeling a partial function mapping indices to elements, which can be achieved with one of the views above. Between equivalent views, choosing the smallest one will reduce the size of formulas generated by CONSTRICTOR, which will usually reduce the tool's run time.

When considering both implementations of `LookupList`, it appears as though both implementations cause state mutation by changing fields. However, one, `MemoizingLookupList`, realizes the contract and does not mutate the state *visibly*, while the other, `UpdatingLookupList`, mutates the state in a way that can be observed from outside the class.

```

class MemoizingLookupList[E](LookupList):
    cached: Pair[int, E]
    data: list[E]
    size: int

    def index_of(self, element: E) -> int:
        if self.cached.second == element:
            return self.cached.first
        for i in range(self.size):
            if self.data[i] == element:
                self.cached = Pair(i, element) # mutation!
                return i
        return -1
    # truncated

class UpdatingLookupList[E](LookupList):
    data: list[E]
    size: int

    def index_of(self, element: E) -> int:
        for i in range(self.size):
            if self.data[i] == element:
                return i
        return -1

    def add(self, element: E):
        self.data.append(element) # mutation!
        self.size += 1 # mutation!

    def remove(self, element: E):
        self.size -= 1 # mutation!
    # truncated

```

Figure 4 Two implementations of the list interface from Figure 3.

This motivates us to define *view-immutability*: a class is view-immutable if calling any of its methods on any instance with any parameters does not affect the return values of any method *in the class's view*. This definition allows `MemoizingLookupList` and rules out `UpdatingLookupList`.

2.1 Reasoning about view-immutability

In order to verify view-immutability, and know that our assumptions about the abstract state hold, we would need to prove a very strong property: for every state that an object can reach, and for every method m that we would like to show is immutable, the state of the object before and after calling m are *indistinguishable* for any trailing sequence of methods in the object's view. In other words, calling m (or not calling it) does not change the information returned from the object's view.

In other words, we would be considering two sequences of calls on object o :

$$\begin{aligned} & init(\vec{a}); m_1(); \dots; m_k(); \mathbf{m}(); m_{k+1}(); \dots; m_{k+n}() \\ & init(\vec{a}); m_1(); \dots; m_k(); \quad \quad m_{k+1}(); \dots; m_{k+n}() \end{aligned}$$

where throughout the sequence, if m_i is part of the class view, the return value of m_i is the same. The calls up to m_k constitute the object's initialization phase, which defines all the reachable object states. We assume that all methods are deterministic, so the values returned during initialization are trivially equal, and it remains to be checked for m_{k+1}, \dots, m_{k+n} . This task is hard to automate because it requires reasoning about unbounded sequences of method calls. At the very least, some user intervention would be needed, in the form of data-structure invariants or other guidance [12, 15, 28].

View abstraction. Our approach is inspired by successful notions from the field of model checking [20]. Instead of tracking sequences of method invocations, we establish an invariant that holds at every step; one “step” being a synchronous method application $m_i(\vec{a})$ on two object states σ_1, σ_2 . The invariant is derived from our notion of *view*: we assume that the methods in V represent the abstract state of the object. Therefore we would like to maintain the invariant that the two states are *view-equivalent* – that is, all the view methods always return equal values when invoked on σ_1 and σ_2 . We denote this by $\sigma_1 \equiv_V \sigma_2$.

To translate the problem to model checking, object *states* are modeled as valuations to the object’s fields (with a signature as defined by the respective class declaration). Methods are then represented as transitions between states. We denote the transition from σ to σ' using the method m as $\sigma \xrightarrow{m} \sigma'$. The problem is reduced to safety verification with the *relational* invariant $\sigma_1 \equiv_V \sigma_2$.

While this abstraction deliberately omits some internal information about the state, which may introduce spurious warnings, this modeling makes the problem amenable to well-established model-checking techniques based on SMT. We employ a Floyd-style approach: we construct the control-flow graph of each method and then trace all control paths up to some bound. Every program statement is associated with a first-order semantics, which are composed along each path to construct a path transition relation. The transition relation for the method is the disjunction over all of these paths. More details are given in Section 5.

2.2 Validation steps

This subsection walks through how CONSTRCTOR performs the check as explained, using our motivating example `MemoizingLookupList` to illustrate how CONSTRCTOR is able to show that this class satisfies the `@immutable` contract despite benign mutations caused by its methods.

The `LookupList` interface is annotated as `@immutable`, indicating all its methods should be non-mutating. The developer of `LookupList` additionally annotates the `__getitem__` and `get_size` methods as `@viewmethod`, defining the view of the object. The `@viewmethod` annotations are inherited by `MemoizingLookupList` along with the `@immutable` annotation on the class. Note that the inherited `@immutable` annotation on the class requires all of its methods to be non-mutating, including ones that are not inherited from `LookupList`.

This annotated code is the input to CONSTRCTOR. CONSTRCTOR first checks that the view of `MemoizingLookupList` is *faithful*, i.e., can represent the abstract state of the class. It then verifies that all methods marked `@immutable` do not affect the values of the view.

Step 1: Encoding to SMT. First, we convert each Python method m to an internal representation describing an approximation of the changes it makes to the object. We denote this the *transition relation* of the function and label it TR_m .

For example, in the transition relation of `UpdatingLookupList.add`, the assignment of `self.size` on line 28 of Figure 4 is expressed as $\sigma'[size] = \sigma[size] + 1$. The method’s transition relation is the composition of the transitions of all statements across all execution paths, in the standard manner.

CONSTRCTOR’s semantics component is called Py2SMT, and it operates at the method level by enumerating all execution paths up to a bound (this is used, for example, in loops such as the one in Figure 1), collecting path constraints and constructing the composed transition relation TR_m symbolically for each method m . As is usually the case with bounded model checking [16], the computed TR_m is an approximation.

Step 2: Agreement formula. The transition relations of the view methods are used to compute a set of predicates that check whether two object states are view-equivalent, i.e. *agree* on the return values of all methods $m \in V$ (with any arguments). These predicates are constructed by considering all possible program states at the end of each method, where the starting states are two given object states σ_1, σ_2 , checking whether the return value is equal in both. A program state – unlike an object state – also evaluates all the local variables and, in particular, the method’s return value, which we denote $\sigma[\text{returned}]$. We use \vec{a} to denote the method’s call arguments, which occur in TR_m as free variables.

$$\begin{aligned} \text{agree}_m(\sigma_1, \sigma_2) &\triangleq \forall \sigma'_1, \sigma'_2, \vec{a}. \\ \text{TR}_m[\vec{a}](\sigma_1, \sigma'_1) \wedge \text{TR}_m[\vec{a}](\sigma_2, \sigma'_2) &\rightarrow \sigma'_1[\text{returned}] = \sigma'_2[\text{returned}] \end{aligned}$$

View equivalence is expressed symbolically by conjoining over all view methods. In this example, there are two:

$$(\sigma_1 \equiv_V \sigma_2) \triangleq \text{agree_getitem_}(\sigma_1, \sigma_2) \wedge \text{agree_get_size}(\sigma_1, \sigma_2)$$

Step 3: View Fidelity. Using the transition relation for all methods and the agreement formula, we compose for each method m the formula for checking the fidelity of the view:

$$\forall \sigma_1, \sigma_2, \sigma'_1, \sigma'_2, \vec{a}. \quad \sigma_1 \equiv_V \sigma_2 \wedge \text{TR}_m[\vec{a}](\sigma_1, \sigma'_1) \wedge \text{TR}_m[\vec{a}](\sigma_2, \sigma'_2) \rightarrow \sigma'_1 \equiv_V \sigma'_2$$

If this formula is found valid for all methods of the class, it means two objects that are visibly indistinguishable remain visibly indistinguishable after any operation. The formula is valid for all four methods of `MemoizedLookupList`, so its view is faithful.

Step 4: View Immutability. Finally, CONSTRUCTOR uses both the transition relation and the view-equivalence relation to construct the immutability check formula for each `@immutable` method: for every object state, executing the checked method on it will not change the view. For `MemoizedLookupList.index_of`, this means:

$$\forall \sigma, \sigma', \text{idx}. \quad \text{TR}_{\text{index_of}}[\text{idx}](\sigma, \sigma') \rightarrow \sigma \equiv_V \sigma'$$

The formula for `index_of` is valid, and it can be validated by an SMT solver. This verifies that `index_of` is view-immutable over V . In contrast, if we try the same with, e.g., `UpdatingLookupList.add`:

$$\forall \sigma, \sigma', \text{el}. \quad \text{TR}_{\text{add}}[\text{el}](\sigma, \sigma') \rightarrow \sigma \equiv_V \sigma'$$

The formula for `add` is *not* valid, and the solver is able to produce a counterexample to this property. For example, if $\sigma = \{\text{data} \mapsto [], \text{size} \mapsto 0\}$, the TR is satisfied by $\sigma' = \{\text{data} \mapsto [\text{el}], \text{size} \mapsto 1\}$; but these are not view-equivalent. In particular, `get_size()` returns 0 for σ , but 1 for σ' .

3 Definitions

In this section, we define the necessary components for CONSTRUCTOR’s analysis. Let C be a class with fields F and methods S .

► **Definition 1** (Object State). *The object state of an instance of C is its logical representation: an assignment giving a value for each field in F .*

22:10 Constrictor: Immutability as a Design Concept

► **Definition 2 (View).** A view of C is a set of methods $V \subseteq S$ that describe the abstract state of the class.

The view will usually contain getters for core fields of the class, while omitting memoization fields, caches and any other data that is not part of the object's abstract state. While there are usually many options for selecting V , any specific choice is an expression of intent.

► **Definition 3 (Method Term).** A method term τ for method $m \in S$ is an expression $m(p_1, \dots, p_k)$ where $p_{1..k}$ are concrete values of the corresponding parameter types. We denote $T(X)$ for $X \subseteq S$ to be the set of method terms for all $m \in X$. We use the shorthand $T \triangleq T(S)$

A method term τ , when operating on an object state σ , has a return value $(\sigma.\tau)$ and a post-state σ' , for which we denote $\sigma \xrightarrow{\tau} \sigma'$.

What we actually want is to reason about two objects being *indistinguishable* in the sense that view methods, which are the representation of the abstract state of the object, cannot tell them apart. If two objects disagree on the values of view method terms, they are clearly not indistinguishable. However, it is possible the objects agree on the values of view method terms, but after applying some method, view methods of the resulting objects will disagree. This can happen for arbitrarily long sequences of methods, motivating the following definition:

► **Definition 4 (Observable Indistinguishability).** Two objects σ_1^0, σ_2^0 are observably indistinguishable (OI) ($\sigma_1 \stackrel{\bullet}{=} \sigma_2$) with respect to view V if for all method terms τ_1, \dots, τ_k , whenever:

$$\begin{aligned} \sigma_1^0 &\xrightarrow{\tau_1} \sigma_1^1 \xrightarrow{\tau_2} \cdots \xrightarrow{\tau_k} \sigma_1^k \\ \sigma_2^0 &\xrightarrow{\tau_1} \sigma_2^1 \xrightarrow{\tau_2} \cdots \xrightarrow{\tau_k} \sigma_2^k \end{aligned}$$

it is the case that σ_1^k, σ_2^k agree on the values of all view methods from V .

Now, view immutability just means that method calls leave objects observably indistinguishable from their previous state:

► **Definition 5 (View Immutability).** A method $m \in S$ is view-immutable with respect to the view V if:

$$\forall \tau \in T(\{m\}). \forall \sigma, \sigma' \in \Sigma. \sigma \xrightarrow{\tau} \sigma' \rightarrow \sigma \stackrel{\bullet}{=} \sigma'$$

A class C is view-immutable if all of its methods are view-immutable, including methods in classes that inherit from C .

This definition is hard to check because observable indistinguishability requires checking arbitrarily long sequences of method calls. However, since we expect the values of the view to reflect the full abstract state of the object, we can consider the following, weaker definition:

► **Definition 6 (View Equivalence).** Instances σ_1, σ_2 of class C are view-equivalent ($\sigma_1 \equiv_V \sigma_2$) if they agree on the values of all method terms of view methods:

$$\forall \tau \in T(V), (\sigma_1.\tau) = (\sigma_2.\tau)$$

For this to work, we expect views to be *faithful* in their representation of the abstract state of the class. A problem arises if there exist two view-equivalent states, and some method term from T , such that when applying the term on both states, the resulting states are no

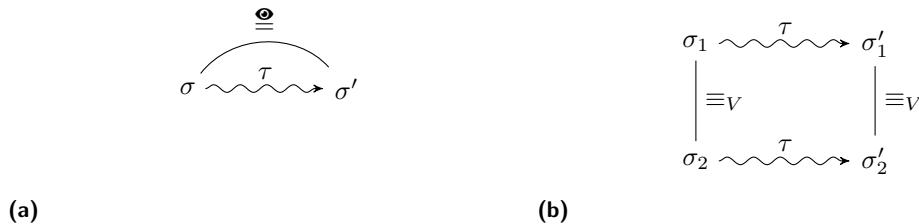

Figure 5 Illustrations of the definitions of (a) View Immutability (Definition 5) and (b) View Fidelity (Definition 7).

longer equivalent. Conceptually, this means that the view must be missing some information, because there exist two objects with the same view, but that are not interchangeable with respect to their subsequent behavior through application of class methods.

This motivates the following definition:

► **Definition 7 (View Fidelity).** *The view V is faithful (or exhibits view-fidelity) if for all two objects σ_1, σ_2 and for all method terms τ :*

$$(\sigma_1 \equiv_V \sigma_2 \wedge \sigma_1 \xrightarrow{\tau} \sigma'_1 \wedge \sigma_2 \xrightarrow{\tau} \sigma'_2) \rightarrow (\sigma'_1 \equiv_V \sigma'_2)$$

Actually, if the view is well-behaved (faithful), view equivalence between two objects implies the stronger property of observable indistinguishability.

► **Theorem 8 (Central Theorem).** *If V is a faithful view, and $\sigma_1 \equiv_V \sigma_2$, then $\sigma_1 \stackrel{\oplus}{\equiv} \sigma_2$.*

Proof. By induction on the length of the distinguishing method call sequence, and using view fidelity for the induction step. ◀

Our algorithm will rely on this theorem: we will check view fidelity and the preservation of view equivalence, and this will allow us to deduce observable indistinguishability.

4 Analysis

Our algorithm for checking if class C is view-immutable, shown in Algorithm 1, starts by computing the immutable set and the view set for the class, by using the class annotations:

- **@immutable**: A method labeled with **@immutable** must not affect the abstract state of the object; a class labeled as **@immutable** is a shorthand for labeling all methods as **@immutable** and all inheriting classes as **@immutable**.
- **@viewmethod**: adds a method to the view set of the object: the set of methods that, if they return the same values on two different objects, we consider them view-equivalent. A **@viewmethod** annotation also implicitly adds a **@immutable** annotation to the method. The user should aspire to providing the smallest view set.

These annotations are passed under inheritance.

In Algorithm 1, **IMMUTABLESET(C)** returns all methods annotated (directly or via inheritance) as **@immutable**, and **VIEWSET(C)** returns all methods annotated as **@viewmethod**.

For each method in the class, the transition relation is computed as a logical predicate between two SMT variable vectors with the appropriate method store signature. The method store signatures are a correspondence between names of memory locations used in methods and their types. In addition, each method store signature contains the special variable **returned** that represents the return value of the method. We denote this operation **GETTRMETHOD**, and it is implemented using Py2SMT, as explained in Section 5.

22:12 Constrictor: Immutability as a Design Concept

■ **Algorithm 1** Immutability checking algorithm.

```

procedure CHECKCLASS( $C$ )
Input: A class  $C$ 
Output: View unfaithful if the class view does not exhibit fidelity, and a mapping of methods
        to either Violation or No-violation otherwise.

 $V \leftarrow \text{VIEWSET}(C)$ 
 $\text{TRs} \leftarrow \{m \mapsto \text{GETTROFMETHOD}(C, m) \mid m \in C\}$ 
if not CHECKVIEWFAITHFUL( $V, \text{TRs}$ ) then
    return View unfaithful

Results  $\leftarrow \{\}$ 
for all  $m \in \text{IMMUTABLESET}(C)$  do
     $\Sigma = \text{METHODSTORESIGNATURE}(m)$   $\triangleright$  Collect types of fields and local variables
     $\varphi \leftarrow \forall \sigma, \sigma' : \Sigma. \text{TRs}[m](\sigma, \sigma') \rightarrow \text{AGREE}(V, \text{TRs})(\sigma, \sigma')$ 
    if CHECKSAT( $\neg \varphi$ ) then
        Results[ $m$ ] = Violation
    else
        Results[ $m$ ] = No-violation
return Results

```

■ **Algorithm 2** View equivalence checking algorithm.

```

function AGREE( $V, \text{TRs}$ )
Input: A set of view methods  $V$  and their transition relations
Output: The set's agree $_V$  predicate
 $\Sigma_s \leftarrow \{f \mapsto \text{METHODSTORESIGNATURE}(f) \mid f \in V\}$ 
return  $\lambda \sigma_0, \sigma_1. \bigwedge_{f \in V} (\forall \sigma'_1, \sigma'_2 : \Sigma_s[f]. (\text{TRs}[f](\sigma_1, \sigma'_1) \wedge \text{TRs}[f](\sigma_2, \sigma'_2)) \rightarrow$ 
 $\sigma'_1[\text{returned}] = \sigma'_2[\text{returned}])$ 

```

Next, the view fidelity of the full class is checked: the TRs are used to create a formula directly based on the definition of view fidelity, and its validity is checked. We denote this CHECKVIEWFAITHFUL in Algorithm 1. If the view is unfaithful, a meta-warning is issued.

Then, for each method in the immutable set I , the algorithm constructs a formula that searches for a counterexample to the immutability of the method. First, we compute a formula that is satisfied between two states that are view equivalent by using the AGREE(V, TRs) function, shown in Algorithm 2, on the set of view methods and their transition relations. Next, we use the result of AGREE to construct a formula that is satisfied by states that are not view-equivalent to their sequent states after application of the method. If the formula is satisfiable, then the class is mutable, and this method is a mutator.

This is essentially a reduction of the problem to model checking. Advancements in SMT solver technology can be applied to achieve better performance in our method as well (also see Section 6.6).

Strengthening optimization. One optimization that we found useful in our implementation is strengthening the claim and trying to prove $\text{TRs}[m](\sigma, \sigma') \rightarrow (\sigma = \sigma')$ instead of $\text{TRs}[m](\sigma, \sigma') \rightarrow (\sigma \equiv_V \sigma')$ in cases where the SMT solver returned `unknown`. This is a stronger property that is easier to check and holds in some cases. If that is the case, we can consider the method as a non-violation.

Correctness. The correctness of the algorithm relies on the following claim:

► **Theorem 9** (Algorithm Correctness). *If V is a faithful view, and for any method m of the class C :*

$$\forall \tau \in T(\{m\}). \forall \sigma, \sigma'. \sigma \xrightarrow{\tau} \sigma' \rightarrow \sigma \equiv_V \sigma'$$

then the class C is view-immutable w.r.t. the view V .

Proof. Let σ, σ' be states such that $\sigma \xrightarrow{m} \sigma'$. We can deduce that $\sigma \equiv_V \sigma'$. For view immutability, we need to prove that $\sigma \cong \sigma'$. We use Theorem 8 and the fidelity of the view V to deduce the desired property. ◀

5 Implementation

In this section we describe implementation details and design choices of CONSTRCTOR. Of these, the lion’s share is our compiler, Py2SMT.

Py2Smt. Py2SMT computes the overapproximations of transition relations of functions and the signatures of classes and functions for CONSTRCTOR. It is implemented using the Z3 [23] Python API.

Py2SMT creates a CFG for each Python function, and optimizes it in order to reduce graph size and path length. Function calls that have no summary SMT encoding are inlined into the graph, which means recursion is currently not supported. On the resulting graph, each path from the start vertex to the end vertex represents a potential execution path of the function. Py2SMT translates each operation to its SMT encoding, and all paths through the function are joined by a logical OR operation.

This translation depends on finite paths, so loops require special care: when the number of iterations is known at compile time, loops are completely unrolled. Unbounded loops, on the other hand, are unrolled and truncated to a configurable maximum length of program steps, rather than a fixed number of iterations – 100 steps in our evaluation – to create finite paths. This creates an underapproximation of the program’s behavior [16].

Moreover, since precise encoding of loops as logical formulas in decidable fragments of first-order logic is fundamentally impossible, Py2SMT currently supports `for` only in the cases of `range` iterations and iterations over lists. These are implemented by (i) utilizing the theory of sequences; and (ii) automatically converting `for` loops to a `while`-like form.

Py2SMT supports most built-in types: integers, floats, booleans, strings, lists, and dictionaries. It also supports arbitrary data types represented by classes, as well as generic classes using the bracket syntax from Python 3.12 [1]. Inheritance is also supported. Py2SMT relies on type hints for method signature inference in some cases. These can be provided by the user, or supplied by any type inference tool, such as PYTYPE [9].

Py2SMT supports reference types and treats class types in the same way as Python – all arguments are passed by reference, except for primitive types.

Use of solvers. Because the formulas created by CONSTRCTOR are at times large and complex, and SMT solvers may have different strengths, CONSTRCTOR first tries CVC5 [14] and, if it returns `unknown`, also tries Z3 [23].

CONSTRCTOR has two different operation modes, that differ in their behavior in the case that both solvers return `unknown` both for the original formula and for the heuristically strengthened one. In “linter-mode”, `unknown` is treated as “no-violation”, while in “verifier-mode”, `unknown` is treated as “violation”.

Unknown view fidelity. Algorithm 1 starts by attempting to prove view fidelity. CONSTRICTOR gives a meta-warning if it detects the view is not faithful, and proceeds if the view is faithful. If it cannot prove either (i.e., the solver returns `unknown`) it assumes the view is faithful and proceeds. This does not necessarily mean that the algorithm will result in an `unknown`, since the view fidelity check reasons about methods that the rest of the algorithm disregards.

6 Evaluation

Our evaluation is guided by these research questions:

- RQ1: Can CONSTRICCTOR validate a plethora of hierarchy-related design violations, as well as other cases involving immutability violations and non-violations?
- RQ2: Can CONSTRICCTOR validate realistic modules implementing data structures meant to be used in a larger projects?
- RQ3: What is the impact of certain types of annotation mistakes on CONSTRICCTOR?

6.1 Benchmarks

We collected 51 benchmarks comprising two sets:

- *Inheritance*: 24 examples of classes in four immutable class hierarchies, including both design violations and non-violations. Violations in this set include adding mutators to an immutable class, overriding immutable methods in a mutating way, defining a view of the object that returns part of the class’s internal state, etc. Some are classic examples of inheritance in object-oriented programming, and others are synthetic, created to measure CONSTRICCTOR’s performance for different sources of design-related immutability violations.
- *Non-inheritance*: 19 examples of immutability violations and non-violations in cases unrelated to immutable hierarchies. These exercise CONSTRICCTOR on a wider array of design issues, taken from online tutorials and the official language documentation for C++ [10]. Benchmarks originally in C++ were manually translated to Python and annotated such that every `const` C++ method is marked as `@viewmethod`.
- *Aspects & Limitations*: 8 synthetic benchmarks crafted to demonstrate various aspects and limitations of CONSTRICCTOR’s technique. The four types of benchmarks in this set explore: 1) loops are unrolled: violations hidden by the unrolling bound; 2) complicated view fidelity checks: views that are not trivially faithful, and the fact that checking view fidelity is separate from immutability violation checks, so the latter can succeed even when the former fails; 3) state space is overapproximated: one benchmark showing how unreachable code can cause a violation due to the overapproximation of object states; and 4) variable types must be explicitly specified: one benchmark showing cases where type inference cannot give an unambiguous answer without user-provided type annotations.

The *Inheritance* set contains 24 benchmarks, together measuring 778 lines of code (avg 32.4LOC) across 70 methods. The set contains 32 loops. Three methods suffer from intentional annotation mistakes. Six benchmarks contain lists and two contain dictionaries.

The *Non-inheritance* set contains 19 benchmarks, together measuring 806 lines of code (avg 39LOC) across 66 methods. The set contains 28 loops. One method suffers from intentional annotation mistakes. Eight benchmarks contain lists and three contain dictionaries.

The *Aspects & Limitations* set contains eight benchmarks, together measuring 248 lines of code and 20 methods.

Each `@immutable` and `@viewmethod` method is classified according whether its implementation violates the annotation. Our benchmark suite contains the following composition:

■ **Table 1** CONSTRICTOR results on the *Inheritance* benchmarks.

	Class	$ I $	$ V $	Fidelity exp/act	Violations Found	Success	Time (ms)

Precision: 0.92 Recall: 0.92

exp: expected act: actual $|I|$ and $|V|$ include inherited annotations

	non-violations	violations	total classes
<i>Inheritance</i>	12	12	24
<i>Non-inheritance</i>	10	9	19
<i>Aspects & Limitations</i>	5	3	8

For all experiments, we define *precision* as the percentage of *no violation* detections made by the tool that were correct and *recall* as the percentage of actual non-violations that were correctly flagged as *no violation* by CONSTRICCTOR. All detections are at the function level.

All experiments ran on a 2022 MacBook Pro with an M2 processor and 16 GB of RAM.

6.2 RQ1: Design violations

To test RQ1, we ran CONSTRICCTOR on all three benchmark sets. CONSTRICCTOR ran on each benchmark separately, without caching the compilation results of PY2SMT. The timeout for CONSTRICCTOR was set at 10 minutes. We recorded the full runtime of CONSTRICCTOR for each class, the result of testing view fidelity, and the result of CONSTRICCTOR for each method in I .

The results for *Inheritance* are shown in Table 1 and *Non-inheritance* and *Aspects & Limitations* in Table 2. The aspect/limitation of each *Aspects & Limitations* benchmark is denoted by a superscript. Displayed times are an average over 10 runs. The repeated runs did not differ significantly, except for the `Graph` benchmark (marked with an asterisk in Table 2), which is discussed below. We computed the precision and recall of CONSTRICCTOR on the *Inheritance* and *Non-inheritance* benchmark sets: since many *Aspects & Limitations* benchmarks are designed to fail, including them does not make sense.

22:16 Constrictor: Immutability as a Design Concept

⁴variable types must be explicitly specified

exp: expected act: actual [†]unknown

CONSTRICCTOR checks all benchmarks but one in under 13 seconds, and all but 8 of the benchmarks (84.3%) in under 5 seconds. 46 benchmarks successfully flag all violations and find no spurious violations. One benchmark was marked as `unknown` by the SMT solver. CONSTRICCTOR succeeds in checking view fidelity for all benchmarks: all unfaithful views in Table 2 are accurately reported.

`Graph` is the only benchmark whose runtimes differed significantly across its 10 runs: two runs completed in under 3 seconds, two more runs completed in about 4 seconds, while the other six completed in about 12 seconds. This discrepancy is due to variations in solver run times; other components of the benchmark's run time did not change between runs.

Six of 51 benchmarks fail. Of these, 2 are *Aspects & Limitations* benchmarks designed to fail (of which, one times out), two benchmarks from the *Non-inheritance* set, and two benchmarks from the *Inheritance* set. Benchmarks `CachedList` (*Non-inheritance*) and `MoveToFrontListSet` (*Inheritance*) find a spurious violation by starting at an unreachable state of the object. Benchmark `WrongImplMoveFrontListSet` (*Inheritance*) misses a violation because the mutation occurs after the bound for loop unrolling. Benchmark `EvilBinarySearchTree` (*Non-inheritance*) was marked as `unknown` by the SMT solver.

■ **Figure 6** Inheritance hierarchies used in the first RQ2 case study.

We conclude that CONSTRUCTOR verifies designs that are view-immutable but do not pass simple C++-style const-checking, and finds design violations where mutation of the abstract state occurs.

6.3 RQ2 – Case Study 1: Kotlin lists

As our first case study, we consider the Kotlin standard library list hierarchy discussed in Section 1, with two implementing classes: the mutation-supporting `ArrayList` from the standard library, and the fully immutable `SmallPersistentVector` from the extension library `kotlinx.collections.immutable` [6]. Figure 6a summarizes the module’s initial hierarchy.

The library’s developer wants to annotate their code for CONSTRUCTOR. This involves:

1. Declaring for each class and interface a set of view methods,
2. Annotating some interface with `@immutable`, which will be inherited, and
3. Running CONSTRUCTOR on the classes in the hierarchy.

Technical setup. This case study is comprised of three copies of the eight classes in Figure 6a in three copies that are identical except for the location of the `@immutable` annotation, and a fourth version with the nine classes in Figure 6b. The interfaces were taken from the Kotlin standard library and translated verbatim, modeling abstract methods as empty methods (this makes no difference for CONSTRUCTOR).

Kotlin uses Java’s `ArrayList`, which we translated to Python as faithfully as possible: arrays were converted to lists which are used like arrays. Overloaded methods in Java were translated with different method names as Python does not support overloading. We attempted to model as many methods as possible: `trim_to_size`, `ensure_capacity`, `grow`, `get_size`, `is_empty`, `contains`, `index_of`, `last_index_of`, `to_array`, `get_element_data`, `get`, `set`, `add`, `remove`, `remove_at`, `_hash_`, `clear`, `add_all`, `remove_all`, `retain_all`, `iterator`, and `contains_all` are all modeled. Two subsets of its public methods were not modeled: (i) `listIterator`, `iterator`, `sublist`, `spliterator` because Py2SMT does not support internal classes, and (ii) `forEach`, `removeIf`, `sort`, `replaceAll` because Py2SMT does not support function objects. `SmallPersistentVector` was similarly translated as faithfully as possible, implementing `_presized_buffer_with`, `get_size`, `add`, `get`, `contains` and `index_of`.

³ Kotlin’s original hierarchy is taken from <https://kotlinlang.org/docs/collections-overview.html#collection-types>

 **Table 3** Run times for the case study in Section 6.3.

Class	Time (ms) for <code>@immutable</code> on			Result	Time (ms) for <code>@immutable</code> on	
	Iterable	Collection	List		ImmutableList	Result
<code>ArrayList</code>	11762	11902	12067	Viol.	5994	No viol.
<code>SmallPersistentVector</code>	2069	2443	2018	No viol.	2060	No viol.

Each of the three copies of the hierarchy in Figure 6a is about 290 lines of code overall. Specifically, our `ArrayList` is 150 lines of code compared to 511 lines of Java, excluding comments and internal classes. The hierarchy in Figure 6b is 296 lines of code and 51 methods overall. Times for all runs of CONSTRCTOR in this case study are shown in Table 3.

First attempt. The programmer declares `get_size` on `Collection` and `get` on `List` (which inherits the annotation on `get_size`) as view methods. They then try annotating `List` with `@immutable`. After running CONSTRCTOR on the classes in the hierarchy, `ArrayList` and `SmallPersistentVector`, CONSTRCTOR will issue a warning on `ArrayList`, which inherits `List`'s `@immutable` annotation but is mutable. CONSTRCTOR flags `ArrayList`'s `add` method as an immutability violation. Since `SmallPersistentVector` does uphold its inherited `@immutable` annotation, it is not flagged as a violation. The programmer then tries moving the `@immutable` annotation to either the `Iterable` or `Collection` interfaces, getting the same result.

In fact, the only class in Figure 6(a) on which the `@immutable` annotation would not cause a violation flag by CONSTRCTOR is `SmallPersistentVector`, on which it is useless. Overall, no interface in the hierarchy represents the immutability properties we expect, and CONSTRCTOR can detect this problem in the hierarchy.

The fix. To fix this issue, the programmer now separates the mutable and immutable hierarchies by creating a new interface: `ImmutableList`, which extends the `List` interface (as seen in Figure 6b). Now there is a clear separation between definitely-mutable classes and definitely-immutable classes. The programmer does not need to change the `@viewmethod` definitions to do so.

The programmer reruns CONSTRCTOR on the class hierarchy as previously described and gets no violation flags. This case study shows how CONSTRCTOR can help developers uphold immutable hierarchy constraints and declare them to their users.

6.4 RQ2 – Case Study 2: Red-Green trees

For our second case study, consider immutable trees with bidirectional references, i.e., both `children` and `parent` references. Smith [52] describes the problem: due to the immutability, we need to set the `parent` and `children` fields during initialization. However, initializing the tree with a `parent` field requires building it top-down, and initializing the tree with a `children` field requires building it bottom-up. These two requirements are contradictory.

Technical setup. We begin with a naïve implementation: a `Node` class with `parent`, `children`, and `data` fields. The class has `get_data`, `get_parent`, `get_children` and `add_child` as its methods, and is meant to be constructed top-down, setting the `parent` field upon construction. After construction, it is now possible to traverse the structure bottom-up and call the `add_child` method to initialize the `children` field.

We implemented this class in Python in 14 non-empty lines. We annotated the class as `@immutable` and annotated the `get_data`, `get_children` and `get_parent` methods as `@viewmethod`.

Table 4 Run times for CONSTRUCTOR on implementations of a bidirectional tree in Section 6.4.

Implementation	Run time (ms)	Result
Naive	322	Violation
Original Red-Green Tree	413	No violation
Memoized Red-Green Tree	582	No violation

As expected, CONSTRUCTOR returns a *violation* on this class, pointing out that `add_child` visibly mutates the class. The run time of CONSTRUCTOR can be found in Table 4.

First attempt. Red-Green trees [38] are a data structure used in the ROSLYN compiler for the .NET framework [3]. Red-Green trees solve the problem of bidirectional references by using two separate node objects to represent each tree node: an internal (and possibly mutable) *green* node and an immutable *red* node. The red tree serves as an immutable façade; the user never sees the green nodes. A green tree is constructed bottom-up, initializing each green node with its children. The red tree never exists as a tree, but rather red nodes are created on the fly to match each green node whenever the children of a red node are accessed. Since `get_children` is a computation instead of a getter, a red node can be initialized with just its parent and internal green node and remain entirely immutable.

We translated the version by Smith, converting 38 lines of C# code to 50 lines of Python code. We marked the `RedNode` class as `@immutable`, with `get_data`, `get_value`, `get_children` and `get_parent` as its view. As expected, CONSTRUCTOR did not detect a violation in this implementation since it stores nothing and mutates no field, even in a non-observable way.

However, this implementation is very inefficient, as it creates new red nodes representing the children of a given node in every call to `get_children`. This can cause both direct run time overhead, and indirect GC overhead caused by the allocation of many small objects, as noted by Lippert [38]. We would like to improve the performance of our implementation.

The fix. We now add memoization to our Red-Green tree: the result of the `get_children` method is stored when first called. Since red trees are immutable there is no reason to recompute this field. The new implementation now measures 55 lines. We then ran CONSTRUCTOR again: CONSTRUCTOR still did not report a violation, because the mutation of a field within `get_children` is non-visible, preserving view immutability.

This case study shows CONSTRUCTOR’s utility not in a class hierarchy but rather on validating the implementation of an immutable data structure. Unlike the previous case study, since Red-Green Trees are used an internal data structure, the `@immutable` annotation would serve the project developers to ensure no changes made to the red trees break their immutability. The classes from both case studies are part of our artifact [36].

6.5 RQ3: Impact of incorrect annotations

In the following small case studies, we set out to explore CONSTRUCTOR’s behavior in the presence of incorrect annotation by the user. We examined four types of annotation mistakes, relating to the `@immutable` and `@viewmethod` annotations: (i) incorrect specification of the class view, (ii) not marking all relevant methods as `@immutable`, (iii) marking a method as `@immutable` instead of `@viewmethod` and vice versa, and (iv) inheritance causing a non-faithful view. Technically, using the correct annotations is the user’s responsibility. We expect CONSTRUCTOR to behave under incorrect annotation as if the given annotations reflect the user intention. The purpose of this research question is to explore the results in cases that can be a little more error-prone.

22:20 Constrictor: Immutability as a Design Concept

```

class ListWithAccessCount[E]:
    arr: List[E]
    size: int
    access_count: int

    @viewmethod
    def get(self, idx: int):
        self.access_count += 1
        return self.arr[idx]

    @immutable
    def get_size(self):
        self.access_count += 1
        return self.size

    def get_access_count(self):
        self.access_count += 1
        return self.access_count

    def add(self, elem: E):
        self.access_count += 1
        self.size += 1
        if len(self.arr) == self.size:
            self.arr.append(elem)
        else:
            self.arr[self.size] = elem

    def remove_last(self):
        self.access_count += 1
        self.size -= 1
# truncated

```

 **Figure 7** A class with an incorrectly annotated view.

Incorrect annotation of the view. Precise view annotations are required to meet the criteria for Theorem 9. Consider the class `ListWithAccessCount` in Figure 7. The view annotations on this class may seem correct to a novice, but the view is too small. The behavior of `get` is undefined for `idx > self.get_size()`, so two `List` objects may *agree* on the values of `get` for all indices for which it is defined, while still not representing the same list, because they have different sizes. Also, CONSTRICITOR issues a fidelity meta-warning on the view in Figure 7.

The user can also incorrectly select a view for `ListWithAccessCount` that is too large: e.g., by adding `get_access_count` to the view. This is wrong for two reasons: (i) marking `get_access_count` as a view method exposes `self.access_count`, which means `get` is now considered to be mutating, and (ii) the `@viewmethod` annotation also denotes `get_access_count` itself as immutable, but it also mutates `access_count` before returning it. This means it cannot be both immutable and part of the view. Running CONSTRICITOR on `ListWithAccessCount` after denoting `get_access_count` as `@viewmethod` the class is flagged as a violation (time: 404ms). We recall that not all “public” methods are expected to be view methods, only those that define the abstract state of the object – the guarantees mentioned in Section 1 for view-immutability only require that the class is seen as immutable through the view, but return values for other methods may be affected.

Not marking a method or class as `@immutable`. In this case, CONSTRICITOR will simply not check the method or class. Because it only impacts *what* is checked, not the view that CONSTRICITOR uses, this does not affect CONSTRICITOR’s performance on other methods/classes.

```

class SettableList[E]:
    arr: List[E]

    @immutable
    def get(self, idx: int):
        return self.arr[idx]

    @viewmethod
    def get_size(self):
        return len(self.arr)

    @immutable
    def set(self, idx: int, elem: E):
        self.arr[idx] = elem

    @immutable
    def add(self, elem: E):
        self.arr.append(elem)
    # truncated

```

Figure 8 A class with `@viewmethod` and `@immutable` swapped.

```

class Collection[E]:
    @viewmethod
    def contains(self, elem: E) -> bool:
        pass
    # truncated

class MyCoolCollection[E](Collection):
    def remove_first(self, elem: E):
        n = self.get_size()
        for i in range(n):
            if self.get(i) == elem:
                self.remove_at(i)
    # truncated

```

Figure 9 An example where annotation inheritance may cause a view to become unfaithful.

Marking a method or class as `@immutable` instead of `@viewmethod` and vice versa. This is analogous to a view that is too large (using `@viewmethod` instead of `@immutable`) or too small (vice versa). For instance, consider the class `SettableList` in Figure 8, whose view is only the `get_size` method. The method `get` is marked as `@immutable` even though the user probably intended for it to be a part of the view. The result only partially captures the class's abstract state. In the current state, CONSTRUCTOR will not flag a violation for `set` that is marked as `@immutable`, because the size of the list does not change.

View fidelity under inheritance. The class `Collection` in Figure 9 represents a collection interface similar to Kotlin's. By itself, the class and its view, `contains`, have no issues. However, a programmer extending it may not be aware that adding methods to an inherited class may cause the view inherited from the parent to be unfaithful. When extended, `MyCoolCollection`'s view is the `contains` method inherited from `Collection`.

The programmer adds to `MyCoolCollection` the method `remove_first`, which removes one instance of an element given as a parameter to the method. This method causes the view of `MyCoolCollection` to be unfaithful, despite there being no change in the view set itself: two collections with the same distinct elements would agree on the return value of `contains` for all arguments, but after running `remove_first`, a collection with one instance of each element would become empty, while a collection with multiple instances of some elements would remain non-empty.

The solution in this case is to add a `get_element_multiplicity` method, which would make the view faithful again.

6.6 Discussion

Our results explore the bounds of CONSTRCTOR’s implementation. In this subsection we tie them back to the theoretical aspects of the technique.

Overapproximation and underapproximation. CONSTRCTOR can find spurious violations because we are overapproximating the TR in multiple ways, most importantly by considering all possible states of an object, including unreachable states. This means CONSTRCTOR can (and does) flag an illegal mutation or leaking of internal state in a benign method when the model found by the solver has an object in such a state.

CONSTRCTOR can also miss violations because of its handling of loops via unrolling. Since the loop is unrolled to a fixed, finite depth, it may be truncated too soon, making a real mutation invisible to CONSTRCTOR. Additional optimizations to CONSTRCTOR, particularly to Py2SMT, or improvements in the SMT solver could allow loops to be unrolled to a greater depth while preserving a reasonable run time. The introduction of loop invariants could help CONSTRCTOR find these violations, but annotating loops with invariants would be an unreasonable burden to the user. Integrating loop invariant inference tools [27] may be a reasonable compromise, but is outside the scope of this work.

View Fidelity. The correctness of Algorithm 1 fundamentally relies on the class being checked having a faithful view. CONSTRCTOR can try to return a result even when the view fidelity check fails, but this result is potentially incorrect. Moreover, view fidelity takes into account all class methods, not only those checked by CONSTRCTOR, causing its check to take a significant portion of CONSTRCTOR’s runtime. In large projects, it may be useful to manually check view fidelity and configure CONSTRCTOR to not check fidelity by itself.

View equivalence is a bisimulation. View fidelity essentially means that view equivalence forms a bisimulation between two traces representing the sequence of method calls on an object. Checking view immutability then means checking whether the view equivalence bisimulation holds between two traces that are identical except for a single point where they diverge: one trace performs a step and the other performs a no-op. Our algorithm for checking view immutability can then be seen as a special case of the symbolic model checking algorithm for checking bisimulation between the two traces, with view equivalence as the candidate bisimulation relation. Indeed, one modern algorithm for bisimulation checking for infinite state spaces is based on SMT [55]. This increases our confidence in the ability of our method to generalize, and implies that future improvements in bisimulation checking can also be applied to our technique.

Reliance on type hints. Some type hints are fundamental to CONSTRCTOR’s approach, and cannot be fully replaced with type inference. This is because some logical claims are valid in some theories and invalid in others. For example, the benchmark `VariableTypesMatter` from the *Aspects & Limitations* set contains two methods with the syntactically identical code segment `if self.some == a1 + a2: self.some = a2 + a1`, which is non-mutating if `a1` and `a2` are integers but mutating if they are strings, because integer addition is commutative and string concatenation is not. Type inference is performed in most cases where it is possible. However, as in the above example, the types of parameters cannot be precisely inferred, so type hints are required for function parameters and field types.

Py2Smt. Py2SMT is expressive, but it has two sets of limitations: (i) unimplemented Python language constructs, e.g., tuples, format strings, and list-, set-, and dictionary-comprehensions, and (ii) language constructs that are not symbolically expressible in SMT, e.g., general `for` loops and full polymorphism. We still support many common special cases, including iteration over lists and `range` objects, which we consider to be the most important cases for `for` loops. Additional work on Py2SMT can extend the scope of CONSTRICITOR.

Reliance on SMT solvers. Even when the formula Py2SMT encodes is accurate, there is no guarantee an SMT solver will be able to decide it. Some theories, e.g., arrays in cases where the domains and ranges are not disjoint, are simply undecidable. In Py2SMT, reference types are represented by using a heap “array”, which is why complex heap-based structures may yield formulas that return `unknown`. Performance on other theories may vary from solver to solver, which is why CONSTRICITOR tries both CVC5 and Z3. For example, certain formulas in the theory of sequences, which Py2SMT uses to encode lists, are not decidable by Z3 but can be decided correctly by CVC5. This affects performance on benchmarks involving lists.

Solvers are not only limited in the types they can represent, but also in the operations on those types. However, in our search for benchmarks we found that most design violations do not involve complex logic as part of the mutation. Therefore, despite the relatively limited expressiveness of SMT solvers, CONSTRICITOR can be useful in finding design violations.

Solvers are also not a great burden on the performance of CONSTRICITOR: across all benchmarks from all three sets, the wait for solver calls is on average 78ms, with the vast majority finishing in under 110ms. This is a small percentage of the runtime of many of the benchmarks, and of it, the majority of the time is spent in proving view fidelity, rather than on the main proof. The rest of CONSTRICITOR’s run time is spent on compilation, as well as other tasks (e.g., building the formulas). Only one benchmark (`WrongfullyImplementedCollatz` from the *Non-inheritance* set) causes a solver call that takes over 1 second (1.71 seconds). In general, no benchmark reaches the timeout set to the solver (3 seconds). The one timeout in Table 2 times out before the solver is called. Across all benchmarks in all benchmark sets, all solver calls take 13.06 seconds in total.

6.7 Threats to validity

The main threat to validity of this work is that complex, real-world code can be less straightforward to annotate. There may be more than one way to annotate a class, and deciding on its view can itself be a design decision. We attempt to mitigate this threat by introducing RQ3 to demonstrate the effect of using less precise annotations, as an inexperienced programmer might. There are still other ways in which a programmer can incorrectly annotate their code, and they may affect our results.

Moreover, in large, logic-heavy classes, proving view fidelity is more likely to fail because it needs to reason about all methods in the class, not only the `@immutable` ones. When the solvers return `unknown` on the fidelity formula, the result of CONSTRICITOR may be unsound, requiring user intervention. This may be unsustainable in a large project setting.

7 Related work

Alternate definitions of immutability. The type of immutability most discussed in the literature is *reference immutability* – non-mutation of an object’s fields through a specific reference [17, 29, 34, 54]. Mutation can also be allowed only in certain contexts [31, 45, 51].

This contrasts with *object immutability* [13], objects whose fields cannot be mutated via any reference. Object immutability requires more complex analyses to enforce [42]. Both definitions may or may not be transitive [46, 48, 49].

Potanin et al. define *abstract immutability* [19, Section 2.4] that permits “benevolent” side effects, but do not define what these effects can be or how this property is enforced. Eyolfson elaborates on this definition [26], roughly describing a desired solution which does not exist and is similar to view immutability.

Pure functions are functions that do not have any side effects, and only depend on their parameters. This is a very strong form of non-mutability, uncommon in OOP. A less strict form is defined by the JETBRAINS `@Contract(pure)` annotation, which indicates that a method does not “affect program state and change the semantics” (but can itself be affected by the state) [2]. Helm et al. [32] and Stewart et al. [53] unify different flavors of side-effect freedom by representing different definitions as a lattice.

Observational purity is a form of purity in which classes can keep and mutate state for their own use, but the mutated state may not leak out of the class. This similar notion to view immutability was introduced by Naumann et al. [43] for the purpose of formal specifications, as (observationally-) pure functions can be used in logical assertions. A method for checking observational purity was introduced in [12], and requires the user to manually supply invariants and specifications for all methods, which is sensible for settings in which writing specifications for all methods is common practice. This is not suitable for software engineering, because programmers typically do not write logical specifications for their classes. CONSTRCTOR implicitly defines an invariant by using view methods, which is slightly less expressive but very lightweight in terms of annotation burden.

Coblenz et al. have compiled a comprehensive classification of immutability types [21], which includes most systems mentioned in this section.

Tools. A well-known work on enforcing reference immutability is JAVARI [35, 41, 47, 54]. JAVARI’s type system distinguishes *unassignable variables* and *read-only references*. The former is more similar to Java’s `final` keyword, while the latter is introduced as part of the type system similar to C++. Another type system is introduced by Milanova [42] and allows distinguishing “maybe mutable” values from “definitely mutable” values, but makes no distinction between a variable and the value it stores, which may be a reference itself. Zibin et al. introduced a method to enforce object or reference immutability without changing Java’s grammar by using generic type parameters [56]. They allow excluding fields from the abstract state, much like C++’s `mutable` keyword. There is some work on automatic inference of immutability qualifiers. Eyolfson [26, Chapter 4] introduced IMMUTABILITY CHECK, which automatically infers `const` qualifiers. Eyolfson also introduced a system that automatically checks and sanitizes writes through `const` references [25].

Applications of immutability. Immutability can be part of the specification of a method [45]. Even if it is not necessarily part of the required semantics, it can be proven as a lemma in order to support analyses such as alias analysis [22] or flow analysis [50].

In concurrency, immutability is often proved as an auxiliary property to show *commutativity* of actions [18] (employing a similar SMT-based technique). This is because calling non-mutating operations in any order should result in the same results for each respective called method. Gordon et al. [30] pursue this in the context of reference immutability.

8 Conclusion

Objects whose values remain constant are desirable in software design. Current verification solutions are either too restrictive, barring all changes to the object and not just ones reflected in the object's abstract state, or too permissive, allowing mutations that can be observed. In this work, we presented a new approachcentering around the *view* of an object, which represents its abstract state, and whose values are expected to remain constant.

We introduced the new concept of *view-immutability* which expresses that the object's view does not change in a abstract sense. This solution is implemented as a linter/verifier, CONSTRICTOR, using an SMT-based method, which checks that method bodies adhere to denoted immutability constraints.

CONSTRICCTOR successfully detects a variety of design violations, with precision and recall both over 85%. We explored two large realistic case studies of data structures for which we found immutability to be useful, and CONSTRICCTOR is able to validate immutability or report violations. We also explore a set of smaller case studies for CONSTRICCTOR's behavior with imprecise annotations.

Abstract

Supporting automatic type inference is in demand in modern language development. It is a challenging task but without appropriate supporting toolkits. This paper presents InferType, a Java library that helps implement constraint-based type inference. A compiler writer uses InferType's classes and methods to describe type constraints and typing rules for type inference. InferType then performs constraint solving by translation to the Z3 SMT solver. InferType is equipped with our developed optimization technique. It reduces the search space for type variables by pre-computing the structures of those type variables for mitigating the performance bottleneck of constraint solving with deeply nested types. We use InferType to implement type inference for a subset of Python, and conduct experiments to evaluate how the developed optimization technique can affect the performance of type inference. Our results show that InferType's optimization can greatly mitigate the performance bottleneck for programs with deeply nested types, and can potentially improve the performance for large nested types.

1 Introduction

The goal of this work is to provide an assisting tool for implementing compilers supporting type inference, which is an in-demand task in modern language development but not well supported by existing approaches. Several supporting toolkits for language development have been proposed such as lexer and parser generators [22, 41], and type checker generators by language workbenches [45, 18]. Since many modern languages support type inference that automatically reconstruct types for programs without explicit type annotations, compiler writers have to implement type inference when developing their own languages. Unfortunately, there are no applicable toolkits for supporting this labor-intensive and also challenging task.

Major static languages support type inference that can be performed in a simple bottom-up manner. It does not need a complex inference engine. However, in recent languages like TypeScript, more aggressive type inference is supported. For example, they may allow programmers to omit a type annotation for a function's return type. A program in such

23:2 InferType

languages may require complicated type inference when it includes mutually recursive functions. Its compiler may contain an intricate type inference engine that solves type constraints retrieved from a program.

One of the approaches to implementing such intricate type inference is utilizing modern Satisfiability Modulo Theories (SMT) solvers. Several static analyses including automatic type inference have been established based on SMT solving [4, 42, 44, 14]. However, it is not simple to implement an efficient type inference engine for practical usage even when using a powerful SMT solver. For example, we observe that the performance of type inference using a SMT solver may drastically degrade when the source program contains nested types such as function types that take other function types as arguments and list types that take other list types as arguments. Such types are frequently used in real-world programs for describing higher-order functions and data structures in hierarchy.

In this paper, we propose InferType, a domain-specific language embedded in Java for implementing constraint-based type inference. A compiler writer implements a constraint-based type inference engine for a target language by describing type constraints and encoding typing rules using InferType’s classes and methods. She then calls an InferType’s method to get a type inference result, which is a binding of type variables to concrete types that satisfies the described type constraints and encoded typing rules. InferType uses the Z3 [7] SMT solver to perform constraint solving for computing that binding by translating the described type constraints and typing rules to Z3 formulae.

We develop an optimization technique for InferType to mitigate the performance bottleneck for handling programs containing deeply nested types. InferType’s optimization is based on the idea of reducing the search space of type variables in SMT solving. It first pre-computes a structure of each type variable in the given type constraints described by the compiler writer. It then generates extra Z3 formulae that explicitly list the possible types each type variable ranges over based on the pre-computed structure for reducing the search space.

We use InferType to implement type inference engines for a small demonstrative language and a subset of Python. This Python subset does not allow explicit type annotations as type annotations are ignored by the ordinary Python without an external type checker. We choose this Python subset for evaluation since type inference for this subset requires complex typing rules to reconstruct static types in dynamically typed programs. We conduct experiments over a collected dataset to evaluate the performance of type inference by our implemented type inference engine for the Python subset, and also to validate the effectiveness of our developed optimization technique. Compared with an existing, manual type inference engine for Python using Z3, the implemented type inference engine using InferType is able to infer types for real-world programs with compatible performance. Furthermore, the experiment results show that the implemented type inference engine can handle programs with deeply nested types much more efficiently. We also observe that InferType’s optimization can potentially improve the performance of type inference for programs containing nested types. Our findings support the claim that InferType is pragmatically applicable of helping implement constraint-based type inference in language development.

The rest of this paper is organized as follows. Section 2 motivates the reader by a scenario of developing a small demonstrative language. Section 3 presents our proposal. Section 4 gives our experiment results by the implemented type inference engine using InferType. Section 5 relates our work to preceding researches and a brief conclusion ends this paper.

2 Implementing Type Inference in Language Development

Many modern languages have support for automatic type inference. Language developers, or compiler writers have to implement type inference when designing a new language. However, it is a challenging task without appropriate tool supports. Classical supporting tools for language development include lex, yacc [22] and bison [41], which are lexer and parser generators. There are also tool suites commonly called “language workbench”, which are development environments for making domain-specific languages [45, 11]. The Spoofax [18] language workbench, for instance, supports code generators that produce type checkers and editor plugins from high-level language definitions. However, existing tools do not support code generators for type inference.

For instance, let us consider implementing a type inference engine for a small language called *Mini-λ*. It automatically reconstructs types for programs without explicit type annotations. We use this language for demonstrative purposes because of its simplicity. One of the common approaches to implementing such a type inference engine is to use a constraint-based type inference. A number of existing type inference systems are formulated into a constraint-based approach because of its extensibility and flexibility [31, 35, 39, 38, 19]. We below consider implementing a constraint-based type inference for *Mini-λ*.

The syntax of expressions and types of *Mini-λ* is given in Listing 1.

```
e := n | r | s | x | fun x. e | e(e) | e + e
t := int | float | str | arrow<t, t>
```

Listing 1 Syntax of *Mini-λ* expressions and types

n, *r* and *s* range over integer, real numbers and string literals. *x* ranges over variables. *fun x. e* represents a function with parameter *x* and a body *e*. *Mini-λ* does not have explicit type annotations. Literals can be regarded as type-annotated expressions. Functions or function parameters do not have type annotations. *e(e)* represents a function application. *e + e* represents an addition of two sub-expressions. In *Mini-λ*, the plus operator can either add numbers or concatenate strings. The type syntax of *Mini-λ* consists of primitive types **int**, **float** and **str**, and the composite type **arrow** for describing function types.

Some of the typing rules in *Mini-λ*’s type system are given in Figure 1. **T-App** specifies how a function application is typed so that the applied expression must be an arrow type consistent with the argument type. The type constraint in the premises specifies the subtype relation that the type variables must satisfy. **T-Plus-Float** and **T-Plus-Str** specify how a plus expression is typed by overloading. The operand and resulting types should all be consistent with either **float** or **str**. **ST-Int-Float** specifies that **int** is a subtype of **float**. **ST-Arrow** specifies that two arrow types are subtype of one another if the parameter type is contravariant and the return type is covariant.

An example program in *Mini-λ* is given in Listing 2. We will use this example program for demonstration in the rest of the paper because of its simplicity although this program is simple enough to be able to perform type inference in a bottom-up manner.

```
fun f. fun x. f(x)
  (fun y. y + "a")
```

Listing 2 An example program in *Mini-λ*

This program first defines a function with parameter **f**; its body is another function with parameter **x**. The body of the function with parameter **x** is a function application **f(x)**. After that, the function with parameter **f** is applied to a function with parameter **y**. The resulting value of the whole expression is a function taking one argument, and its body concatenates the passed argument to a string literal “**a**”.

$$\begin{array}{c}
 \frac{\Gamma \vdash e_1: t_1 \quad \Gamma \vdash e_2: t_2 \quad t_1 <: \text{arrow}\langle t_2, t_3 \rangle}{\Gamma \vdash e_1(e_2): t_3} (\text{T-App}) \\[10pt]
 \frac{\Gamma \vdash e_1: \text{float} \quad \Gamma \vdash e_2: \text{float}}{\Gamma \vdash e_1 + e_2: \text{float}} (\text{T-Plus-Float}) \\[10pt]
 \frac{\Gamma \vdash e_1: \text{str} \quad \Gamma \vdash e_2: \text{str}}{\Gamma \vdash e_1 + e_2: \text{str}} (\text{T-Plus-Str}) \\[10pt]
 \frac{}{\text{int} <: \text{float}} (\text{ST-Int-Float}) \\[10pt]
 \frac{t_{21} <: t_{11} \quad t_{12} <: t_{22}}{\text{arrow}\langle t_{11}, t_{12} \rangle <: \text{arrow}\langle t_{21}, t_{22} \rangle} (\text{ST-Arrow})
 \end{array}$$

Figure 1 Part of the typing rules of Mini- λ .

To implement a constraint-based type inference for Mini- λ , a compiler writer first assigns a type variable to every variable and expression in a program. Then the compiler writer generates the relations between type variables by applying the typing rules while traversing the abstract syntax tree (AST) of the program. A relation between type variables, which we call a *type constraint*, is a logical assertion that describes how the type variables should be constrained. In this paper, we consider those type constraints in Listing 3.

```

constraint := t <: t
             | constraint ∧ constraint
             | constraint ∨ constraint
             | constraint → constraint
             | ¬ constraint
  
```

Listing 3 Type constraints

$<:$ represents the subtype relation between two types. \wedge and \vee represent logical conjunction and disjunction; \rightarrow and \neg represent logical implication and negation.

Type constraints are generated during AST traversal by applying part of the typing rules in the target language, which we call *syntax-related typing rules*. A syntax-related typing rule is a typing rule that includes program syntax symbols. For example, T-App, T-Plus-Float and T-Plus-Str are syntax-related typing rules in Mini- λ . The compiler writer will generate the type constraints in Listing 4 for the program in Listing 2 by traversing its AST.

```

(1) tf <: arrow<tx, tfx>
(2) arrow<tf, arrow<tx, tfx>> <: arrow<arrow<ty, tplus>, te>
(3) (ty <: float ∧ str <: float ∧ float <: tplus)
    ∨ (ty <: str ∧ str <: str ∧ str <: tplus)
  
```

Listing 4 Type constraints for the example program

$t_?$ represents the unique type variables assigned to the variables and expressions in the program. t_f , t_x and t_y are assigned to parameter f , x and y of the defined functions. t_{fx} and t_{plus} are assigned to the resulting types of $f(x)$ and $y + "a"$. t_e is assigned to the resulting type of the whole expression. Constraint (1) and (2) arise from T-App. For example, in (1), t_f is constrained to be a subtype of $\text{arrow}\langle t_x, t_{fx} \rangle$ generated from the application $f(x)$. Constraint (3) arises from T-Plus-Float and T-Plus-Str. This constraint must be properly included in the generated set of type constraints to represent the overloading of

the plus operator. It describes that the operand types, t_y and str (type of the string literal "a"), and the resulting type t_{plus} must be subtype and supertype of either `float` or `str`, represented using logical connectives.

After constraint generation, the compiler writer must then implement a constraint solver considering the rest of the typing rules to solve the generated type constraints. The solver must find a consistent binding of concrete types assigned to the type variables that satisfies all the type constraints. The solver must consider the other typing rules from the applied typing rules in AST traversal, which we call *subtype-related typing rules*, to find such a binding. Unlike syntax-related typing rules applied during AST traversal, a subtype-related typing rule derives a conclusion in the form of a subtype relation and a subtype-related typing rule does not include syntax symbols of program expressions. For example, the implementing solver for Mini- λ must consider `ST-Int-Float` and `ST-Arrow` in Figure 1 to solve the type constraints in Listing 4. Although well-known algorithms such as unification [37] and closure computation [33] have been developed, implementing these algorithms is technically labor-intensive and error-prone. Furthermore, implementing an efficient solver becomes more sophisticated especially for handling complex programs when developing real-world languages. As we will show in 3.3, it would be time consuming for inferring types of programs with nested types by a straightforward implementation of such a solver. Technical approaches are needed to overcome those challenges considering practical usage.

3 InferType

InferType is an embedded domain-specific language that helps compiler writers implement efficient constraint-based type inference. A compiler writer gives type constraints derived by syntax-related typing rules and subtype-related typing rules to InferType by using InferType's classes and methods. InferType then solves the given type constraints based on the subtype-related typing rules by invoking the Z3 SMT solver. To perform constraint solving efficiently, InferType pre-computes structures for type variables involved in the given type constraints, and then reduces the search space of the involved type variables in SMT solving.

InferType supports constraint-based type inference whose type system is expressed by one single binary type relation, which is often called "subtype". InferType assumes that the supported binary type relations hold reflexivity and transitivity. InferType does not support type systems expressed by more than one type relation. For example, InferType could not support a gradual type system [40] which contains a subtype relation and also a type consistency relation.

Below in this section, we first demonstrate how compiler writers can use InferType to implement their type inference engines in Section 3.1. Then we show how InferType performs type inference by translation to Z3 in Section 3.2. In Section 3.3, we present the pre-process of InferType for mitigating the performance bottleneck in constraint solving, which is our main scientific contribution in this paper.

3.1 Programming Interface

InferType is a Java library for implementing constraint-based type inference engines, which are softwares that automatically infer types for programs without explicit type annotations in the target languages. A compiler writer uses InferType's classes and methods to describe type constraints derived by syntax-related typing rules and encode subtype-related typing rules. Constraint solving is then performed by calling an InferType's method to get a type inference result.

3.1.1 Describing types and type constraints

First, types in the target language must be described in InferType. In InferType, a type is an object taking one string argument as the name of that type, and zero or more type arguments.

```
type(typename, type, type, ...)
```

For instance, a primitive type `int` in Mini-λ is described as

```
InferType inf = new InferType();
Type intTy = inf.type("int");
```

`inf` is an instance of InferType's main class. The compiler writer declares this instance to describe types, type constraints and encode subtype-related typing rules. `Type` is the class representing types. Primitive types are described as types taking zero type argument in InferType. A composite type `arrow<int, str>` is described as

```
inf.type("arrow", inf.type("int"), inf.type("str"))
```

InferType also deals with type variables. A type variable is an object taking one string identifier.

```
typevar(identifier)
```

A type variable t_k is described as

```
inf.typevar("t_k")
```

Type variables can also be used as type arguments to make a composite type. An arrow type `arrow< t_k , int>` is described as

```
inf.type("arrow", inf.typevar("t_k"), inf.type("int"))
```

InferType can also help produce a type variable with a generated, unique string identifier by calling `inf.typevar` without an argument.

```
inf.typevar() // a fresh generated type variable
```

Then, the compiler writer describes type constraints generated by applying syntax-related typing rules during AST traversal, and gives the type constraints to InferType for type inference. A compiler writer describes the type constraints using InferType's methods:

```
inf.subtype(t1, t2) // <:
inf.and(c1, c2) // ^
inf.or(c1, c2) // ∨
inf.implies(c1, c2) // →
inf.not(c) // ¬
```

t_1, t_2 represent types and c, c_1, c_2 represent type constraints. Each method corresponds to each kind (comments on the right) of the type constraints in Listing 3. For example, constraint (3) in Listing 4 is described as

```
Constraint cst3 = inf.or(
    inf.and(inf.subtype(t_y, floatTy), inf.subtype(strTy, floatTy), inf.
        subtype(floatTy, t_plus)),
    inf.and(inf.subtype(t_y, strTy), inf.subtype(strTy, strTy), inf.subtype
        (strTy, t_plus)));
```

`Constraint` is the class representing type constraints. `t_y` and `t_plus` refer to type variables `t_y` and `t_plus` created by `inf.typevar`. `floatTy` and `strTy` are primitive types created by `inf.type`.

Finally, the described type constraint is given to `InferType` for type inference by

```
inf.add(cst3);
```

The other type constraints in Listing 4 can be described and given to `InferType` in a similar manner.

3.1.2 Encoding subtype-related typing rules for constraint solving

The compiler writer encodes the rest of the typing rules, which are not used in Section 3.1.1 and are called subtype-related typing rules, and give them to `InferType` for type inference. A subtype-related typing rule in `InferType` is an implication from zero or more premises to one conclusion encoded as

```
inf.ruleBuilderdeclare(conclusion).when(premise, premise, ...)
```

A premise or conclusion is one single subtype relation created by `inf.subtype`.

```
premise, conclusion := inf.subtype(t1, t2)
```

Method `declare` specifies the conclusion; the following method `when` specifies the premises. In `InferType`, all type variables involved in the premises must be included in the conclusion of an encoded subtype-related typing rule. For example, ST-Arrow in Figure 1 is encoded as

```
inf.ruleBuilder
  .declare(inf.subtype(inf.type("arrow", t11, t12), inf.type("arrow", t21
    , t22)))
  .when(inf.subtype(t21, t11), inf.subtype(t12, t22));
```

`t11, t12, ...` are type variables created by `inf.typevar`.

A subtype-related typing rule without premises can also be encoded as

```
inf.ruleBuilderdeclare(conclusion).always()
```

Method `always` specifies that the conclusion holds without a condition, which is a syntax sugar for method `when` without argument. For example, ST-Int-Float is encoded as

```
inf.ruleBuilderdeclare(inf.subtype(intTy, floatTy)).always();
```

Encoded subtype-related typing rules by `inf.ruleBuilder` are implicitly given to `InferType` for type inference.

3.1.3 Solving type constraints based on the encoded subtype-related typing rules

After describing type constraints and encoding subtype-related typing rules, the compiler writer calls method `solve` to solve the given type constraints based on the given encoded subtype-related typing rules.

```
Map<Typevar, Type> solution = inf.solve();
```

`Typevar` is a subclass of `Type` representing only type variables. By calling this method, `InferType` computes if there is a binding of the involved type variables in the given type constraints to concrete types so that all type constraints are evaluated to be true under the

23:8 InferType

given encoded subtype-related typing rules by replacing the type variables with their concrete types. If yes, InferType outputs that binding as the type inference results. For Listing 2, it will output a Map object representing the following binding.

```
{tf ↦ arrow<str, str>, tx ↦ str, tfx ↦ str,  
ty ↦ str, tplus ↦ str, te ↦ arrow<str, str>}
```

Otherwise, it indicates that the constraint solving fails such that InferType could not find a binding that makes all the given type constraints hold. InferType then can provide a set of type variables appearing in the ill-typed constraints.

```
if (!inf.untypableTypevars.isEmpty()) { // type error occurred  
    Set<Typevar> untvarts = inf.untypableTypevars();  
    // further locate type errors  
}
```

The compiler writer can manually track the type variables to program expressions such as recording them into a Map object during AST traversal:

```
locTrack.put(tv, String.format("at file %s: line %s, column %s",  
    fileName, lineNumber, columnNum));
```

where locTrack is the Map object that associates a type variable tv to its program location. Here, a value in the Map object is a string representation of a program location, where fileName, lineNumber and columnNum are managed by the compiler writer. Then she is expected to use the untypable type variables returned by InferType to retrieve the expressions that causes the type error, and further generate a type error message.

3.1.4 Declaring User-Defined Types

InferType also supports user-defined types such as `struct` in the C language and classes in object-oriented languages. During AST traversal, a compiler write can declare subtype-related typing rules for those user-defined types, and give those declarations to InferType. A compiler writer can describe new types, encode new subtype-related typing rules and give them to InferType at any phrase before calling `inf.solve` for constraint sovling.

For example, suppose that a compiler writer is implementing a type inference engine for a language supporting class definitions. When traversing an AST node for a class definition such as

```
class Car(Vehicle):  
    ...
```

which defines a class `Car` that inherits another class `Vehicle`, the compiler writer describes a new type for that class as

```
Type carTy = inf.type("car");
```

She then encodes a new subtype-related typing rule specifying the inheritance as

```
inf.ruleBuilder.declare(inf.subtype(carTy, vehicleTy)).always();
```

where `vehicleTy` is the type for class `Vehicle` described as `inf.type("vehicle")`. Like other subtype-related typing rules, the encoded subtype-related typing rule here is also implicitly given to InferType for type inference. InferType will perform constraint solving considering this encoded subtype-related typing rule when method `inf.solve` is called.

3.2 Translation to Z3

InferType performs constraint solving using the Z3 SMT solver. When method `inf.solve` is called, it translates the type constraints and subtype-related typing rules given by the compiler writer to Z3 formulae. The translated Z3 formulae are all asserted to check satisfaction by invoking the Z3 SMT solver to find if there is an interpretation of variables that makes all the asserted formulae true.

3.2.1 Translating types and type constraints

Types are translated to Z3 constants over a generated Z3 data type declaration. The data type declaration is generated by accumulating all the `Type` objects created by method `inf.type` included in the type constraints and encoded subtype-related typing rules given to InferType. This generated data type declaration represents the type definition of the target language. For Mini- λ , the data type declaration for `ztype` is generated as (represented using the SMT-LIBv2 [3] syntax)

```
(declare-datatypes () ((ztype
  (Int) (Float) (Str)
  (Arrow (ArrowP1 ztype) (ArrowP2 ztype)))))
```

It corresponds to t in Listing 1. `Int`, `Float` and `Str` are translated Z3 constructors representing the primitive types. `Arrow` represents the composite type `arrow`, where `ArrowP1` and `ArrowP2` are generated accessors for `Arrow`, which indicates that arrow types take two arguments. A type variable t_k is translated to a Z3 constant z_k ranging over `ztype`.

```
(declare-constant z_k ztype)
```

A composite type `arrow< t_k , int>` is translated to an application of `ztype` constructors.

```
(Arrow z_k Int)
```

The given type constraints are straightforwardly translated to Z3 boolean propositional formulae by the following translation function.

```
trans{inf.subtype(t1, t2)} = (zsubtype z1 z2)
trans{inf.and(c1, c2)} = (and trans{c1} trans{c2})
trans{inf.or(c1, c2)} = (or trans{c1} trans{c2})
trans{inf.implies(c1, c2)} = (=> trans{c1} trans{c2

```

c , c_1 and c_2 represent type constraints. The subtype relation $<$: is declared as `zsubtype` in Z3.

```
(declare-fun zsubtype (ztype ztype) Bool)
```

It specifies that `zsubtype` is a Z3 function that takes two arguments of the data type `ztype` and returns a boolean value. Logical connectives in type constraints are directly translated to Z3 logical operators. \Rightarrow is the logical implication operator in Z3. For instance, `cst3` in Section 3.1.1 is translated to

```
(or (and (zsubtype z_y Float) (zsubtype Str Float) (zsubtype Float z_plus
  ))
  (and (zsubtype z_y Str) (zsubtype Str Str) (zsubtype Str z_plus)))
```

z_y and z_{plus} in Z3 refer to `t_y` and `t_plus` in Java.

3.2.2 Translating subtype-related typing rules

The encoded subtype-related typing rules are processed by InferType to compute subtype relations, which are then translated into Z3 formulae. Since InferType implicitly assumes the reflexivity and transitivity rules, it also considers these rules when computing subtype relations. We borrow the idea of this process from Typette [14].

For each primitive type and composite type, InferType enumerates all its subtypes and super types in accordance with given subtype-related typing rules. It may also generate type constraints that those subtypes and super types must hold. We below mention how InferType enumerates subtypes. InferType does the same for enumerating super types.

Suppose that InferType enumerates subtypes for a target type $type_T$. Since InferType assumes the reflexivity rule, it first obtains this subtype relation: $type_T$ is a subtype of $type_T$. Next, suppose that the following subtype-related typing rule is given:

$$\frac{premise_1}{type_1 <: type_2}$$

Here, $type_k$ is either a primitive type, a composite type, or a type variable. If $type_2$ and $type_T$ can be *unified*, that is, they are lexically equivalent by replacing the type variables in $type_2$ and $type_T$ with other type variables, primitive types, or composite types, then InferType obtains the following subtype relation: $type_1$ is a subtype of $type_T$ when $premise_1$ holds, where the occurrences of some type variables in $type_1$ and $premise_1$ are replaced as they are for the unification between $type_2$ and $type_T$. When enumerating subtypes and super types for composite types, InferType only enumerates for the most generic forms of composite types, where all type arguments are type variables. For example, InferType computes subtypes and super types for $\text{arrow}\langle t_1, t_2 \rangle$, where t_1 and t_2 are type variables; but it does not compute subtypes or super types for an individual type such as $\text{arrow}\langle \text{int}, \text{int} \rangle$ or $\text{arrow}\langle \text{int}, t_1 \rangle$. Besides, InferType does not consider the reflexivity rule when enumerating subtypes and super types for composite types.

By this enumeration, in the case of Mini- λ , InferType enumerates float (by reflexivity) and int (by ST-Int-Float) as subtypes of float . By ST-Arrow, InferType enumerates $\text{arrow}\langle t_{11}, t_{12} \rangle$ as a subtype of $\text{arrow}\langle t_1, t_2 \rangle$ under premises $t_1 <: t_{11}$ and $t_{12} <: t_2$.

Furthermore, InferType considers the transitivity rule. Given the following rules, if $type_2$ and $type_3$ are unified,

$$\frac{premise_1}{type_1 <: type_2} \quad \frac{premise_2}{type_3 <: type_4}$$

InferType combines the two rules to derive the following new rule:

$$\frac{premise_1 \quad premise_2}{type_1 <: type_4}$$

where the occurrences of some type variables in $type_1$, $type_4$ and $premise_1$, $premise_2$ are replaced as they are for the unification between $type_2$ and $type_3$. They are replaced according to the substitution for a most general unifier [20], which is a complete and minimal substitution. Existential quantifiers are added¹ to the type variables that are included in $premise_1$ and $premise_2$ but not in $type_1$ or $type_4$. When $premise_1$ and $premise_2$ include $type_i <: type_j$ and $type_j <: type_k$, and all the type variables in $type_j$ are not included except $type_i$, $type_j$, and $type_k$, InferType combines $type_i <: type_j$ and $type_j <: type_k$ and transforms them into $type_i <: type_k$ by the transitivity rule.

¹ When an existential quantifier is included in the resulting Z3 formulae, Z3 might fail to correctly derive types. This is a limitation of InferType but it is out of the scope of this paper.

The derived new subtype-related typing rules are used to enumerate a subtype of the target type $type_T$. Furthermore, it may be combined with another rule to derive another new rule by the transitivity rule. InferType iterates this to enumerate all subtypes of $type_T$. It tries all possible combinations between subtype-related typing rules including the derived ones.

For example, suppose that InferType is computing a subtype of `intArray` (which is described as a primitive type `inf.type("intArray")`) and given two subtype-related typing rules:

$$\frac{t_1 <: t_2 \quad t <: int}{list<t_1> <: array<t_2>} \text{(a)} \quad \frac{t <: int}{array<t> <: intArray} \text{(b)}$$

InferType first unifies `array<t_2>` and `array<t>`, and finds a substitution $\{t_2 \mapsto t\}$ for that unification. Then it combines the rules and derives:

$$\frac{t_1 <: t \quad t <: int}{list<t_1> <: intArray} \text{(a and b)}$$

Furthermore, InferType implicitly applies the transitivity rule and obtains:

$$\frac{t_1 <: int}{list<t_1> <: intArray} \text{(a and b)}$$

This new rule is considered for the subtype enumeration, and InferType obtains `list<t_1>` as a subtype of `intArray` under the premise $t_1 <: int$.

The derived new rule may be combined with existing other rules, and another new rule may be derived from that combination by the transitivity rule. The iteration of this combining may not terminate within finite steps. For example, this iteration never terminates if the given subtype-related typing rules include a self-recursive subtype relation such as:

$$\frac{t_1 <: t_2 \quad t <: array<t>}{list<t_1> <: array<t_2>} \text{(a)} \quad \frac{t <: array<t>}{r} \text{(r)}$$

Here, the conclusion of `r` includes a self-recursive subtype relation such that a type is a subtype of an array type of itself. InferType combines `a` and `r`, and derives:

$$\frac{t_1 <: t_2 \quad t <: array<array<t_2>>}{list<t_1> <: array<array<t_2>>} \text{(a and r)}$$

InferType will further combine `a` and `r` and `r`. It will then infinitely combine and derive new rules. It is the InferType users' responsibility to ensure that the given subtype-related typing rules do not cause infinite iteration.

After enumerating all subtypes and super types for each primitive and composite type, InferType generates Z3 formulae representing type constraints for these subtype relations. Suppose that, for a target type $type_T$, its subtypes are $subtype_1$ when $premise_1$ holds, $subtype_2$ when $premise_2$ holds, ..., InferType then generates the following Z3 formula:

```
(forall ((z ztype) (z0 ztype) (z1 ztype) ...)
  (=> (zsubtype z typeT)
    (or (and (= z subtype1) premise1)
        (and (= z subtype2) premise2)
        ...)))
```

`(z ztype)` expresses that a Z3 variable `z` represents a type in the target language such as Mini- λ . `zsubtype` is the Z3 function returning true if the first argument is a subtype of the second argument. In the above formula, `z0`, `z1`, ... are Z3 variables representing type variables appearing in $type_T$, $subtype_1$, $subtype_2$, ... and $premise_1$, $premise_2$, `=>` is an implication operator in Z3. For example, for the subtypes of `arrow` in Mini- λ , InferType generates the following formula:

23:12 InferType

```
(forall ((z ztype) (z21 ztype) (z22 ztype))
  (=> (zsubtype z (Arrow z21 z22))
    (and (= z (Arrow (ArrowP1 z) (ArrowP2 z)))
      (zsubtype z21 (ArrowP1 z))
      (zsubtype (ArrowP2 z) z22)))))
```

This reads as, for all z , $z21$ and $z22$, if z is a subtype of $\text{arrow}(z21, z22)$, then z is an arrow type, $z21$ is a subtype of the first argument of z , and the second argument of z is a subtype of $z22$. InferType also generates a Z3 formula for the super types of `arrow`.

Finally, all translated Z3 formulae are asserted to find if there is an interpretation of variables that makes all the translated Z3 formulae true. If Z3 can find such an interpretation, InferType retrieves and translates that interpretation back to a binding of type variables to concrete types. This binding is returned to the compiler writer. Otherwise, InferType uses the unsat core extraction feature of Z3 to obtain a list of unsat translated type constraints. It then returns type variables in those unsat translated type constraints by calling `inf.untypableTypevars` in Section 3.1.3.

3.3 Optimizing Constraint Solving for Deeply Nested Types

Using Z3 in a straightforward way as in Section 3.2 works with respect to performance in common cases such as Listing 2. However, the constraint solving sometimes becomes extremely slow: we observe that the constraint solving time increases exponentially when the programs contain deeply nested types.

Consider another program in Mini- λ given in Listing 5.

```
fun f2. fun f. fun x. f2(f)(x)
  (fun g. g)
  (fun y. y + "a")
```

Listing 5 Another program with nested types in Mini- λ

This program extends Listing 2 by adding an outer function with parameter `f2`. The body of the function with parameter `x` is a function application, whose argument is `x` and the called function is another function application `f2(f)`. The function with parameter `f2` is then applied to the function with parameter `g`; its resulting value is applied to the function with parameter `y`. The type of parameter `f2` is supposed to be inferred as `arrow<arrow<str, str>, arrow<str, str>>`, which we call a nested type (arrow of arrow). In this paper, a nested type is a composite type that takes composite types as arguments. This program can be further modified by defining another outer function `f3` to create a larger nested type, where the type of `f3` is supposed to be inferred as a nested arrow of arrow of arrow type. We create the programs containing `f4` and `f5` by adding more outer functions for larger nested types. By our testing, a straightforward translation to Z3 in Section 3.2 performed constraint solving for the programs with `f3` in 0.18s, `f4` in 14.07s and `f5` in 179m15.35s!

We expect that this slow down arises from the increasing search space for SMT solving. For example, when a type variable is constrained to be a subtype (or super type) of a type taking arrow types as arguments in a given type constraint, that type variable ranges over increasingly many possible types by the size of arrow types in the arguments. In Mini- λ , such a type variable ranges over possible types `int`, `float`, `str`, `arrow<int, int>`, `arrow<arrow<int, ...>, int>`, ... by the increasing size of the arrow types in the arguments. When Z3 solves the given type constraints, it tries to search for a possible solution by instantiating the type variables over their possible types.

To mitigate the performance bottleneck of constraint solving containing deeply nested types in Z3, we develop a pre-process for InferType. It first computes structures for the type variables involved in the given type constraints. We call these structures *shapes*. Then it generates and asserts extra Z3 formulae based on the computed shapes. They reduce the search space of the involved type variables since type variables range over only limited depth of nested types (or primitive types) specified by the computed shapes.

A shape is either a shape variable, a symbol `*`, or a nested structure starting with a symbol `?`.

```
shape := shapevar | * | ?<shape, shape, ...>
```

`*` represents only primitive types; it can never be any composite type. `?` represents composite-type names such as “`arrow`” in Mini- λ , which constructs a nested structure for shapes by taking other shapes as arguments. For example, suppose that the shape of a type variable in Mini- λ is pre-computed as `?<*, *, ...>`, that type variable would range over only arrow types with primitive types as arguments, which are `arrow<int, int>, arrow<int, str>, ...`

3.3.1 Pre-Computing Shapes

InferType’s pre-process first computes shapes for the type variables involved in the given type constraints generated from syntax-related typing rules during AST traversal. Subtype-related typing rules are not considered when computing shapes.

Given the type constraints from syntax-related typing rules, our pre-process first converts the involved types to shapes by the following function:

```
shapeof{tk} = sk
shapeof{primType} = *
shapeof{compTypeName<t1, t2, ...>} = ?<shapeof{t1}, shapeof{t2}, ...>
```

A type variable is converted to a shape variable. A primitive type is converted to `*`. A composite type is converted to a nested structure with `?`. For example, a type `arrow<tk, int>` is converted to a shape `?<sk, *>`.

Then, *shape equations* are derived from the given type constraints. A shape equation is a logical assertion with conjunctions and disjunctions over a binary equality between two shapes.

```
shape-eq := shape == shape
| shape-eq ∧ shape-eq
| shape-eq ∨ shape-eq
```

A binary equality `shape1 == shape2` specifies that `shape1` and `shape2` are lexically identical. Shape equations do not contain logical implication or negation. Shape equations are derived by the following function:

```
derive{t1 <: t2} = shapeof{t1} == shapeof{t2}
derive{¬ t1 <: t2} = TRUE
derive{c1 ∧ c2} = derive{c1} ∧ derive{c2}
derive{c1 ∨ c2} = derive{c1} ∨ derive{c2}
```

The input is the Negation Normal Form (NNF) converted from the given type constraints in the form of Listing 3. The NNF is converted to handle type constraints in logical implication and negation. A subtype relation `t1 <: t2` is derived to a binary equality `s1 == s2` between the converted two shapes. Note that no shape equations are derived from subtype relations in logical negation (represented as returning a logical `TRUE` literal). For example, a shape equation `¬ sh == *` cannot be derived even if a type constraint `¬ th <: int` is given. `sh` can be arbitrary because `th` can be any type except a subtype of `int`.

23:14 InferType

For instance, the shape equations in Listing 6 are derived from the given type constraints in Listing 4.

```
(1') sf == ?<sx, sfx>
(2') ?<sf, ?<sx, sfx>> == ?<?<sy, splus>, se>
(3') (sy == * ∧ * == * ∧ * == splus)
    ∨ (sy == * ∧ * == * ∧ * == splus)
```

Listing 6 Shape equations for the type constraints

Next, the derived shape equations are solved to find a binding of shape variables to shapes so that all those shape equations are satisfied. A shape equation consists of conjunction, disjunction, and equality. Disjunctions may make it time-consuming to solve shape equations. An equality such as $?<s_1> == ?<*>$ may need to run an expensive unification algorithm when solving shape equations.

To make the shape computation fast, InferType adopts an approximate approach. Each shape equation is first transformed into a disjunctive normal form (DNF). Then, each clause in the DNF is separately solved; a set of substitutions for shape variables is found so that the left and right operands of every $==$ operator included in that clause will be lexically identical after the substitutions are applied to the operands. These substitutions are found by unification, which we implement by the disjoint-set (union-find) algorithm. For example, when a clause of DNF is $?<s_1> == ?<*> \wedge s_2 == s_1$, a set of substitutions $\{s_1 \mapsto *, s_2 \mapsto s_1\}$ is found. Note that one arbitrary set of substitutions is found when there exists multiple valid sets of substitutions.

After the unification, the resulting set of substitutions are compared with the sets of substitutions for the other clauses of the shape equation. If all the sets of substitutions are identical, the first clause of the shape equation, which is a conjunction of equalities, is used in the next step. Otherwise, the whole shape equation is excluded in the next step. This makes our shape computation approximate. When valid sets of substitutions are not found for some clauses, the shape equation is also excluded.

Finally, the remaining clauses, which are not excluded in the previous step, are combined by conjunction, and they are solved. The substitutions for shape variables are found by unification as in the previous step. A shape variable is bound to a shape obtained by applying those substitutions to that shape variable. If a shape is not obtained, the shape variable does not have a binding.

For example, our approximate shape computation computes the following binding for Listing 6:

```
{sf ↦ ?<*, *>, sx ↦ *, sfx ↦ *, 
sy ↦ *, splus ↦ *, se ↦ ?<*, *>}
```

Note that some shape variables do not have a binding. For the type variables corresponding to those shape variables, InferType does not generate extra Z3 formulae in the next step in Section 3.3.2. Those type variables are not optimized for constraint solving. For example, in a target language, suppose that a composite type `arrow` is a subtype of a primitive type `object`, and an operator `!=` takes operands of `object` type. Then, suppose that a variable v_k is initialized with a value of an arrow type and v_k appears as an operand for `!=`. This will generate a shape equation $s_k == ?<*, *> \wedge s_k == *$, where s_k corresponds to a type variable t_k for the variable v_k . The initialization of v_k generates $s_k == ?<*, *>$, but the `!=` operator generates $s_k == *$. s_k does not have a binding since there is no concrete shape for s_k to satisfy that shape equation. Note that not all shape variables s_k lose a binding when an arrow type is a subtype of a primitive type `object`. They lose a binding only when

the type variables t_k corresponding to s_k appears in an expression where a syntax-related typing rule specifies that t_k is a subtype of `object`. Recall that shape computation does not consider subtype-related typing rules.

3.3.2 Reducing Search Space

After solving shape equations, InferType generates extra Z3 formulae that explicitly represent what types the involved type variables range over regarding the computed shapes for reducing the search space. If a shape is `*`, its type variable ranges over only all primitive types. If a shape is `?` with n arguments, its type variable ranges over all composite types with n arguments.

Given a type variable t_k and the computed shape `?<shape1, shape2, ..., shapen>` for its corresponding shape variable s_k , where $shape_i$ represents some computed shapes, InferType generates extra Z3 formulae for t_k as

```
(or (= zk (c1n shape1 shape2 ... shapen))
    (= zk (c2n shape1 shape2 ... shapen))
    ...)
(or (= shape1 (c1m shape11 shape12 ... shape1m))
    (= shape1 (c2m shape11 shape12 ... shape1m))
    ...)
(or (= shape2 p1) (= shape2 p2) ...)
...
(or (= shapen ...) ...)
```

z_k is the translated Z3 constant for t_k . c_i^n represents all composite types that take n arguments in the target language. The possible types for z_k are explicitly listed by logical disjunction. If $shape_j$ is a nested structure with `?` that takes m arguments, InferType will then generate extra Z3 formulae for $shape_j$ similar to the extra Z3 formulae for z_k . An example is $shape_1$ in the above code. $shape_{1i}$ represents its arguments. If $shape_j$ is `*`, InferType will then generate extra Z3 formulae specifying that $shape_j$ ranges over only primitive types. An example is $shape_2$ in the above code. p_i represents all primitive types in the target language.

For example, by the computed shape `?*>` for t_f in Listing 4, the extra Z3 formulae are generated as

```
(or (= zf (Arrow sh_1, sh_2)))
(or (= sh_1 Int) (= sh_1 Float) (= sh_1 Str))
(or (= sh_2 Int) (= sh_2 Float) (= sh_2 Str))
```

They specify that z_f ranges over only arrow types with arguments of primitive types. `?` here corresponds to composite type names that take two arguments, which only “arrow” matches in Mini-λ. The arguments `sh_1` and `sh_2` are generated Z3 constants.

Suppose that Mini-λ defined list types `list<t>` and array types `array<t>`, and also that the shape of a type variable t_h were computed as `?<?<*>>`. Then InferType would generate the extra Z3 formulae as:

```
(or (= zh (List sh_4)) (= zh (Array sh_4)))
(or (= sh_4 (List sh_5)) (= sh_4 (Array sh_5)))
(or (= sh_5 Int) (= sh_5 Float) (= sh_5 Str))
```

z_h is the translated Z3 constant for t_h . sh_4 and sh_5 are generated Z3 constants for the arguments. `?` here corresponds to composite type names that take one argument, which “list” or “array” matches.

Note that asserting extra Z3 formulae generated from some approximately computed shapes in our shape computation might cause type inference failure, that is, the constraint solving would result in unsat even though the types in the given type constraints could be

23:16 InferType

inferred. When our shape computation approximately computes some shapes by excluding some shape equations, InferType would encounter this limitation if that type variable in the given type constraints does not have an inferred type with that approximately computed shape.

For example, consider the following type constraints in the Mini- λ extended with type `object` where an arrow type is a subtype of the `object` type:

```
(21) arrow<int, int> <: tc
(22) object <: tc ∨ td <: tc
(23) object <: td
```

The (only) valid binding that satisfies the type constraints is $\{t_c \mapsto \text{object}, t_d \mapsto \text{object}\}$. The shape equations are derived as:

```
(21') ?<*, *> == sc
(22') * == sc ∨ sd == sc
(23') * == sd
```

By applying the approximate shape computation, (22') will be excluded because it finds two different substitutions $\{s_c \mapsto *\}$ and $\{s_d \mapsto s_c\}$ by unification over the clauses of DNF. The approximate shape computation then only computes (21') and (23'), and outputs $\{s_c \mapsto ?<*, *>, s_d \mapsto *\}$. The constraint solving will then fail because t_c will be restricted to range over only arrow types by the extra Z3 formulae generated from the approximately computed shape $?<*, *>$ for s_c . On the other hand, a precise shape computation by considering (22') would discard the shapes for s_c and s_d , and then the type constraints can be correctly solved.

To handle this limitation for InferType producing correct type inference, in our implementation, when InferType cannot infer the types with the pre-process, it will recover the constraint solving once again without the pre-process. In the second run of the recovery, there is no extra Z3 formula from the computed shapes and all the constraint solving is not optimized. Note that if the given type constraints contain type errors, both the first and second run will result in unsat. InferType can produce correct type inference instead of producing some wrongly inferred types, though it will take extra time by running 2 times when our approximate shape computation encounters this limitation.

3.3.3 Discussion

InferType's shape computation is sound, that is: If InferType can compute a binding that satisfies the given type constraints with the asserted extra Z3 formulae from the shape computation, then that binding must be one of the bindings that satisfies the original type constraints. Since InferType asserts the extra Z3 formulae by conjunction with the given original type constraints, if InferType computes a binding for satisfaction, then that binding must also satisfy the original type constraints. Although InferType might not be able to compute some of the bindings that satisfy the original type constraints because the possible inferred types for the type variables are restricted by the computed shapes, a computed binding by InferType must be a valid solution. InferType is guaranteed to never produce a wrongly inferred type if a program is ill-typed.

InferType's shape computation is not complete in general, where the completeness of the shape computation is defined as: InferType can compute a binding that satisfies the type constraints with the asserted extra Z3 formulae if the original type constraints can be satisfied. InferType's shape computation would be complete under the following assumption: all subtype relations hold only between types with the same structure. In such a target language, if a type variable is constrained to be a subtype or super type of a type, then the

structure of the inferred type for that type variable must be lexically identical to the structure of that type. For instance, the shape computation for Mini- λ is complete. InferType's shape computation is not complete when the target language supports subtype relations between types with different structures. In practical cases, such languages often support a type called `object` which is a super type of any type. For example, suppose that the following type constraints are given in a target language where the only common super type of arrow and map types is a primitive type `object`:

```
arrow<int, int> <: ta
map<int, int> <: ta
```

The type variable t_a can be only inferred as `object` for satisfaction. The shape computation will compute the shape for t_a as $?<*, *>$ from the derived shape equations:

```
?<*, *> == sa
?<*, *> == sa
```

However, InferType then could not find a binding for t_a with the asserted extra Z3 formulae because t_a cannot be inferred as a type with that computed shape.

InferType incorporates a workaround to avoid its failure of computing shapes when the target language supports subtype relations between types with different structures. Some shape variables lose their bindings in our shape computation if part of the shape equations cannot be solved by unification, while the other shape variables can still be computed and the constraint solving for those corresponding type variables can still be optimized. For the previous example containing arrow and map types, a common practice for InferType correctly computing shapes and further computing types is by programmers' type annotations. If a programmer annotates the expression for t_a as type `object`, a type constraint $t_a <: \text{object}$ will be collected by AST traversal and given to InferType together with the other type constraints. As we discussed in the last paragraph in Section 3.3.1, s_a will lose a binding in the shape computation because the derived shape equations including s_a cannot be solved by unification. InferType would then correctly perform type inference although the constraint solving for t_a would not be optimized.

When InferType wrongly computes some shapes and cannot infer types because of the incompleteness of the shape computation, InferType would encounter a fallback to recover the constraint solving as we mentioned in Section 3.3.2. Although the constraint solving is entirely unoptimized in such cases, InferType would be able to correctly compute a binding as the type inference result.

4 Experiment

We implemented a type inference engine for Mini- λ using InferType. We include it in our artifact on Zenodo ². The source code contains 291 LOC in Java with (manually counted) 48 LOC using InferType. Owing to InferType's optimization, the implemented engine performed type inference within around 0.18s for each program with nested types `f3`, `f4` and `f5` as shown in Listing 5, which is way faster than a straightforward translation to Z3.

To further demonstrate the usage of InferType and the effectiveness of InferType's optimization, we conduct several experiments by implementing a type inference engine using InferType for a subset of Python. We choose Python as the target language because we

² <https://zenodo.org/records/10981733>

 **Table 1** Dataset overview. Each value is the average number per program/project in each set.

	set1-Typpete	set2-fs	set3-CodeNet	set4-large	set5-ill
LOC	37	17	29	490	18
def	3	5	0.4	45	0.3
typevar	61	29	175	745	35
constraint	45	12	79	613	32

suppose that it is a good testbed for evaluating the usage capability of InferType when implementing a type inference engine with complex typing rules for a dynamic language like Python. Another concern of choosing Python is being aware of an existing work Typpete [14]. Typpete is one of the state-of-the-art type inference engines for Python using the Z3 SMT solver. Comparing a type inference engine by InferType with generated Z3 code with a manually written one would be a valuable evaluation for the usage of InferType.

Subpet is a re-implementation of a subset of Typpete using InferType. Typpete performs type inference by a manual encoding of type constraints and subtype-related typing rules to Z3 formulae while Subpet does it by using InferType. Subpet adopts a similar type system to Typpete. The main differences between Subpet’s and Typpete’s type systems are: The type system of Subpet is flow-insensitive; Subpet does not support some container types such as sequence types `sequence<t>`. Subpet contains 2,892 LOC in Java with (manually counted) 226 LOC using InferType. It uses the Python `ast` module to parse the source programs. The other code mainly consists of AST traversal and typing environment, class table definitions. Typpete encodes the type inference of Python programs into a MaxSMT problem by a manual encoding of type constraints and typing rules to Z3 formulae. It outputs type annotations for an input Python program. Typpete contains 6,189 LOC implemented in Python. Subpet is not so powerful as Typpete because Subpet is limited by the amount of our implementation resource. Besides, InferType encodes the type inference for a target language as a SMT problem while Typpete encodes it for Python into a MaxSMT problem. Typpete could possibly infer some principle types by manually encoding soft and hard constraints in syntax-related typing rules, while principle typing is generally not considered by InferType. Nevertheless, Subpet could be able to infer types for the programs in our dataset including real-world programs.

For the experiments, we build a dataset. It is publicly available in our artifact. The dataset contains five sets of Python programs including no type annotations:

The first set (set1-Typpete) contains 44 Python benchmark programs obtained from Typpete’s artifact ³. A few innocuous code modifications are made to overcome the implementation limitations of Subpet such as using explicit arguments instead of implicit ones. These modifications do not impact the functionality of the code.

The second set (set2-fs) is a series of 7 artificial Python programs containing larger nested types. One of these programs, for example, is manually created as

```
def f0(x):
    return x + x
def f1(f0, x):
    return f0(x)

f1(f0, 42)
```

³ <https://zenodo.org/records/3996670>

`f1` is a function taking functions as parameter. Its type is assumed to be inferred as a nested type. This Python program can be considered as a similar correspondence to Listing 5 in Mini- λ . The program can be further extended with more function definitions `f2`, `f3`, ... for larger nested types similar to what we showed in Mini- λ . We created the cases up to `f7`.

The third set (set3-CodeNet) contains 30 programs obtained from *Project CodeNet* [36]. Project CodeNet is a open-source, large-scale dataset containing solution programs to coding problems from online judge websites. It is expected to be diverse and representative for real-world programs. We downloaded its Python benchmarks, Version 1 at Sep. 6, 2023. We used the `grep` command to search programs containing keywords `graph` and `dijkstra`. Then we obtained 12 problem sets that had more than 10 hits of the two keywords. We used such keyword searching because we expect that there is a high potential of programmers defining data of nested types to solve graph coding tasks using the Dijkstra's algorithm [16]. Then 5 programs were randomly picked up from each problem set (each problem set contains 100 ~ 300 solution programs), resulting in 60 programs. 30 of the 60 programs were filtered by the implementation limitation of Subpet (mostly because of unknown library usage with respect to types). The remaining 30 programs were finally included in the third set.

The fourth set (set4-large) contains 4 larger programs/projects. The programs in this set are aimed to estimate the scalability of the shape computation in InferType. Two of the larger programs with 358 and 445 LOC were collected from the MOPSA project ⁴. A few code modifications were made to overcome the implementation limitations of Subpet. The other two projects were collected from Typete's artifact. One project includes 5 Python files with 312 LOC. The other project includes 9 Python files with 846 LOC. Although these programs and projects are not exceedingly large, each of them is more than 10 times larger than the average of the programs in the other sets by LOC.

The fifth set (set5-ill) contains 4 ill-typed programs. These programs are used to demonstrate the behaviour of handling type errors in InferType. Two of the ill-typed programs are benchmark programs collected from MOPSA. The other two ill-typed programs are from set1-Typete. We manually modified the programs to make them become ill-typed. A complete list of all the code changes in the dataset is included in our artifact.

Table 1 gives an overview of our dataset. Each value represents the average number per program/project in each set. LOC shows the average number of line of code. def shows the average number of function and method definitions. typevar and constraint show the average number of generated type variables and type constraints derived by syntax-related typing rules during Subpet's AST traversal.

4.1 Comparing Subpet with Typete

Firstly, we show the performance of type inference by Subpet and Typete. Table 2 shows the time results by running the two engines over set1-Typete and set2-fs in our dataset. We selected and included some of the larger programs by LOC in set1-Typete in Table 2a. The experiments were conducted on a Ubuntu 19.10 machine with 2.8 GHz Intel(R) Core(TM) i7-6700T CPU and 32GB RAM, equipped with OpenJDK 14, Python 3.9.6, Z3 4.12.2 and Typete 0.1. The results from Subpet were the average elapsed time of the later 10 runs by looping Subpet 20 times within the same JVM execution for each input Python program. This is in the interest of the slow JVM startup time. For fair comparison, we also modified Typete to loop 20 times for each input Python program and then took the average of the later 10 runs.

deceitful	36	1.41s	0.12s	prog_f3	15	1.51s	0.11s
disjoint_sets	45	2.20s	0.20s	prog_f4	17	6.52s	0.17s
lattice	81	2.50s	0.16s	prog_f5	20	101.4s	0.28s
rockpaperscissor	79	2.87s	0.13s	prog_f6	23	†	1.04s
vehicle	92	2.65s	0.14s	prog_f7	27	†	3.08s

Both Subpet and Typpeete could infer the types for normal programs without nested types or with smaller nested types (programs in set1-Typpeete and prog_f1 to prog_f3 in set2-fs) within a reasonable time period. Subpet was faster than Typpeete mainly because of the language advantage: Subpet is implemented in Java and Typpeete is implemented in Python. However, Typpeete exposed its performance downside for prog_f4 to prog_f7 in set2-fs with deeply nested types. Subpet could finish their type inference much faster. Typpeete ran prog_f5 within 101.4s; it ran into timeout (†) for prog_f6 and prog_f7 after 1,000s. The performance advantage is not simply because Subpet is implemented in Java rather than Python. It mainly comes from InferType’s optimization. We will show our findings in the later subsection.

We also demonstrate the behaviour of handling type errors by Subpet. It can detect the type errors for all the ill-typed programs in set5-ill. Subpet tracks the types and type variables to program locations (including the file name, line number and column number) in a Map object during constraint generation in the AST traversal methods. By invoking InferType for type inference, Subpet uses the untypable type variables returned by InferType to retrieve the program locations and report them to the programmer, though a better readable text message is not given due to our limited implementation resource. For example, one of the ill-typed programs in set5-ill is written as

```
0 # arg_mismatch.py
1 def f(x):
2     return x
3
4 f()
```

This program is ill-typed because function `f` is called without argument but it is defined as taking one argument. Subpet reports the type error message as

```
type inference failed.
type error location:
arg_mismatch.py: line 4, column 0
```

Typpeete would report a similar type error message to the above by Subpet. Note that InferType can detect and help report type errors whenever the optimization is disabled or enabled. InferType would not wrongly infer types with our shape computation if the program is ill-typed.

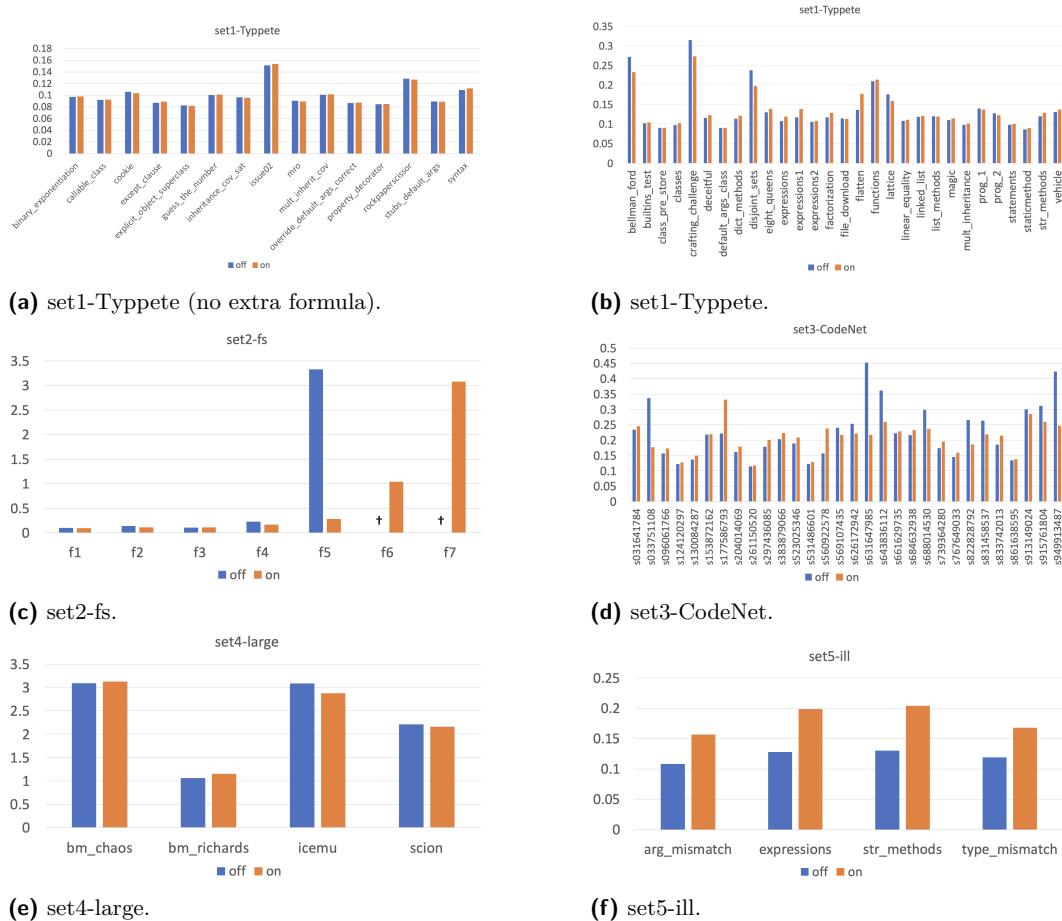

Figure 2 Time for Type Inference by disabling and enabling InferType’s shape computation. *off* columns are results by disabling shape computation. *on* columns are results by enabling shape computation. y-axes are the elapsed time in second. x-axes are program names. Figure 2a gives the results where the shape computation is enabled in *on* but extra Z3 formulae are not added in constraint solving. The other subfigures gives the results where extra Z3 formulae are added in *on*. †timeout (after 1,000s)

4.2 Validating the Effectiveness of InferType’s Optimization

We measure and compare the elapsed time of Subpet by disabling and enabling InferType’s shape computation in Section 3.3 to validate how our shape computation can affect the performance of type inference. Figure 2 shows the elapsed time for the programs in our dataset by disabling and enabling InferType’s shape computation. Each data column is the average elapsed time of the later 10 runs by looping Subpet 20 times. Column *off* and *on* show the elapsed time when InferType disables and enables the shape computation. When the shape computation is disabled, InferType performs type inference by a straightforward translation to Z3 shown in Section 3.2.

The results from Figure 2a show that InferType gives a small performance overhead by the shape computation. Figure 2a gives the results for part of the programs in set1-Typete. Particularly, extra Z3 formulae were not asserted in the constraint solving when the shape computation was enabled in the programs in Figure 2a for evaluating the overhead of the shape computation. Extra Z3 formulae were asserted for all the other programs when the shape computation was enabled in the other subfigures in Figure 2. In average, Subpet degraded the performance of type inference by 0.23% with the shape computation than

without the shape computation among all the programs in Figure 2a. Here and below, the performance rate is calculated as $(t_{off} - t_{on}) / t_{off}$ for each program, where t_{off} and t_{on} are the elapsed time when the shape computation is disabled and enabled. This 0.23% was the overhead of InferType’s shape computation for computing the shapes.

The results from Figure 2c show that InferType’s optimization can greatly mitigate the performance bottleneck for constraint solving containing deeply nested types. When the shape computation was enabled, Subpet performed type inference for all the programs in set2-fs within a reasonable time period. When the shape computation was disabled, Subpet performed much slower for `prog_f5`; it could not finish `prog_f6` or `prog_f7` within a time limit. These results were similar to those obtained by Typpe given in Table 2b. It indicates that the better performance by Subpet against Typpe was not simply because of the language advantage, but because of InferType’s optimization.

Our results demonstrate a tendency that InferType’s optimization has a higher potential to improve the performance of type inference for programs containing larger nested types. Subpet with the shape computation outperformed that without the shape computation in 8/29 (27.6%) programs among Figure 2b (set1-Typpe). Among these 8 programs that Subpet with the shape computation gave a better performance, it outperformed by an average of 8.87%. For example, program `bellman_ford` (containing a nested list of list type) and `crafting_challenge` (containing a nested dict of dict type) in Figure 2b had a better performance by 16.7% and 15.1%. Subpet with the shape computation outperformed that without shape computation in 11/30 (36.7%) programs among Figure 2d (set3-CodeNet). Among these 11 programs, it outperformed by an average of 40.9%. In the best case (`s631647985`), it accelerated the performance of type inference by 108.2%. The programs in set3-CodeNet have more nested types than programs in set1-Typpe because set3-CodeNet was collected on purpose by specific keyword search. Since set3-CodeNet has bias collected by specific keyword searching, we could not clearly show how frequently nested types are used in real-world Python programs. However, our results provide evidence that at least there are programs using nested types in wild Python programs. InferType is practically useful to help implement type inference engines such as Subpet to potentially handle such programs more efficiently. It is also observable that InferType’s optimization would not always give a better performance for the constraint solving with nested types. It sometimes degrades the performance even if the programs contain nested types. For example, the optimization degraded the performance of the two programs `s177586793` and `s560922578` by 49.6% and 51.6% in Figure 2d.

Our experiments empirically show the scalability of the shape computation to larger programs. Figure 2e presents the time results of type inference for the collected programs/-projects in set4-large. Subpet took around 2 seconds for type inference in average, which is 10 times longer than the average elapsed time for the programs in set1-Typpe and set3-CodeNet. InferType’s shape computation does not significantly boost or degrade the performance of type inference. These results show that it is practically feasible to apply our shape computation to larger real-world programs.

Figure 2f gives the elapsed time of type inference for the ill-typed programs in our dataset. Subpet took a longer time to find the type error in type inference when the shape computation was enabled. This is because InferType launches a second run of constraint solving if it cannot find a binding to satisfy the given type constraints in the first run for handling the limitation of our shape computation. Yet, Subpet could detect the type errors in all the ill-typed programs whenever the shape computation was disabled or enabled.

Table 3 Average number of computed shapes and average shape computation time. Each data cell shows the results by Approximate / Precise shape computation.

	set1-Typpe	set2-fs	set3-CodeNet	set4-large	set5-ill
shape	23 / 35	17 / 28	41 / 69	370 / 443	17 / 25
time	0.91ms / 74.3ms	0.71ms / 30.4ms	1.75ms / 434ms	68.7ms / 2.58s	0.69ms / 38.9ms

4.3 Assessing the Precision of the Approximate Shape Computation

We assess the precision of our approximate shape computation by counting the number of computed shapes for type variables, compared with an implemented, precise shape computation. Instead of computing only part of the shape equations in the approximate shape computation, the precise shape computation processes all the derived shape equations including disjunctions. It is implemented using Z3 by a straightforward translation from shape equations to Z3 formulae. For example, the shape equations in Listing 6 (which are derived from Listing 4) are translated to the following Z3 formulae to compute the shapes in the precise shape computation.

```
(= s_f (Q2 s_x s_fx))
(= (Q2 s_f (Q2 s_x s_fx)) (Q2 (Q2 s_y s_plus) s_e))
(or (and (= s_y Star) (= Star Star) (= Star s_plus))
         (and (= s_y Star) (= Star Star) (= Star s_plus)))
```

`s_?` represents translated Z3 constants for shape variables, which ranges over a Z3 datatype declaration `zshape` for shapes generated as

```
(declare-datatypes () ((zshape
  (Star)
  (Q2 (Q2P1 zshape) (Q2P2 zshape)))))
```

`Star` represents the symbol `*`. `Q2` represents the symbol `?` that takes two arguments, where `Q2P1` and `Q2P2` are generated accessors. The precise shape computation outputs a binding of shape variables to shapes by invoking Z3. InferType then generates and asserts extra Z3 formulae for type variables regarding the computed shapes to optimize constraint solving same as in Section 3.3.2. Our approximate shape computation is implemented in Java.

The approximate shape computation computes more than half of the shapes that the precise shape computation computes in average among all the programs in the dataset. The first row in Table 3 shows the average number of computed shapes of all programs in each dataset by the approximate and precise shape computation. The approximate shape computation computed 70.3%, 55.5%, 60.4%, 83.6% and 68.0% shapes of those by the precise one in each set of programs.

The approximate shape computation is much faster than the precise shape computation. The second row in Table 3 lists the average elapsed time of the two shape computations for all programs in each dataset. Same as the measuring before, the elapsed time of the shape computation for each program was the average of the later 10 runs by looping 20 times. The elapsed time of the approximate and precise shape computation differed in scale.

In our dataset, we did not find a program that had a faster elapsed time for type inference with the precise shape computation than approximate by Subpet, though the precise shape computation could compute more shapes in average and reduce the search space of more type variables for expected, faster constraint solving. This might suggest that our approximate shape computation is practically useful enough with respect to the performance, or the programs in our dataset are relatively small so that the precise shape computation could

not show its advantage. We could not show clear evidence to support these claims. Besides, we did not find a case such that Subpet performed a type inference failure caused by the limitation of the approximate shape computation as we discussed in Section 3.3.2. This is because Subpet’s syntax-related typing rules during AST traversal do not generate a type constraint like (22) given in Section 3.3.2, by excluding whose derived shape equation the approximate shape computation would imprecisely compute a shape. However, it is possible that our approximate shape computation encounters this limitation when developing other languages whose syntax-related typing rules generate such type constraints.

5 Related Work

Language development is enjoying significant growth in number and diversity both by academia and industry. Language workbenches such as MPS [45] and Xtext [11] are development environments that provide high-level mechanisms for implementing domain-specific languages [12]. Spoofax [18] allows language developers to write declarative specifications of language definitions to produce parsers, interpreters and editor plugins. Efftinge [10] presented a Java framework, Xbase, for implementing DSLs based on Xtext. Recent studies proposed a standardization of name resolution and type checking with a constraint-based approach integrated in Spoofax [1, 43]. Unlike existing language development toolkits such as Spoofax, our proposed tool produces constraint-based type inference.

Specifying and implementing type inference using constraints is an established approach. A number of existing type inference systems adopt constraint-based approaches because of the modularity of separating constraint generation and solving for providing high flexibility and extensibility [31, 35, 39, 38, 19, 27]. Our proposed tool adopts the constraint-based type inference for similar reasons to support various type systems of handling type inequalities such as subtyping. Besides the constraint-based approaches, one of the most traditional and influential type inference approaches is the Hindley-Milner type inference [15, 23, 6]. The Hindley-Milner type inference targets one particular type system and infers types by unification as the heart of its algorithm. Another approach is the bidirectional type checking [32, 26], which is regarded as local type inference, developed by carefully controlling the introduction and elimination of type variables for inferring parameter types. Turnstile [5] is a meta-language for creating typed languages supporting bidirectional type checking. Compared with Turnstile, InferType is designed for languages supporting global type inference by the constraint-based approach. Jones introduced wobbly types [30] to distribute over type constructors for handling GADT type inference using type annotations. Later, Pottier [34] proposed a stratified type inference with a pre-process of inferring shapes for propagating type annotations by local type inference. The idea of a two-strata type inference and the computation for shapes in this research are similar to those in [34, 46]. However, our shapes are automatically computed from the given type constraints without extra information like type annotations, and the computed shapes are used for optimizing constraint solving.

Satisfiability Modulo Theories (SMT) is an area of automated deduction for checking the satisfiability of first-order formulae with respect to logical theories [4, 3]. State-of-the-art SMT solvers include Yices [9], CVC5 [2], and Z3 [7]. InferType currently relies on Z3 for performing constraint solving. Translating InferType expressions to a higher-level language such as JavaSMT [17] can be a possible extension for enabling different SMT solvers. There have been works on improving the performance of SMT solvers in general such as pruning the search space by detecting symmetries in the input formulae [8]. Later, Niemetz [25] presented an approach for accelerating quantified constraint solving. The developed optimization in our proposal is rather a domain-specific approach to reducing the search space of type variables in SMT solving based on InferType’s shape computation.

SMT solving has been a critical part of several static analyses including automatic type inference. Swamy [42] presented the language F* with a dependent type and effect system using a combination of SMT solving and manual proofs. Vazou and Jhala [44] introduced LiquidHaskell, which is a refinement type-based verifier for Haskell using SMT solvers. InferType does not directly support such type systems. However, a compiler writer can handle complex types such as generics by manually resolving them (instantiating fresh type variables) before encoding them into InferType, though InferType would compute a concrete type instead of a generic type as the inferred type. Pavlinovic [28] presented an encoding of the OCaml type system to a weighted MaxSMT problem for localizing type errors when the type inference fails. InferType considers type errors by providing the type variables in a minimal set of unsat type constraints for helping locate ill-typed program expressions, while the generation of a text message is left to the compiler writer. Generating and customizing type error messages by InferType is treated as our future work. Hassan [14] proposed a type inference engine, Typete, that generates Python 3 type annotations by encoding type constraints as a MaxSMT problem using Z3. In this paper, we implemented a subset of Typete by using the proposed tool for the experiments. There are also emerging studies of statically typing Python programs based on other techniques [21, 13, 24, 29].

6 Conclusion

We presented InferType, a Java library for implementing constraint-based type inference. InferType performs constraint solving by translation to the Z3 SMT solver. Because the constraint solving in SMT may be exponentially slow by the increasing search space for large nested types, we developed an optimization technique for InferType to relieve the performance bottleneck for better practical usage. InferType pre-computes a structure of a type variable and reduces the search space of that type variable based on the pre-computed structure.

We demonstrated the usage of InferType and experimented the effectiveness of its optimization by implementing a type inference engine for a Python subset using InferType. We found that, the implemented engine had compatible performance of type inference compared with a state-of-the-art type inference engine for Python using Z3 with a manual encoding of Z3 formulae. InferType's optimization could greatly improve the performance for programs with deeply nested types. We also observed that InferType could potentially improve the performance of type inference for programs containing nested types. We believe that InferType is practically useful to help implement constraint-based type inference for language development.

Abstract

Because of the probabilistic/nondeterministic behavior of quantum programs, it is highly advisable to verify them formally to ensure that they correctly implement their specifications. Formal verification, however, also traditionally requires significant effort. To address this challenge, we present QAFNY, an automated proof system based on the program verifier Dafny and designed for verifying quantum programs. At its core, QAFNY uses a type-guided quantum proof system that translates quantum operations to classical array operations modeled within a classical separation logic framework. We prove the soundness and completeness of our proof system and implement a prototype compiler that transforms QAFNY programs and specifications into Dafny for automated verification purposes. We then illustrate the utility of QAFNY’s automated capabilities in efficiently verifying important quantum algorithms, including quantum-walk algorithms, Grover’s algorithm, and Shor’s algorithm.

1 Introduction

Quantum computers can be used to program substantially faster algorithms compared to those written for classical computers. For example, Shor’s algorithm [48] can factor a number in polynomial time, which is not known to be polynomial-time-computable in the classical setting. Developing more and more comprehensive quantum programs and algorithms is essential for the continued practical development of quantum computing [11, 49]. Unfortunately, because quantum systems are inherently probabilistic and must obey quantum physics laws, traditional validation techniques based on run-time testing are virtually impossible to develop for large quantum algorithms. This leaves *formal methods* as a viable alternative for program checking, and yet these typically require a great effort; for example, four experienced researchers needed two years to formally verify Shor’s algorithm [38]. To alleviate the effort required for formal verification, many frameworks have been proposed to verify quantum algorithms [26, 56, 3, 59, 20, 16] using interactive theorem

provers, such as Isabelle, Coq, and Why3, by building quantum semantic interpretations and libraries. Some attempts towards proof automation have been made by creating new proof systems for quantum data structures such as Hilbert spaces; however, building and verifying quantum algorithms in these frameworks are still time-consuming and require great human effort. Meanwhile, automated verification is an active research field in classical computation with many proposed frameworks [17, 42, 27, 39, 37, 18, 50, 31, 44, 45, 21, 6] showing strong results in reducing programmer effort when verifying classical programs. None of the existing quantum verification frameworks utilize these classical verification infrastructures, however.

We present QAFNY, a framework that enables programmers to develop and verify *quantum programs* based on quantum program semantics and classical automated verification infrastructure. It has several elements (Figure 1). The core is a strongly typed, flow-sensitive imperative quantum language QAFNY, admitting a classical separation-logic-style proof system, in which users specify quantum programs and input the properties to be verified as pre- and post-conditions and loop invariants, such as GHZ, Quantum Walk, and Shor’s algorithm. QAFNY programs and specifications are verified via translation to a classical Hoare/separation logic framework implemented in the Dafny program verifier [22]. QAFNY programs may also be compiled into quantum circuits and run on a quantum computer via the QAFNY to SQIR and SQIR to OpenQASM 2.0 [7] compilers in our technical report (TR) [24] C.6. Quantum programs can be components of *hybrid classical-quantum* (HCQ) programs, so the compiled QAFNY code can also be a library function called by an HCQ program defined. For example, one can extract the compiled Dafny program to a programming language, such as C#, PHP, and Java, and utilize quantum programs compiled from QAFNY to OpenQASM [21].

A key component of the design of QAFNY is to encode quantum states as array-like structures and quantum operations as aggregate array operations on the states. In Figure 2, a quantum state in superposition $\psi = \sum_{j=0}^{2^n-1} 1 |j\rangle$ is prepared by applying a Hadamard gate to each qubit. QAFNY treats ψ as an array containing 2^n elements, one for each indexed basis element in ψ . Each element is a pair of a complex and a natural number (computational basis, essentially a bitstring). For example, Bell pair $\frac{1}{\sqrt{2}} |00\rangle + \frac{1}{\sqrt{2}} |11\rangle$ can be thought of as a two-element array, with two pairs: $(\frac{1}{\sqrt{2}}, |00\rangle)$ and $(\frac{1}{\sqrt{2}}, |11\rangle)$, where the first one is a complex number and the second one is a bitstring that can be represented as a natural number. Applying a quantum oracle ($f(|j\rangle) = (-i)^j |j\rangle$) on ψ , which evolves each indexed element $1 |j\rangle$ to $(-i)^j |j\rangle$, is similar to an array map function that applies $f'(\alpha_j, j) = ((-1)^j \alpha_j, j)$ to each element j in the 2^n -array. The design and analysis of many quantum algorithms leverage the representation of different groups of qubits in terms of classical arrays [13, 35, 47]. Besides the opportunities for automated reasoning provided by representing quantum states as arrays, QAFNY also uses language abstractions such as quantum conditionals and loops, which generalize quantum controlled gates to enable local reasoning in the presence of quantum entanglement. In the prior works above, the usual approach in reasoning about

quantum controlled gates such as `CNOT` and controlled- U gates is to transform these operations into a monolithic representation, such as a unitary matrix, not scaling up well for automated verification, because the relations among different entries, representing inductive relation among program constructs, are largely omitted. In QAFNY, reasoning about comprehensive constructs, such as controlled gates, amount to building a structural inductive relation among different parts, such as a quantum conditional and its subparts, through deliberately designed proof rules in Sections 3.4 and 4.4; such design permits automated local reasoning.

These designs pose several challenges: 1) quantum operations can be performed on any qubit positions, e.g., f above could apply on arbitrary bits in every bitstring j ; 2) performing automated local reasoning requires one to know which states and qubits can be excluded locally, but qubits can form entangled groups that are typically viewed as not separable; and 3) the QAFNY proof system should obey quantum physical laws, such as no-cloning and no quantum observer effects. To address these problems, we first introduce different types of quantum-state representations and special data structures (*loci* in Section 3) to partition qubits into disjoint entanglement groups for local reasoning. We then combine a flow-sensitive type system (Section 4.3) with our proof system, capable of 1) statically identifying the quantum state types and tracking entanglement group transformations and 2) performing type-guided quantum-state rewrites in the assertions and automated local operation reasoning on canonicalized quantum states, without violating quantum laws.

The paper's contributions are listed as follows.

- We present the QAFNY language, including a big-step semantics and flow-sensitive type system, which provides a simple way of enforcing quantum program properties, such as no-cloning and no observer breakdown. We also prove type soundness for QAFNY in Coq.
- The QAFNY type-guided proof system permits classical-array-operation views of quantum operations and captures the inductive behaviors of quantum conditionals and loops. Soundness and relative completeness are also proved in Coq. To the best of our knowledge, QAFNY provides the first proof-rule definitions for quantum conditionals and for-loops.
- We exhibit a prototype QAFNY to Dafny compiler as evidence of connecting quantum-program verification to classical Hoare/separation logic. We verify a number of quantum algorithms (Figure 16) with a high degree of automation. Sections 5.2 and 7 compares proof automation in QAFNY with other frameworks.
- We faithfully implement several algorithms, such as GHZ, Shor's, and quantum walk, as case studies in this paper to demonstrate how QAFNY can help programmers to efficiently verify quantum-algorithm implementations. The program operations of these examples are a high-level abstraction of the algorithms' quantum circuit-based description, while the QAFNY program state specifications are directly based on the algorithms' state representations based on Dirac notations.

2 Background

Here, we provide background information on quantum computing.

Quantum Value States. A quantum value state¹ consists of one or more quantum bits (*qubits*), which can be expressed as a two-dimensional vector $(\begin{smallmatrix} \alpha \\ \beta \end{smallmatrix})$ where the *amplitudes* α and β are complex numbers and $|\alpha|^2 + |\beta|^2 = 1$. We frequently write the qubit vector

¹ Most literature mentioned Quantum value states as *quantum states*. Here, we refer to them as quantum value states or quantum values to avoid confusion between program and quantum states.

as $\alpha|0\rangle + \beta|1\rangle$ (the Dirac notation [8]), where $|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $|1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ are *computational basis-kets*. When both α and β are non-zero, we can think of the qubit being “both 0 and 1 at once,” a.k.a. in a *superposition* [35], e.g., $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ represents a superposition of $|0\rangle$ and $|1\rangle$. Larger quantum values can be formed by composing smaller ones with the *tensor product* (\otimes) from linear algebra, e.g., the two-qubit value $|0\rangle \otimes |1\rangle$ (also written as $|01\rangle$) corresponds to vector $[0 \ 1 \ 0 \ 0]^T$. However, many multi-qubit values cannot be *separated* and expressed as the tensor product of smaller values; such inseparable value states are called *entangled*, e.g. $\frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$, known as a *Bell pair*, which can be rewritten to $\sum_{d=0}^1 \frac{1}{\sqrt{2}}|dd\rangle$, where dd is a bit string consisting of two bits, each of which must be the same value (i.e., $d = 0$ or $d = 1$). Each term $\frac{1}{\sqrt{2}}|dd\rangle$ is named a *basis-ket* [35], consisting an amplitude ($\frac{1}{\sqrt{2}}$) and a basis vector $|dd\rangle$.

Quantum Computation and Measurement. Computation on a quantum value consists of a series of *quantum operations*, each acting on a subset of qubits in the quantum value. In the standard form, quantum computations are expressed as *circuits*, as in Figure 3a, which depicts a circuit that prepares the Greenberger-Horne-Zeilinger (GHZ) state [12] – an n -qubit entangled value of the form: $|\text{GHZ}^n\rangle = \frac{1}{\sqrt{2}}(|0\rangle^{\otimes n} + |1\rangle^{\otimes n})$, where $|d\rangle^{\otimes n} = \otimes_{d=0}^{n-1} |d\rangle$. In these circuits, each horizontal wire represents a qubit, and boxes on these wires indicate quantum operations, or *gates*. The circuit in Figure 3a uses n qubits and applies n gates: a *Hadamard* (H) gate and $n - 1$ *controlled-not* (CNOT) gates. Applying a gate to a quantum value *evolves* it. Its traditional semantics is expressed by multiplying the value’s vector form by the gate’s corresponding matrix representation: n -qubit gates are 2^n -by- 2^n matrices. Except for measurement gates, a gate’s matrix must be *unitary* and thus preserve appropriate invariants of quantum values’ amplitudes. A *measurement* operation extracts classical information from a quantum value. It collapses the value to a basis state with a probability related to the value’s amplitudes (*measurement probability*), e.g., measuring $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ collapses the value to $|0\rangle$ with probability $\frac{1}{2}$, and likewise for $|1\rangle$, returning classical value 0 or 1, respectively. A more general form of quantum measurement is *partial measurement*, which measures a subset of qubits in a qubit array; such operations often have simultaneity effects due to entanglement, i.e., in a Bell pair $\frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$, measuring one qubit guarantees the same outcome for the other – if the first bit is measured as 0, the second bit is too.

Quantum Conditionals. Controlled quantum gates, such as controlled-not gates (CNOT), can be thought of as quantum versions of classical operations, where we view a quantum value as an array of basis-kets and apply an array map operation of the classical operation to every basis-ket. This is evident when using Dirac notation. For example, in preparing a two-qubit GHZ state (Figure 3a, also a Bell pair) for qubit array x , the H gate evolves the value to $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|10\rangle$ (same as $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \otimes |0\rangle$). The quantum conditional maps the classical conditional `if` $(x[0]) \{x[1] \leftarrow x[1] + 1\}$ onto the two basis-kets, where the operation $x[1] + 1$ acts as a modulo 2 addition to flip $x[1]$ ’s bit. Here, we do not flip the $x[1]$ position in the first basis-ket ($\frac{1}{\sqrt{2}}|00\rangle$) due to $x[0] = 0$, and we flip $x[1]$ in the second basis-ket because of $x[0] = 1$. Such behaviors can be generalized to other controlled gates, such as the controlled- U gate appearing in Shor’s algorithm (Figure 6), where U refers to a modulo-multiplication operation. The controlled nodes (Boolean guards) in these quantum conditionals can also be generalized to other types of Boolean expressions, e.g., it can be a quantum inequality $((\kappa < n) @ x[i])$ that compares every basis vector of qubit array κ ’s value state with the number n and stores the result in qubit $x[i]$, and the controlled node queries $x[i]$ to determine if the conditional body is executed, more in Sections 4 and 6.2.

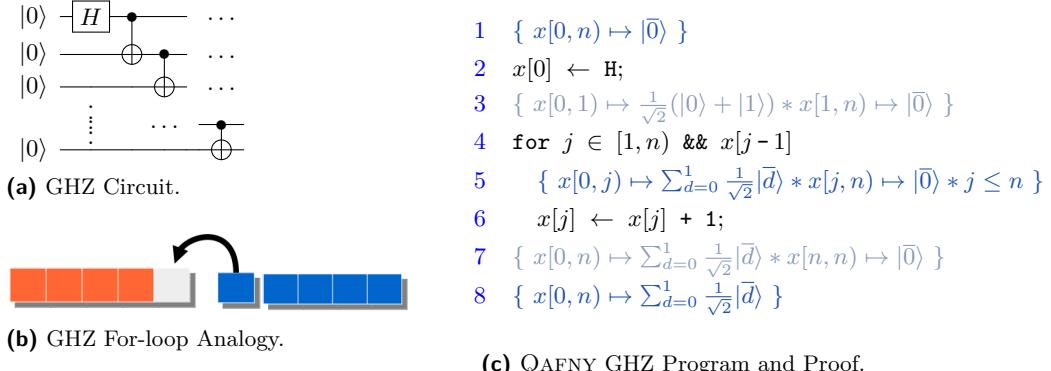

Figure 3 GHZ Examples. $x[t_1, t_2] \mapsto |\bar{0}\rangle$ means $\bar{0}$ is a bitstring of length $t_2 - t_1$. $x[t_1, t_2] \mapsto \sum_{d=0}^1 |\bar{d}\rangle$ means \bar{d} is a bitstring of length $t_2 - t_1$ and $d \in [0, 1]$ is a bit. $*$ is the separation conjunction. In (c), black parts are QAFNY programs, while blue and gray parts are QAFNY state predicates.

Quantum Oracles. Quantum algorithms manipulate input information encoded in “oracles,” which are callable black-box circuits. Quantum oracles are usually quantum-reversible implementations of classical operations, especially arithmetic operations. Their behavior is defined in terms of transitions between single basis-kets. We can infer its global state behavior based on the single basis-ket behavior through the quantum summation formula below. This resembles an array map operation in Figure 2. OQASM [23] is a language that permits the definitions of quantum oracles with efficient verification and testing facilities using the summation formula.

$$\frac{\forall j. |x_j\rangle \longrightarrow f(|x_j\rangle)}{\Sigma_j \alpha_j |x_j\rangle \longrightarrow \Sigma_j \alpha_j f(|x_j\rangle)}$$

No Cloning and Observer Effect. The *no-cloning theorem* suggests no general way of copying a quantum value. In quantum circuits, this is related to ensuring the reversible property of unitary gate applications. For example, the Boolean guard and body of a quantum conditional cannot refer to the same qubits, e.g., `if (x[1]) {x[1] ← x[1] + 1}` violates the property as $x[1]$ is mentioned in the guard and body. The quantum *observer effect* refers to leaking information from a quantum value state. If a quantum conditional body contains a measurement or classical variable updates, the quantum system breaks down due to the observer effect. QAFNY enforces no cloning and no observer breakdown through the syntax and flow-sensitive type system.

3 Qafny Design Principles: Locus, Type, and State

Here, we show the QAFNY fundamental design principles for quantum program verification. We use the GHZ example in Figure 3a to highlight these principles, with a proof outline in Figure 3c; x is initialized to an n -qubit `Nor` typed value $|0̄⟩$ (n number of $|0\rangle$ qubits). After preparing a superposition ($x[0] \leftarrow H$) for a single qubit $x[0]$ in line 2, we execute a *quantum for-loop* that entangles each pair of adjacent qubits in x to prepare the GHZ state. We can unroll each iteration of the loop as a quantum conditional (`if (x[j-1]) {x[j] ← x[j] + 1}`). When verifying the program in QAFNY, it is only needed to provide the program and specifications in `blue`, with the `grayed out` parts automatically inferred. We show critical features in our type-guided proof system, making the above verification largely automatic.

3.1 Loci, Types, and States

Figure 4 shows QAFNY *loci*, types, and states, which are used for tracking possibly entangled qubits. In GHZ (Figure 3c), each loop step in lines 4-6 entangles the qubit $x[j]$ with $x[0, j]$, i.e., the entangled qubit group is expanded from $x[0, j]$ to $x[0, j+1]$. However, the entanglement here is implicit: the program syntax does not directly tell if $x[j]$ is entangled with $x[0, j]$ but relies on an analysis to resolve the entanglement scopes, which is captured by introducing

- 1) *loci* (κ) to group possibly entangled qubits,
- 2) standard *kind environments* (Ω) to record variable *kinds* (explained below), and
- 3) *locus type environments* (σ) to keep track of both loci and their quantum state types.

QAFNY variables may represent one of three *kinds*² of values (Figure 4). C and M kinds are scalars; the former is an integer³, and the latter is a measurement outcome (r, n) where r is the probability of outcome n . Q m kind variables represent a physical m -length qubit array conceptually living in a heap. For simplicity, we assume no aliasing in variable names, no overlapping between qubit arrays referred to by any two different variables, and scalar and qubit array variables are always distinct. Quantum values are categorized into three different types: Nor, Had and EM. A *normal* value (Nor) is an array (tensor product) of single-qubit values $|0\rangle$ or $|1\rangle$. Sometimes, a (Nor)-typed value is associated with an amplitude z , representing an intermediate partial program state; an example is in Section 6.1. A *Hadamard* (Had) typed value represents a collection of qubits in superposition but not entangled, i.e., an n -qubit array $\frac{1}{\sqrt{2}}(|0\rangle + \alpha(r_0)|1\rangle) \otimes \dots \otimes \frac{1}{\sqrt{2}}(|0\rangle + \alpha(r_{n-1})|1\rangle)$, can be encoded as $\frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} (|0\rangle + \alpha(r_j)|1\rangle)$, with $\alpha(r_j) = e^{2\pi i r_j}$ ($r_j \in \mathbb{R}$) being the *local phase*, a special amplitude whose norm is 1, i.e., $|\alpha(r_j)| = 1$. The most general form of n -qubit values is the *entanglement* (EM) typed value, consisting of a linear combination (represented as an array) of basis-kets, as $\sum_{j=0}^m z_j \beta_j \eta_j$, where m is the number of elements in the array. In QAFNY, we extend traditional basis-ket structures in the Dirac notation to be the above form, so each basis-ket of the above value contains not only an amplitude z_j and a basis β_j but also a frozen basis stack η_j , storing bases not directly involved in the current computation. Here, β_j can always be represented as a single $|c_j\rangle$ by the equation in Figure 4. Every β_j in the array has the same cardinality, e.g., if $|c_0| = n$ ($\beta_0 = |c_0\rangle$), then $|c_i| = n$ ($\beta_j = |c_j\rangle$) for all j .

A QAFNY quantum state (φ), representing a quantum heap, maps *loci* to *quantum values*. Loci in a heap φ partition it into regions that contain possibly entangled qubits, with the guarantee that cross-locus qubits are not entangled. Each locus is a list of *disjoint ranges* (s), each represented by $x[n, m]$ – an in-place array slice selected from n to m (exclusive) in a physical qubit array x (always being Q kind). Ranges in a locus are pairwise disjoint, written as $s_1 \sqcup s_2$. For conciseness, we abbreviate a singleton range $x[j, j+1]$ as $x[j]$. At the type level, we maintain a locus type environment (σ) mapping loci to quantum types: any quantum state φ always has an entry in σ , guaranteeing that $\text{dom}(\varphi) = \text{dom}(\sigma)$, i.e., loci mentioned in φ and σ are the same. Locus type environments are stateful, i.e., a statement that starts with the environment σ could end up with a different one σ' because a locus could be modified during the execution. In addition to the locus type environment, we keep a kind environment between variables and their kinds. However, it is scoped and immutable as the kind of any scoped variable does not change.

² C and M kinds are also used as context modes in type checking. See Figure 9.

³ Any classical values are permitted in our implementation. For simplicity, we only consider integers here.

Basic Terms:	
Nat. Num $m, n \in \mathbb{N}$	Real $r \in \mathbb{R}$
Variable x, y	Bit $d ::= 0 \mid 1$
	Amplitude $z \in \mathbb{C}$
	Bitstring $c \in d^+$
	Phase $\alpha(r) ::= e^{2\pi ir}$
	Basis Vector $\beta ::= (c\rangle)^*$
Modes, Kinds, Types, and Classical/Quantum Values:	
Mode $g ::= \mathbb{C}$	\mathbb{M}
Classical Scalar Value $v ::= n$	(r, n)
Kind $g_k ::= g$	$\mathbb{Q} n$
Frozen Basis Stack $\gamma ::= (\hat{\beta})$	
Full Basis Vector $\eta ::= \beta\gamma$	
Basic Ket $w ::= z\eta$	
Quantum Type $\tau ::= \text{Nor}$	Had
Quantum Value (Forms) $q ::= w$	$\frac{1}{\sqrt{2^n}} \bigotimes_{j=0}^{n-1} (0\rangle + \alpha(r_j) 1\rangle)$
Quantum Loci, Environment, and States	
Qubit Array Range $s ::= x[n, m)$	
Locus $\kappa ::= \bar{s}$	concatenated op \sqcup
Kind Environment $\Omega ::= x \rightarrow g_k$	
Type Environment $\sigma ::= \kappa : \tau$	concatenated op \sqcup
Quantum State (Heap) $\varphi ::= \bar{\kappa} : \bar{q}$	concatenated op \sqcup
Syntax Abbreviations and Basis/Locus Equations	
$\sum_{j=0}^0 w_j \simeq w_0$	$\sum_{j=0}^m w_j \simeq \sum_j w_j$
$1\gamma \simeq \gamma$	$z\beta(\emptyset) \simeq z\beta$
$ c_1\rangle c_2\rangle \equiv c_1 c_2\rangle$	$x[n, n) \equiv \emptyset$
$\emptyset \sqcup \kappa \equiv \kappa$	$x[n, m) \sqcup \kappa \equiv x[n, j) \sqcup x[j, m) \sqcup \kappa$ where $n \leq j \leq m$

Figure 4 QAFNY element syntax. Each range $x[n, m)$ in a locus represents the number range $[n, m)$ in physical qubit array x . Loci are finite lists, while type environments and states are finite sets. The operations after “concatenated op” are concatenations for loci, type environments, and quantum states.

On the bottom of Figure 4, we show abbreviations (\simeq) rules for presentation purposes; $A \simeq B$ means we write B to mean A . The left-most rule shows that **Nor** typed value is a singleton **EN** typed array; see the type-guided state rewrites in Section 3.3. We can also omit the (\emptyset) in a basis-ket presentation and color the basis stack with a hat sign $\widehat{\cdot}$, e.g., $\frac{1}{\sqrt{2}}|0\rangle \widehat{|1\rangle}$ means $\frac{1}{\sqrt{2}}|0\rangle (|1\rangle \mid)$; additionally, $\frac{1}{\sqrt{2}}|0\rangle \widehat{|1\rangle}$ means $\frac{1}{\sqrt{2}}|0\rangle |\widehat{1}\rangle (\emptyset)$. Below the \simeq rules in the figure, we present structural equations (\equiv) among bases and loci: 1) the locus concatenation \sqcup holds identity and associativity equational properties; 2) a range ($x[n, n)$) containing 0 qubit is empty; and 3) it is free to split a range ($x[n, m)$) into two ($x[n, j)$ and $x[j, m)$), preserving the disjointness of \sqcup .

3.2 Simultaneity for Tracking Qubit Positions and Entanglement Scopes

QAFNY uses locus transformations, captured by the type inference on program operations, to track entanglement scopes. Figure 5 describes the automated proof steps for verifying a loop-step in Figure 3c. The bottom pre-condition contains the quantum values for the two disjoint loci $x[0, j)$ and $x[j, n)$. The quantum conditional’s Boolean guard and body are applied to the qubits $x[j-1]$ and $x[j]$, respectively, appearing in the above two loci. The application entangles $x[j]$ with the locus $x[0, j)$ and transforms the locus to be $x[0, j+1)$, by appending $x[j]$ to the end of $x[0, j)$. The append, as the first (bottom) proof step in Figure 5, happens *automatically* through rewrites guided by the locus transformations in the type environment σ associated with each proof triple. After the rewrites, we preserve the property of no entangled cross-locus qubits.

In the above example, the static rewrites of a locus in a type environment simultaneously gear and change the rewrites of the locus value form in the associated state. We call this manipulation mechanism *simultaneity*. As shown in Section 1, quantum operations can apply on arbitrary qubit positions, which might seriously harm proof automation, based on previous experiments [16, 3] (Section 5.2), even if they tried hard for automation tactics. It is necessary to statically track qubit positions to permit the canonicalization of quantum state rewrites, allowing a uniform way of defining proof rules for operations.

$$\begin{array}{c}
 \frac{\Omega; \{\kappa_2 : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \kappa_2 \mapsto \frac{1}{\sqrt{2}} |0\rangle |\bar{1}\rangle |\bar{1}\rangle \right\} e \left\{ \kappa_2 \mapsto \frac{1}{\sqrt{2}} |1\rangle |\bar{1}\rangle |\bar{1}\rangle \right\}}{\Omega; \{\kappa_1 : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle |\bar{1}\rangle \right\} e \left\{ \kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |1\rangle |\bar{1}\rangle \right\}} \text{P-ORACLE} \\
 \frac{\Omega; \{\kappa_1 : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle |\bar{1}\rangle \right\} e \left\{ \kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |1\rangle |\bar{1}\rangle \right\}}{\Omega; \{\kappa_1 : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \mathcal{F}(x[j-1], \kappa_1) \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |0\rangle \right\} e \left\{ \kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |1\rangle |\bar{1}\rangle \right\}} \text{EQ} \\

 \frac{\Omega; \{\kappa : \text{EN}\} \vdash_{\mathbb{C}} \left\{ \kappa \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |0\rangle \right\} \text{if } (x[j-1]) e \left\{ U(\neg x[j-1]) \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |0\rangle * U(x[j-1]) \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |1\rangle |\bar{1}\rangle \right\}}{\Omega; \sigma \vdash_{\mathbb{C}} \left\{ x[0, j] \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle * x[j, n] \mapsto |\bar{0}\rangle \right\} \text{if } (x[j-1]) e \left\{ x[0, j+1] \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle * x[j+1, n] \mapsto |\bar{0}\rangle \right\}} \text{P-IF} \\
 \kappa = x[j-1] \sqcup \kappa_1 \quad \kappa_1 = x[0, j-1] \sqcup x[j] \quad \kappa_2 = x[j] \sqcup x[0, j-1] \\
 e = x[j] \leftarrow x[j] + 1; \quad \sigma = \{x[0, j] : \text{EN}, x[j, n] : \text{Nor}\} \quad U(b) = u(b, x[j-1], \kappa)
 \end{array}$$

 **Figure 5** Detailed automated proof for a loop-step in GHZ. Constructed from the bottom up.

To permit automated proof inference, we design the uniformity in QAFNY proof rules to require that the locus fragments for qubits that an operation is directly applied always be prefixed. For example in Figure 5 P-IF, instead of having locus $x[0, j+1]$, we rewrite it further to $\kappa (x[j-1] \sqcup x[0, j-1] \sqcup x[j])$, so the qubit $x[j-1]$ that the Boolean guard is applied to appears at the start position. These rewrites simultaneously and appropriately rearrange the quantum value associated with the loci. In a QAFNY quantum state, qubits in a locus are arranged as a list of indices pointing to qubit positions. The locus indices point to particular qubits in a `Nor` and `Had` typed value since they essentially represent an array of qubits. An `EN` typed value consists of a list of basis-kets; the locus indices refer to the corresponding bases appearing in each basis-ket.

$$\boxed{x[j-1] \sqcup x[0, j-1] \sqcup x[j] \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |\bar{d}\rangle |0\rangle} \quad x[0, j-1] \sqcup x[j] \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle |\bar{1}\rangle \quad x[j] \sqcup x[0, j-1] \mapsto \frac{1}{\sqrt{2}} |0\rangle |\bar{1}\rangle |\bar{1}\rangle$$

In the three example states above from Figure 5, the first maps the locus $\kappa (x[j-1] \sqcup x[0, j-1] \sqcup x[j])$ to the pre-state in the bottom of line P-IF, where $|\bar{d}\rangle$ is expanded to $|d\rangle |\bar{d}\rangle$. In each basis-ket (d is 0 or 1), the first qubit $x[j-1]$ of the locus κ corresponds to the first basis bit, while the last qubit $x[j]$ corresponds to $|0\rangle$, the last basis bit. Applying an operation on $x[j]$ performs the application on the last basis bit $|0\rangle$ for every basis-ket. We can also refer a consecutive fragment of a locus to its basis bits, e.g., range $x[0, j-1]$ refers to $|\bar{d}\rangle$, the middle portion of each basis-ket, provided that they have the same cardinality. In this paper, we call the corresponding basis bits of qubits or locus fragments for a value (or a basis-ket set) as the *qubit's/locus's position bases* of the value (or the basis-ket set). A locus's position bases are linked and moved according to the rewrites of the locus, e.g., the middle and right examples above represent the rewrites from locus $\kappa_1 = x[0, j-1] \sqcup x[j]$ to $\kappa_2 = x[j] \sqcup x[0, j-1]$ in the pre-states (bottom to upper) of Figure 5 line EQ.

The rewrite moves $x[j]$ in κ_1 to the front in κ_2 ; correspondingly, $x[j]$'s position basis ($|0\rangle$) is also moved to the front. These examples show the functionality of *frozen basis stacks*. The two basis-kets' frozen basis stacks both contain a basis $|\bar{1}\rangle$, which are not referenced by any part of a locus and therefore unreachable qubits. As shown in Section 1, we want local reasoning and preserving quantum theorems, i.e., a quantum state for a program piece does not mention qubits that are not reachable in the piece, e.g., accessing $x[j-1]$ above inside the conditional body means a violation of no-cloning. However, quantum states can be entangled, so unreachable qubits cannot be separated from the states. Instead, we hide

the unreachable qubits, such as $x[j-1]$, in the frozen stack and retrieve it after jumping out of the conditional body. A comprehensive example is given in Section 6.2. We show how to unfreeze the frozen bases and explain the motivation for having frozen bases shortly below.

3.3 Rewrites based on Locus Type and State Equivalence Relations

The QAFNY type system maintains simultaneity through the type-guided state rewrites, formalized as equivalence relations (Section 4.3). Other than the locus qubit position permutation introduced above, the types associated with loci in the environment also play an essential role in the rewrites. In QAFNY, a locus represents a possibly entangled qubit group. From the study of many quantum algorithms [2, 4, 35, 48, 1, 43, 30, 14], we found that the establishment of an entanglement group can be viewed as a loop structure of incrementally adding a qubit to the group at a time, representing the entanglement’s scope expansion; as the analogy in Figure 3b, qubits in the blue part are added to the orange part one by one. This behavior is similar to splits and joins of array elements if we view quantum states as arrays. However, joining and splitting two EN-typed values are hard problems ⁴. Another critical observation in studying many quantum algorithms is that the entanglement group establishment usually involves splitting a qubit in a `Nor/Had` typed value and joining it to an existing EN typed entanglement group. We manage these join and split patterns type-guided equations in QAFNY, suitable for automated verification. The GHZ example above (Figure 3c line 5) is an example of `Nor` and an EN type state split and join, where in each loop-step in Figure 3c, a `Nor`-typed qubit $x[j]$ is split from locus $x[j, n)$ and moved to the end of the EN-typed locus $x[0, j)$. Details are in Section 4.3.

3.4 The Qafny Proof System Glance Via Quantum Conditional Proofs

We integrate our type system with the QAFNY proof system, where QAFNY’s type-guided proof triple $(\Omega; \sigma \vdash_g \{P\} e \{Q\})$ states that from a pre-condition P , executing e results in a post-condition Q , provided that P and Q are resp. well-formed w.r.t σ and σ' , where $\Omega, \sigma \vdash_g e \triangleright \sigma'$ is a valid typing judgment (explained in Section 4.3).

A key design principle for proof automation rules is compositional and rule generalization, i.e., automated proof steps should be compositional, where each proof step is localized regarding a localized state, and the generalization means that automation should not depend on the specific local states. The issue with quantum proof rule designs is entanglement, i.e., a program execution on a local state might have global effects, which force the proof automation system to perform case analyses on the local states to resolve the global effects. For example, in verifying the conditional `if` ($x[j-1]$) e in the bottom of Figure 5, e can be applied to an entangled qubit state outside the visibility of qubits mentioned in e . Since e can be arbitrarily complicated, the prior work [56] handles the verification of the quantum conditional by expanding it as a whole matrix applied to a whole quantum state and performing case analyses. For proof automation, we need to design a uniform procedure, expressed as proof rules, to derive the verification; such a task is handled by predicate transformers and frozen stacks built on our locus structures.

An example is given at the line P-If in Figure 5, we utilize two locus predicate transformers \mathcal{F} and \mathcal{U} to transform the pre- and post-conditions so that they focus on the loci and basis-kets relevant to the current computation. In verifying the quantum conditional (`if` ($x[j-1]$) $\{x[j] \leftarrow x[j+1]\}$), we first apply \mathcal{F} to transform the pre-condition. For the value

⁴ The former is a Cartesian product; the latter is $\geq NP$ -hard, both unsuitable for automated verification.

$\frac{1}{\sqrt{2}} |\bar{0}\rangle |0\rangle + \frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle$, we filter out the basis-ket $\frac{1}{\sqrt{2}} |\bar{0}\rangle |0\rangle$, as the Boolean guard ($x[j-1]$) is not satisfiable for $x[j-1]$'s position basis ($|0\rangle$) of the basis-ket. For the remaining basis-ket $\frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle$, we freeze $x[j-1]$'s position basis ($|1\rangle$), by pushing $|1\rangle$ to the frozen stack as an unreachable position, highlighted by $\widehat{|1\rangle}$, since it represents the qubit appearing in the Boolean guard that should not join any computation in e ($x[j] \leftarrow x[j]+1$). A frozen stack represents the link between the local state and its entangled global state. Each basis-ket in a superposition state can be associated with a single frozen stack, and we utilize a predicate transformer to manipulate all these frozen stacks in a state, recording the side-effects of the entangled global state caused by local state changes.

Notice that the locus is transformed from κ to κ_1 by removing $x[j-1]$ to preserve simultaneity. The post-condition $\kappa_1 \mapsto \frac{1}{\sqrt{2}} |\bar{1}\rangle |1\rangle \widehat{|1\rangle}$ contains only the computation result of the basis-ket $\frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle$, and we want the final post-state to contain all other missing pieces, which is the task of the two \mathcal{U} transformers. $\mathcal{U}(b, x[j-1], \kappa)$ points to the basis-ket satisfying the Boolean guard ($\frac{1}{\sqrt{2}} |\bar{1}\rangle |0\rangle$), from the above result post-condition. The transformer transforms $x[j-1]$'s position basis, currently in the stack, back to its normal position. $\mathcal{U}(\neg b, x[j-1], \kappa)$ represents the basis-ket not satisfying the guard ($\frac{1}{\sqrt{2}} |\bar{0}\rangle |0\rangle$), where we retrieve it from the pre-condition through the transformer. Finally, the two transformers transform and assemble the two states into one as the post-condition at the bottom Figure 5. Section 4.4 contains more details.

4 Qafny Formalism

This section formalizes QAFNY's syntax, semantics, type system, proof system, and the corresponding soundness and completeness theorems. Running example in Figure 6 describes quantum order finding, the core component of Shor's algorithm (complete one in TR [24] C.5). The program assumes that an n -qubit H gate and an addition ($y[0, n]+1$) respectively applied to ranges $x[0, n]$ and $y[0, n]$ before line 3. The for-loop entangles range $y[0, n]$ with every qubit in $x[0, n]$, one per loop step, and applies a modulo multiplication in each step. $\text{measure}(y)$ (partial measurement) in line 8 non-deterministically outputs a classical value $a^t \% N$ for y , and interconnectively rearranges $x[0, n]$'s quantum state, with all basis kets' bases related to a period value p . We unveil the details along with the section.

4.1 Qafny Syntax

QAFNY is a C-like flow-sensitive language equipped with quantum heap mutations, quantum conditionals, and for-loops. We intend to provide users with a high-level view of quantum operations, e.g., viewing H and $\text{QFT}^{[-1]}$ gates as state preparation, quantum oracles (μ in [23]) as quantum arithmetic operations, and controlled gates as quantum conditionals and loops. As in Figure 7, aside from standard forms such as sequence ($e ; e$) and $\text{SKIP}(\{\})$, statements e also include let binding ($\text{let } x = am \text{ in } e$), quantum heap mutations ($_ \leftarrow _$), quantum/classical conditionals ($\text{if } (b) e$), and loops ($\text{for } j \in [a_1, a_2] \&& b \{e\}$). The let statement binds either the result of an arithmetic expression (a) or a *computational basis measurement* operator ($\text{measure}(y)$) to an immutable C/M kind variable x in the body e . This design ensures all classical variables are immutable and lexically scoped to avoid quantum observer breakdown due to mutating a classical variable inside a quantum conditional body.

(1) `int u = 0; if (x[0]) u = 1;` ✗ (2) `if (x[0]) let u=1 in {};` ✓ (3) `let u=1 in if (x[0]) {};` ✓

Here, case (1) declares u as 0 and changes its value to 1 inside the quantum conditional,

```

 $1 < a < N \quad E(t) = x[t, n] \mapsto \frac{1}{\sqrt{2^n-t}} \bigotimes_{i=0}^{n-t-1} (|0\rangle + |1\rangle) * x[0, t] \boxplus y[0, n] \mapsto \sum_{i=0}^{2^t-1} \frac{1}{\sqrt{2^t}} |i\rangle |a^i \% N\rangle$ 
1 { $x[0, n] \mapsto \frac{1}{\sqrt{2^n}} \bigotimes_{j=0}^{n-1} (|0\rangle + |1\rangle) * y[0, n] \mapsto |\bar{0}\rangle |1\rangle$ } { $x[0, n] : \text{Had}, y[0, n] : \text{Nor}$ }
2 { $E(0)$ } { $x[0, n] : \text{Had}, x[0, 0] \boxplus y[0, n] : \text{EN}$ }
3 for  $j \in [0, n)$  &&  $x[j]$  { $x[j, n] : \text{Had}, x[0, j] \boxplus y[0, n] : \text{EN}$ }
4 { $E(j)$ } { $x[0, 0] : \text{Had}, x[0, n] \boxplus y[0, n] : \text{EN}$ }
5  $y[0, n] \leftarrow a^{2^j} \cdot y[0, n] \% N;$  { $x[0, 0] : \text{Had}, x[0, n] \boxplus y[0, n] : \text{EN}$ }
6 { $E(n)$ } { $x[0, n] \boxplus y[0, n] \mapsto \sum_{i=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |i\rangle |a^i \% N\rangle$ } { $x[0, n] \boxplus y[0, n] : \text{EN}$ }
7 let  $u = \text{measure}(y)$  in ...
8 { $x[0, n] \mapsto \frac{1}{\sqrt{r}} \sum_{k=0}^{r-1} |t+kp\rangle * p = \text{ord}(a, N)$ } { $x[0, n] : \text{EN}$ }
9 { $* u = (\frac{p}{2^n}, a^t \% N) * r = \text{rnd}(\frac{2^n}{p})$ } { $x[0, n] : \text{EN}$ }

```

Figure 6 Snippets from quantum order finding in Shor’s algorithm; full proof in TR [24] C.5. $\text{ord}(a, N)$ gets the order of a and N . $\text{rnd}(r)$ rounds r to the nearest integer. We interpret integers as bitstrings in $|i\rangle$ and $|a^i \% N\rangle$. The right column presents the types of all loci involved.

Figure 7 Core QAFNY syntax. Element syntax is in Figure 4 and oQASM is in [23]. $\text{QFT}^{[-1]}$ refers to the QFT and reversed QFT. An arithmetic expression x is a C/M kind variable, $x[i, j)$ is a quantum array range, and v is a C/M kind value. $x[a]$ is the a -th element of qubit array x .

which creates an observer effect because u ’s value depends on qubit $x[0]$. Cases (2) and (3) show that our immutable `let` binding can avoid the issue because the binding in (2) can be compiled to (3) due to the immutability; thus, u ’s value does not depend on the qubit.

A quantum heap mutation operation mutates qubit array data by applying to a locus κ either a unitary state preparation operation (op) (one of Hadamard H , quantum Fourier transformation QFT , and its inverse QFT^{-1}) or a unitary oracle operation (μ).⁵ Other unitary operations, including quantum diffusion and amplification operations, are in TR [24] C.1.

Quantum reversible Boolean guards b are implemented as OQASM oracle operations, expressed by one of $(a_1 = a_2) @ x[a]$, $(a_1 < a_2) @ x[a]$, and $x[a]$, which intuitively amounts to computing $a_1 = a_2$, $a_1 < a_2$ and `false` respectively as b_0 and storing the result of $b_0 \oplus x[a]$ as a binary in qubit $x[a]$.⁶ In both conditionals and loops, guards b are used to represent the qubits that are controlling. In addition to the `let` bindings, the quantum for-loop also introduces and enumerates C-kind value j over interval $[a_1, a_2)$ with j visible to both the guard b and the loop body e . As a result of immutability, loops in QAFNY are guaranteed to terminate. If all variables in the guard b are classical, the conditional or

⁵ μ can define all quantum arithmetics, e.g., $x[j]+1$ (Fig. 3c) & $a^{2^j} y[0, n] \% N$ (Fig. 6). See [23].

⁶ a_1 and a_2 can possibly apply to a range, like $y[0, n)$, in an entangled locus.

 **Figure 8** Selected semantic rules. $\{c\}$ turns basis c to an integer.

loop becomes a standard classical one, which is differentiated and definable by our type system, described in TR [24] C. Obviously, users can always view a QAFNY program as a quantum sub-component in a Dafny program, which provides better library support for classical conditionals. Predicates and predicate loci in Figure 7 describe quantum state properties in the QAFNY proof system, explained in Section 4.4.

4.2 Qafny Semantics

The QAFNY semantics is formalized as a big-step transition relation $(\varphi, e) \Downarrow \varphi'$, with φ / φ' being quantum states as described in Figure 4. The judgment relation states that a program e with the pre-state φ transitions to a post-state φ' . A selection of the rules defining \Downarrow may be found Figure 8, and the additional rules are in TR [24] C.2. $FV(\Omega, -)$ produces a locus by unioning all qubits in $-$ with the quantum variable kind information in Ω ; its definition is given in TR [24] A.

Assignment and Mutation Operations. Rules S-EXPC and S-EXPM define the behaviors for C and M kind classical variable assignments, which perform variable-value substitutions. Rule S-OP defines a quantum heap mutation applying a state preparation operation (op) or an oracle expression (μ) to a locus κ for a EN-typed state. Here, the locus fragment κ to which the operation is applied must be the very first one in the locus $\kappa \boxdot \kappa'$ that refers to the entire quantum state q . If not, we will first apply equivalence rewrites to be explained in Section 4.3 to move κ to the front. With κ preceding the rest fragment κ' , the operation’s semantic function $\llbracket \circ \rrbracket^n$ (\circ being H or μ) is then applied to κ ’s position bases in the quantum value q . More specifically, the function is only applied to the first n (equal to $|\kappa|$) basis bits of each basis-ket in the value while leaving the rest unchanged. The semantic interpretations of the op and μ operations are essentially the quantum gate semantics given in Li et al. [23]. For example, in Figure 5 line P-ORACLE, we apply an oracle operation $x[j]+1$ to $x[j]$, the first position of the locus κ_2 (i.e., $x[j] \boxdot x[0, j-1]$), which transforms the first basis bit to $|1\rangle$.

Before the application, we rewrite the pre-state containing κ_1 below the line EQ in Figure 5, to the form corresponding to the locus κ_2 above the line.

Quantum Conditionals. As in rule S-IF, for a conditional $\text{if } (b) e$, we first evaluate the Boolean guard b on κ 's position bases ($FV(\Omega, b) = \kappa$) of the quantum value state q to $\llbracket b \rrbracket^{|\kappa|} q$ ⁷ because b 's computation might have side-effects in changing κ 's position bases, as the example in Section 6.2. The quantum value referred by $\kappa \sqcup \kappa'$ is further partitioned into $q\langle\kappa, b\rangle + q\langle\kappa, \neg b\rangle$ where $q\langle\kappa, b\rangle$ is a set of basis-kets whose κ 's position bases satisfying b and $q\langle\kappa, \neg b\rangle$ is the rest. Since the body e only affects the basis-kets ($q\langle\kappa, b\rangle$) satisfying the guard b , we rule out the basis-kets $q\langle\kappa, \neg b\rangle$ (unsatisfying the guard) in e 's computation. We also need to push κ 's position bases in $q\langle\kappa, b\rangle$ to the frozen stacks through the S^n operation to maintain the locus-state simultaneity in Section 3.2.

We describe rule S-IF along with an example in Figure 6 line 3-5. Here, the j -th iteration is unrolled to a quantum conditional $\text{if } (x[j]) \{y[0, n] \leftarrow a^{2^j} \cdot y[0, n]\% N\}$. The loci involved in the computation are $x[j]$ and $x[0, j] \sqcup y[0, n]$, and their state transitions are given as:

$$\begin{aligned} & \left\{ x[j] : \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \right\} \sqcup \left\{ x[0, j] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |i\rangle |a^i \% N\rangle \right\} \\ \equiv & \left\{ x[j] \sqcup x[0, j] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |1\rangle |i\rangle |a^i \% N\rangle + \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |0\rangle |i\rangle |a^i \% N\rangle \right\} \\ \xrightarrow{\text{S-IF}} & \left\{ x[j] \sqcup x[0, j] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |1\rangle |i\rangle |(a^i \cdot a^{2^j}) \% N\rangle + \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |0\rangle |i\rangle |a^i \% N\rangle \right\} \\ \equiv & \left\{ x[0, j+1] \sqcup y[0, n] : \sum_{i=0}^{2^{j+1}-1} \frac{1}{\sqrt{2^{j+1}}} |i\rangle |a^i \% N\rangle \right\} \end{aligned}$$

The first equation transition (\equiv) merges the two locus states and turns the merged state into two sets (separated by \sqcup), respectively representing basis-kets where $x[j]$'s position bases are 1 and 0. Since the Boolean guard $x[j]$ has no side-effects, the application $\llbracket b \rrbracket^{|\kappa|}$ is an identity. The S-IF application performs a modulo multiplication oracle application on the basis-ket set where $x[j]$'s position bases being 1, while the last equation merges the two sets back to one summation formula. The S-IF application above can be further decomposed into two additional transitions in between:

$$\begin{aligned} \longrightarrow & \left\{ x[0, j] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |i\rangle |a^i \% N\rangle |\overline{1}\rangle \right\} \\ \xrightarrow{\text{S-OP}} & \left\{ x[0, j] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |i\rangle |(a^i \cdot a^{2^j}) \% N\rangle |\overline{1}\rangle \right\} \end{aligned}$$

The first transition removes the $q\langle\kappa, \neg b\rangle$ part, e.g., the basis-ket set where $x[j]$'s position bases are 0. Additionally, for every basis-ket in the $q\langle\kappa, b\rangle$ set, e.g., the basis-ket set where $x[j]$'s position bases being 1, we freeze κ 's position bases by pushing the bases into the basis-ket's stacks through the function application $S^{|\kappa|}(q\langle\kappa, b\rangle)$, which finds the first $|\kappa|$ bits in every basis-ket and push them into the basis-ket's stack so that e 's application targets locus κ' instead of $\kappa \sqcup \kappa'$. As the first transition above, for each basis-ket, we push $x[j]$'s position basis ($|1\rangle$) to the basis-ket's stack, as the $|\overline{1}\rangle$ part and the pointed-to locus is rewritten to $x[0, j] \sqcup y[0, n]$. After applying the body e to the state, for every basis-ket, we pop κ 's position bases ($P(q')$) from the basis-ket's stack and relabel the locus of the state to be $\kappa \sqcup \kappa'$; in doing so, we also need to add the unmodified basis-kets $q\langle\kappa, \neg b\rangle$ back into the whole state. After applying S-OP on locus $x[0, j] \sqcup y[0, n]$ above, we pop $|\overline{1}\rangle$ from every basis-ket's stack and assemble the unchanged part ($\sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^{j+1}}} |0\rangle |i\rangle |a^i \% N\rangle$) back to the state of locus $x[j] \sqcup x[0, j] \sqcup y[0, n]$; the result is shown as the state after the $\xrightarrow{\text{S-IF}}$ application above.

⁷ This is defined formally as an oracle, same as μ above.

 \end{array}$$

 **Figure 9** QAFNY type system. $FV(\Omega, -)$ gets a locus containing qubits in $-$ w.r.t. Ω (TR [24] A).

Quantum Measurement. A measurement (`let x = measure(y) in e`) collapses a qubit array y , binds a \mathbb{M} -kind outcome to x , and restricts its usage in e . Rule S-MEA shows the partial measurement behavior⁸. Assume that the locus containing the qubit array y is $y[0, n) \sqsubseteq \kappa'$, the measurement is essentially a two-step array filter: (1) the basis-kets of the EN typed value is partitioned into two sets (separated by $+$): $(\sum_{j=0}^m z_j |c\rangle |c_j\rangle) + q\langle \kappa, c \neq \kappa \rangle$ with $\kappa = y[0, n)$, by randomly picking a $|\kappa|$ -length basis c where every basis-ket in the first set have κ 's position basis c ; and (2) we create a new array value by removing all the basis-kets not having c as prefixes (the $q\langle \kappa, c \neq \kappa \rangle$ part) and also removing the κ 's position basis in every remaining basis-ket; thus, the quantum value becomes $\sum_{j=0}^m \frac{z_j}{\sqrt{r}} \eta_j$. Notice that the element size of the post-state $m+1$ is smaller than the size of the pre-state before the measurement. Since the amplitudes of basis-kets must satisfy $\sum_i |z_i|^2 = 1$, we need to normalize the amplitude of each element in the post-state by multiplying a factor $\frac{1}{\sqrt{r}}$, with $r = \sum_{j=0}^m |z_j|^2$ as the sum of the amplitude squares appearing in the post-state. When proving quantum program properties, the amplitudes appearing in basis-kets usually follow a periodic pattern that users can provide, so computing r will be relatively simple, see Section 4.4. In Figure 6, the measurement (line 8) transitions the state from lines 7 to 9. Locus $y[0, n)$'s position basis is $|a^i \% N\rangle$ for each basis-ket in $\sum_{i=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |i\rangle |a^i \% N\rangle$. We then randomly pick the basis value $a^t \% N$ as a measurement result, stored in u , and the probability of the pick is $\frac{p}{2^n}$ where p is the order of a and N . The probability is computed solely based on p because it represents the period of the factorization in Shor's algorithm. The number (r) of remaining basis-kets in range $x[0, n)$ is computed by rounding $\frac{2^n}{p}$.

4.3 Qafny Locus Type System

The QAFNY typing judgment $\Omega; \sigma \vdash_g e \triangleright \sigma'$ states that e is well-typed under the context mode g (the syntax of kind g is reused as context modes) and environments Ω and σ . The kind environment Ω is populated through `let` and `for` loops that introduce \mathbb{C} and \mathbb{M} kind variables, while \mathbb{Q} -kind variable mappings in Ω are given as a global environment. Selected type rules are in Figure 9; the rules not mentioned are similar and given in TR [24] C.3. For every type rule, well-formed domains ($\Omega \vdash \text{dom}(\sigma)$) are required but hidden from the rules,

⁸ A complete measurement is a special case of a partial measurement when κ' is empty in S-MEA

$$\begin{array}{ll}

Figure 10 QAFNY type/state relations. \cdot is math mult. Term $\sum^{n+m} P$ is a summation omitting the indexing details. \otimes expands a Had array, as $\frac{1}{\sqrt{2^{n+m}}} \otimes_{j=0}^{n+m-2} q_j = (\frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} q_j) \otimes (\frac{1}{\sqrt{2^m}} \otimes_{j=0}^{m-1} q_j)$.

such that every variable used in all loci of σ must appear in Ω , while $\Omega \vdash a : \mathbb{M}$ judges that the expression a is well-formed and returns an \mathbb{M} kind; see TR [24] A and B. The type system enforces three properties below.

No Cloning and Observer Breakdown. We enforce no cloning by disjointing qubits mentioned in a quantum conditional Boolean guard and its body. In rule T-IF, κ and κ' are disjoint unioned, and the two *FV* side-conditions ensure that the qubits mentioned in the Boolean guard and conditional body are respectively within κ and κ' ; thus, they do not overlap. QAFNY is a *flow-sensitive* language, as we enforce no observer breakdown by ensuring no classical variable assignments through the QAFNY syntax and no measurements inside a quantum conditional through context restrictions. Each program begins with the context mode C , which permits all QAFNY operations. Once a type rule switches the mode to M , as in T-IF, measurement operations are suspended in this scope, as T-MEA is valid only if the context mode is C . For instance, let's imagine that the measurement in Figure 6 line 8 lives inside the for-loop in line 5, which our type system would forbid because type checking through T-LOOP calls rule T-IF that marks the context mode to M , while the application of rule T-MEA requires a C mode context to begin with.

Guiding Locus Equivalence and Rewriting. The semantics in Section 4.2 assumes that the loci in quantum states can be in ideal forms, e.g., rule S-OP assumes that the target locus κ are always prefixed. This step is valid if we can rewrite (type environment partial order \preceq) the locus to the ideal form through rule T-PAR, which interconnectively rewrites the locus appearing in the state, through our state equivalence relation (\equiv), as the locus state simultaneity enforcement (Section 3.2). The state equivalence rewrites have two components.

First, the type and quantum value forms have simultaneity, i.e., given a type τ_1 for a locus κ in a type environment (σ), if it is a subtype (\sqsubseteq) of another type τ_2 , κ 's value q_1 in a state (φ) can be rewritten to q_2 that has the type τ_2 through state equivalence rewrites (\equiv_n) where n is the number of qubits in q_1 and q_2 . Both \sqsubseteq and \equiv_n are reflexive and

types `Nor` and `Had` are subtypes of `EN`, which means that a `Nor` typed value ($|c\rangle$) and a `Had` typed value ($\frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} (|0\rangle + \alpha(r_j)|1\rangle)$) can be rewritten to an `EN` typed value (TR [24] C.3). For example, range $x[0, n]$'s `Had` typed value $\frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} (|0\rangle + |1\rangle)$ in Figure 6 line 1 can be rewritten to an `EN` type as $\sum_{i=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |i\rangle$. If such a rewrite happens, we correspondingly transform $x[0, n]$'s type to `EN` in the type environment.

Second, type environment partial order (\preceq) and state equivalence (\equiv) also have simultaneity – in a proof judgment, we associate the state predicate, representing a state φ , with the type environment σ by sharing the same domain, i.e., $\text{dom}(\varphi) = \text{dom}(\sigma)$. Thus, the environment rewrites (\preceq) happening in σ gear the state rewrites in φ , e.g., the bottom proof step of Figure 5 transforms locus $x[0, j]$ in σ to locus κ ($x[j-1] \sqcup x[0, j-1] \sqcup x[j]$) above it, and the state rewrites in the pre-condition predicate happen accordingly as (left to right):

$$\begin{array}{lll} \{x[0, j] : \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle\} \uplus \{x[j] : |0\rangle\} & \equiv & \{x[0, j+1] : \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |0\rangle\} \\ \{x[0, j] : \text{EN}\} & \uplus \{x[j] : \text{Nor}\} & \preceq \{x[0, j+1] : \text{EN}\} \\ & & \preceq \{\kappa : \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle |0\rangle\} \end{array}$$

Here, we add qubit $x[j]$ ($|0\rangle$) to the end of locus $x[0, j]$ and transform locus $x[0, j+1]$ to κ , so the upper proof step (P-IF) in Figure 5 can proceed. The above rewrites are derived by the rules in Figure 10, where the rules in environment partial order and state equivalence are one-to-one corresponding. The first three lines describe the properties of reflective, identity, and subtyping equivalence. The fourth line enforces that the environment and state are close under locus permutation. After the equivalence rewrite, the position bases of ranges s_1 and s_2 are mutated by applying the function $q^{|\kappa_1|}(|s_1| \asymp |s_2|)$. One example is the locus rewrite in Figure 6 line 7 from left to right, as:

$$\begin{array}{lll} \{x[0, n] \sqcup y[0, n] : \text{EN}\} & \preceq & \{y[0, n] \sqcup x[0, n] : \text{EN}\} \\ \{x[0, n] \sqcup y[0, n] : \sum_{i=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |i\rangle |a^i \% N\rangle\} & \equiv & \{y[0, n] \sqcup x[0, n] : \sum_{i=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |a^i \% N\rangle |i\rangle\} \end{array}$$

The last two lines in Figures 10a and 10b describe locus joins and splits, where the latter is an inverse of the former but much harder to perform practically. In the most general form, joining two `EN`-typed states computes the Cartesian product of their basis-kets, shown in the bottom of Figure 10, which is practically hard for proof automation. Fortunately, the join operations in most quantum algorithms are between a `Nor/Had` typed and an `EN`-typed state. Joining a `Nor`-typed and `EN`-typed state puts extra qubits in the right location in every basis-ket of the `EN`-typed state as discussed in Section 3.3. Joining a `Had`-typed qubit (single qubit state) and `EN`-typed state duplicates the `EN`-typed basis-kets. In every loop step in Figure 6 line 3-5, we add a `Had`-typed qubit $x[j]$ to the middle of an `EN`-typed locus $x[0, j] \sqcup y[0, n]$, transform the state to:

$$\{x[0, j+1] \sqcup y[0, n] : \sum_{i=0}^{2^j-1} \frac{1}{\sqrt{2^j}} |i\rangle |0\rangle |a^i \% N\rangle + \sum_{j=0}^{2^j} \frac{1}{\sqrt{2^{j-1}}} |i\rangle |1\rangle |a^i \% N\rangle\}$$

The state can be further rewritten to the one in Figure 6 by merging the above two parts (separated by $+$). Notice that the basis-kets are still all distinct because the two parts are distinguished by $x[j]$'s position basis, i.e., $|0\rangle$ and $|1\rangle$. TR [24] F shows practical ways to perform additional state joins and splits, including an upgraded dependent type system to permit a few cases of splitting `EN` typed values.

Approximating Locus Scope. The type system approximates locus scopes. In rule T-IF, we use $\kappa \approx \kappa'$ as the approximate locus large enough to describe all possible qubits directly and indirectly mentioned in b and e . Such scope approximation might be over-approximated, which does not cause incorrectness in our proof system, while under-approximation is forbidden.

 **Figure 11** Select proof rules.

For example, if we combine two Had-typed qubits in our system and transform the value to EN-type as $\frac{1}{2}(|00\rangle + |01\rangle + |10\rangle + |11\rangle)$, this is an over-approximation since the two qubits are not entangled. Partially measuring the first qubit leaves the second qubit's value unchanged as $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$.

In addition to the above properties, we allow C-kind classical variables introduced by `let` to be evaluated in the type checking stage ⁹, while tracks M variables in Ω . Rule T-EXPC enforces that a classical variable x is replaced with its assigned value n in e , and classical expressions in e containing x are evaluated, so the proof system can avoid handling constants.

4.4 The Qafny Proof System

Every valid proof judgment $\Omega; \sigma \vdash_g \{P\} e \{Q\}$, shown in Figure 11, contains a pre- and post-condition predicates P and Q (syntax in Figure 7) for the statement e , satisfying the type restriction that $\Omega; \sigma \vdash_g e \triangleright \sigma'$; we also enforce that the predicate well-typed restrictions $\Omega; \sigma \vdash P$ and $\Omega; \sigma' \vdash Q$, meaning that all loci mentioned in P must be in the right forms and as elements in $\text{dom}(\sigma)$, introduced in TR [24] B. We state the restrictions as the typechecking constraint (TC) below:

$$TC(\sigma, P, Q) \triangleq \Omega; \sigma \vdash_g e \triangleright \sigma_1 \wedge \Omega; \sigma \vdash P \wedge \Omega; \sigma_1 \vdash Q$$

Rule P-CON describes the consequence rule where a well-formed pre- and post-conditions P and Q under σ is replaced by P' and Q' , well-formed under σ' . Under the new conditions, we enforce a new type constraint $TC(\sigma', P', Q')$. Rule P-FRAME is a specialized separation logic frame rule that separates the locus type environment and the quantum value to support local reasoning on quantum states. Rule M-FRAME in Figure 12 describes the predicate semantics

⁹ We consider all computation that only needs classical computers is done in the compilation time.

Predicate Model Rules:

M-MAP	$\Omega; \psi; \sigma; \varphi \uplus \{\kappa : \sum_j z_j c_j\rangle \langle \beta_j\}\models_g \kappa \mapsto \sum_j z_j c_j\rangle \langle \beta'_j\}$
M-LOCAL	$\Omega[x \mapsto M]; \psi[x \mapsto (r, v)]; \sigma; \varphi \models_g P \quad \text{if } \Omega; \psi; \sigma; \varphi \models_g P[(r, v)/x]$
M-FRAME	$\Omega; \psi; \sigma \uplus \sigma'; \varphi \uplus \varphi' \models_g P * Q \quad \text{if } \Omega; \psi; \sigma; \varphi \models_g P \text{ and } \Omega; \psi; \sigma'; \varphi' \models_g Q$

Transformation Rules:

M- \mathcal{F}	$\mathcal{F}(b, \kappa, \kappa') \mapsto q = \kappa' \mapsto \sum_j z_j \beta_j \langle c_j\rangle \beta'_j \rangle$
	where $\llbracket b \rrbracket^{ \kappa } q = q(\kappa, b) + q(\kappa, \neg b) \wedge q(\kappa, b) = \sum_j z_j c_j\rangle \beta_j \langle \beta'_j \rangle \wedge \forall j. c_j = \kappa $
M- \mathcal{U}	$\begin{aligned} \mathcal{U}(\neg b, \kappa, \kappa') &\mapsto \sum_j z_j c_j\rangle \eta_j + q(\kappa, \neg b) \\ * \mathcal{U}(b, \kappa, \kappa') &\mapsto \sum_j z'_j \beta_j \langle c_j\rangle \beta'_j \rangle \end{aligned} = \kappa' \mapsto \sum_j z'_j c_j\rangle \beta_j \langle \beta'_j \rangle + q(\kappa, \neg b) \quad \text{where } \forall j. \kappa = c_j $
M- \mathcal{M}	$\mathcal{M}(x, n, \kappa) \mapsto \sum_j z_j c\rangle \eta_j + q(\kappa, c \neq \kappa) = \kappa \mapsto \sum_j \frac{z_j}{\sqrt{r}} \eta_j * x = (r, \{c\}) \quad \text{where } n = c $

Figure 12 Predicate semantics.

of the separating conjunction $*$, where ψ is a local store mapping from M-kind variables to M-kind values (r, n) ; we require $\text{dom}(\psi) \subseteq \text{dom}(\Omega)$ and M-kind variables modeled by M-LOCAL. Besides predicate well-formedness, the predicate semantic judgment $(\Omega; \psi; \sigma; \varphi \models_g P)$ also ensures the states (φ) being well-formed $(\Omega; \sigma \vdash_g \varphi)$, defined as follows:

- **Definition 1** (Well-formed QAFNY state). A state φ is *well-formed*, written as $\Omega; \sigma \vdash_g \varphi$, iff $\text{dom}(\sigma) = \text{dom}(\varphi)$, $\Omega \vdash \text{dom}(\sigma)$ (all variables in φ are in Ω), and:
 - For every $\kappa \in \text{dom}(\sigma)$, s.t. $\sigma(\kappa) = \text{Nor}$, $\varphi(\kappa) = z |c\rangle \langle \beta|$ and $|\kappa| = |c|$ and $|z| \leq 1$; specifically, if $g = C$, $\beta = \emptyset$ and $|z| = 1$.¹⁰
 - For every $\kappa \in \text{dom}(\sigma)$, s.t. $\sigma(\kappa) = \text{Had}$, $\varphi(\kappa) = \frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} (|0\rangle + \alpha(r_j) |1\rangle)$ and $|\kappa| = n$.
 - For every $\kappa \in \text{dom}(\sigma)$, s.t. $\sigma(\kappa) = \text{EN}$, $\varphi(\kappa) = \sum_{j=0}^m z_j |c_j\rangle \langle \beta_j|$, and for all j , $|\kappa| = |c_j|$ and $\sum_{j=0}^m |z_j|^2 \leq 1$; specifically, if $g = C$, for all j , $\beta_j = \emptyset$ and $\sum_{j=0}^m |z_j|^2 = 1$.

Here, an M mode state, representing a computation living in an M mode context, has a relaxed well-formedness, where $\sum_{j=0}^m |z_j|^2 \leq 1$ and $\beta_j \neq \emptyset$. This is needed for describing the state inside the execution of a conditional body in rule S-IF in Section 4.2, where unmodified basis-kets are removed before the execution. There is a trick to utilizing the frozen stacks for promoting proof automation, as the modeling rule M-MAP equates two quantum values by discarding the frozen stack qubits, and we will see an example in Section 6.1.

The predicate syntax (Figure 7) introduces three locus predicate transformers \mathcal{F} , \mathcal{U} , and \mathcal{M} in the locus syntax category, but their semantics (Figure 12) essentially transform quantum states in the predicates, as we define them in equational style, explained below.

Assignment and Heap Mutation Operations. Rule P-EXPC describes C-kind variable substitutions. Rule P-OP is a classical separation logic style heap mutation rule for state preparations $\kappa \leftarrow op$ and oracles $\kappa \leftarrow \mu$, which analogize such operations as classical array map operations mentioned in Figure 2. Here, we discuss the cases when the state of the target loci $\kappa \uplus \kappa'$ is of type EN, while some other cases are introduced in TR [24] C.4. Each element in the array style pre-state q , for locus $\kappa \uplus \kappa'$, represents a basis-ket $z_j |c_j\rangle \eta_j$, with $|\kappa| = |c_j|$. Here, we first locate κ 's position basis $|c_j\rangle$ in each basis-ket of q , and then apply the operations op or μ to $|c_j\rangle$.

Quantum Conditionals. As in Section 3.4 and Figure 5, the key in designing a proof rule for a quantum conditional $\text{if } (b) \{e\}$ with its locus scope $\kappa \uplus \kappa'$, is to encode two transformers: \mathcal{F} and \mathcal{U} . In rule P-IF (Figure 11), we require the σ only contains locus $\kappa \uplus \kappa'$, which can be done

¹⁰ $|\kappa|$ and $|c|$ are the lengths of κ and c , and $|z|$ is the norm.

through P-FRAME. We then utilize $\mathcal{F}(b, \kappa, \kappa')$ to finish two tasks: (1) it computes b 's side-effects on the κ 's position bases ($\llbracket b \rrbracket^{|\kappa|} q$), and (2) it freezes all basis-kets that are irrelevant when reasoning about the body e . This freezing mechanism modeled by the equation M- \mathcal{F} (Figure 12) is accomplished at two levels: stashing all kets unsatisfying b ($q\langle \kappa, \neg b \rangle$) and moving κ 's position bases to basis stacks for the rest of basis-kets. After substituting $\kappa \bowtie \kappa'$ for $\mathcal{F}(b, \kappa, \kappa')$, besides expelling the parts not satisfying b , we also shrink the locus $\kappa \bowtie \kappa'$ to κ' , which in turn marked the κ 's position basis in every basis-ket inaccessible as κ is now invisible in the locus type environment.

After the body e 's proof steps, the post-state Q describes the computation result for κ' without the frozen parts. To reinstate the state for $\kappa \bowtie \kappa'$ by retrieving the frozen parts, we first substitute locus $\kappa \bowtie \kappa'$ for $\mathcal{U}(\neg b, \kappa, \kappa \bowtie \kappa')$ in P , which represents the unmodified part, unsatisfying b , in the pre-state. We also substitute κ' for $\mathcal{U}(b, \kappa, \kappa \bowtie \kappa')$ in Q , which represents the part satisfying b , evolved due to the execution of e . Rule M- \mathcal{U} (Figure 12) describes the predicate transformation, empowered by the locus construct \mathcal{U} , that utilizes the innate relation of separating conjunction and logical complement to assemble the previously unmodified and the evolved parts. Rule P-LOOP proves a **for** loop where $P(j)$ is the loop invariant parameterized over the loop counter j . Other rules are introduced in TR [24] C.4.

Measurement. A measurement (`let x = measure(y) in e`) collapses a qubit array y , binds an M kind outcome to x and restricts its usage in e . These statements usually appear in periodical patterns in many quantum algorithms, which users formalize as predicates to help verify algorithm properties. In rule P-MEA, we first select an n -length prefix bitstring c from one of range $y[0, n)$'s position bases; it then computes the probability r and assigns $(r, \{c\})$ to variable x . We then replace the locus $y[0, n) \bowtie \kappa$ in P with a locus predicate transformer $\mathcal{M}(x, n, \kappa)$ and update the type state Ω and σ by replacing $y[0, n) \bowtie \kappa$ with κ . The construct $\mathcal{M}(x, n, \kappa)$, with its transformation rule M- \mathcal{M} (Figure 12), is introduced to do exactly the two steps in Section 4.2 for describing measurement operations, i.e., we remove basis-kets not having c as $y[0, n)$'s position bases ($q\langle \kappa, c \neq \kappa \rangle$) and truncate $y[0, n)$'s position bases in the rest basis-kets.

$$\frac{\Omega[u \mapsto \text{M}]; \{x[0, n) : \text{EN}\} \vdash_c \{\mathcal{M}(u, n, x[0, n)) \mapsto C\} \{\} \{x[0, n) \mapsto D * E\}}{\Omega; \{y[0, n) \bowtie x[0, n) : \text{EN}\} \vdash_c \{y[0, n) \bowtie x[0, n) \mapsto C\} \text{ let } u = \text{measure}(y) \text{ in } \{\} \{x[0, n) \mapsto D * E\}}$$

$$C \triangleq \sum_{j=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |a^j \% N\rangle |j\rangle \quad D \triangleq \frac{1}{\sqrt{r}} \sum_{k=0}^{r-1} |t + kp\rangle \quad E \triangleq p = \text{ord}(a, N) * u = (\frac{p}{2^n}, a^t \% N) * r = \text{rnd}(\frac{2^n}{p})$$

We show a proof fragment above for the partial measurement in Figure 6 line 8. The proof applies rule P-MEA by replacing locus $y[0, n) \bowtie x[0, n)$ with $\mathcal{M}(u, n, x[0, n))$. On the top, the pre- and post-conditions are equivalent, as explained below. In locus $y[0, n) \bowtie x[0, n)$'s state, for every basis-ket, range $y[0, n)$'s position basis is $|a^j \% N\rangle$; the value j is range $x[0, n)$'s position basis for the same basis-ket. Randomly picking a basis value $a^t \% N$ also filters a specific j in range $x[0, n)$, i.e., we collect any j having the relation $a^j \% N = a^t \% N$. Notice that modulo multiplication is a periodic function, which means that the relation can be rewritten $a^{t+kp} \% N = a^t \% N$, and p is the period order. Thus, the post-measurement state for range $x[0, n)$ can be rewritten as a summation of k : $\frac{1}{\sqrt{r}} \sum_{k=0}^{r-1} |t + kp\rangle$. The probability of selecting $|a^j \% N\rangle$ is $\frac{r}{2^n}$. In the QAFNY implementation, we include additional axioms for these periodical theorems to grant this pre- and post-condition equivalence so that we can utilize QAFNY to verify Shor's algorithm.

4.5 Qafny Metatheory

We now present QAFNY’s type soundness and its proof system’s soundness and relative completeness. These results have all been verified in Coq. We prove our type system’s soundness with respect to the semantics, assuming well-formedness (TR [24] Definition 5 and Definition 1). The type soundness shows that our type system ensures the three properties in Section 4.3 and that the “in-place” style QAFNY semantics can describe all different quantum operations without losing generality because we can always use the equivalence rewrites to rewrite the locus state in ideal forms.

► **Theorem 2** (QAFNY type soundness). If $\Omega; \sigma \vdash_g e \triangleright \sigma'$ and $\Omega; \sigma \vdash_g \varphi$, then there exists φ' such that $(\varphi, e) \Downarrow \varphi'$ and $\Omega; \sigma' \vdash_g \varphi'$.

Our proof system is sound and relatively complete w.r.t. its semantics for well-typed QAFNY programs. Our system utilizes a subset of separation logic admitting completeness by excluding qubit array allocation and pointer aliasing. Since every quantum program in QAFNY converges, the soundness and completeness refer to the total correctness of the QAFNY proof system. $\psi(e)$ refers to that we substitute every variable $x \in \text{dom}(\psi)$ in e with $\psi(x)$.

► **Theorem 3** (proof system soundness). For any program e , such that $\Omega; \sigma \vdash_g e \triangleright \sigma'$ and $\Omega; \sigma \vdash_g \{P\} e \{Q\}$, and for every ψ and φ , such that $\Omega; \sigma \vdash_g \varphi$ and $\Omega; \psi; \sigma; \varphi \models_g P$, there exists a state φ' , such that $(\varphi, \psi(e)) \Downarrow \varphi'$ and $\Omega; \sigma' \vdash_g \varphi'$ and $\Omega; \psi; \sigma'; \varphi' \models_g Q$.

► **Theorem 4** (proof system relative completeness). For a well-typed program e , such that $\Omega; \sigma \vdash_g e \triangleright \sigma'$, $(\varphi, e) \Downarrow \varphi'$ and $\Omega; \sigma \vdash_g \varphi$, and for all predicates P and Q such that $\Omega; \emptyset; \sigma; \varphi \models_g P$ and $\Omega; \emptyset; \sigma'; \varphi' \models_g Q$, we have $\Omega; \sigma \vdash_g \{P\} e \{Q\}$.

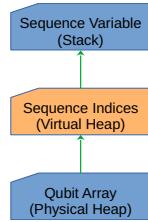

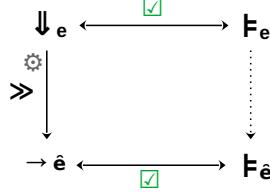

5 Qafny Compilation and Implementation Evaluation

Here, we focus on the QAFNY proof system compilation to a subset of separation logic.

5.1 Translation from Qafny to Separation Logic

The QAFNY types and loci are extra annotations associated with QAFNY programs and predicates for proof automation. In the QAFNY implementation in Dafny, these annotations are not present – qubits are arranged as simple array structures without extra metadata such as locus types. This section shows how QAFNY annotations can be safely erased with no loss of expressiveness, e.g., loci are represented as virtual-level dynamic sequences without types, and equational rewrites are compiled with extra operations in the compiled language. We present a compilation algorithm that converts from QAFNY to SEP, a C-like language admitting a subset of an array separation logic proof system.

Target Compilation Language. SEP is based on a variant of the separation logic introduced by Yang and O’Hearn [55], which is sound and complete. Mainly, we utilize the allocation (`alloc`), heap lookup and mutation operations (`mutate`) in the work, with three additional operations (marked red in Figure 13). In SEP, program states are divided into virtual and physical levels in Figure 14. Every SEP program starts with a physical qubit array, analogous to physical heap structures. The program operations are applied to qubit sequences of array indices (A), representing a collection of physical qubit locations that live at the virtual level. SEP permits immutable program variables (x) representing these sequences.

$$\begin{aligned}
 A, B &::= \bar{n} \\
 \tilde{o}p &::= \mu \mid op \\
 \tilde{e} &::= x = \text{alloc}(A) \\
 &\quad \mid \text{mutate}(n, \tilde{o}p, x) \\
 &\quad \mid (r, n) = \text{pick}(x, m) \\
 &\quad \mid \text{filter}(x, b) \\
 &\quad \mid \text{amp}(x, r) \\
 &\quad \dots
 \end{aligned}$$
Figure 13 SEP Syntax.**Figure 14** Heap Layout.**Figure 15** Compilation Proof Diagram.

An allocation $x = \text{alloc}(A)$ allocates a new array x that copies A 's content and has the same length as A , while a heap mutation $\text{mutate}(n, \tilde{o}p, x)$ mutates the first n elements of the array pointed to by x , by applying the operation $\tilde{o}p$. Operations pick , filter , and amp are variations of heap lookups and mutations. $(r, n) = \text{pick}(x, m)$ measures the first m qubits in x , with the outcome $n = \{\text{c}\}$ and its probability r , similar to the computation in S-MEA (Figure 8). $\text{filter}(x, b)$ mutates x 's pointed-to quantum value by filtering out basis-kets that are not satisfying b , and $\text{amp}(x, r)$ multiples r to every basis-ket in x 's quantum value. Yang and O'Hearn maintain completeness by carefully designing the proof rules so heap mutations do not modify pointer references. SEP ensures the same property by immutable variables, i.e., if a sequence changes, we allocate a new array and a new variable pointing to the array. For example, to join two loci represented by two sequences A and B , respectively pointed to by variables x and y , we allocate a new space for the two sequences' concatenation ($A@B$); so we compile the join to $u = \text{alloc}(A@B)$. We must abandon using x and y after the join and only refer to u in the following computation.

Compilation Procedure. As shown in Figure 15, we compile the QAFNY language to SEP and achieve the proof system compilation through the proof system completeness in QAFNY and SEP. For every QAFNY program, we translate the program and states to SEP. Then, every provable triple in QAFNY can be translated to a provable SEP triple through the language translation from QAFNY to SEP as the diagram (Figure 15). The compilation is defined by extending QAFNY's typing judgment thusly: $\Omega; \sigma \vdash_g (\theta, \varphi, e) \gg (\theta, \tilde{\psi}, \tilde{\varphi}, \tilde{e})$. We include an initial QAFNY state φ , the output local store $(\tilde{\psi})$, mapping variables to qubit location sequences, and state $(\tilde{\varphi})$, mapping from locations to quantum values. θ and θ' are maps from locus locations in φ to SEP qubit locations in $\tilde{\varphi}$.

Here, we explain the rules for compilation by examples of compiling the QAFNY operations to SEP. The locus rewrites (Section 4.3) are compiled to the array allocations, such as the join operation above. Additionally, the split of a locus is compiled to two consecutive allocations of two sequences, respectively representing the two split result loci. In compiling a measurement statement (`let x=measure(y) in ...`), where y locates in the locus $y[0, n] \sqcup \kappa$, let's assume that the locus is mapped in θ by sequence $[0, n+m]$, pointed to by u in $\tilde{\psi}$, while the range $y[0, n]$ is mapped by the sequence $[0, n]$; the operation is compiled to:

$$(r, p) = \text{pick}(u, m) ; \text{filter}(u, u[0, n] = p) ; \text{amp}(u, \sum_j \frac{z_j}{\sqrt{r}}) ; t = \text{alloc}([n, n+m])$$

We first pick a key p , filter out the basis-kets whose $u[0, n]$'s position bases are not p , normalize the amplitudes of the remaining basis-kets (Section 4.4), and allocate a new space t for the quantum residue after the measurement. We also update κ in θ to map to the newly allocated space of t instead of $[n, n+m]$. We compile an operation $x[0, n] \sqcup y[0] \leftarrow (x < 5) @ y[0]$ with its initial state φ ($C = \frac{1}{\sqrt{2^n}} \otimes_{j=0}^{n-1} (|0\rangle + |1\rangle)$) to SEP, with $D = \sum_{j=0}^{2^n-1} |j\rangle |j < 5\rangle$. Such an operation computes the Boolean comparison of $x < 5$ and stores the value to $y[0]$.

Figure 17 QAFNY data for case studies in Section 6.

$$\begin{aligned} \varphi &= \{x[0, n] : C, y[0] : |0\rangle\} \\ x[0, n] \sqcup y[0] &\leftarrow (x < 5) @ y[0] \quad \Rightarrow \quad \tilde{\psi} = \{p : [0, n], t : \{n\}\}, \tilde{\varphi} = \{[0, n] : C * \{n\} : |0\rangle\} \\ \varphi' &= \{x[0, n] \sqcup y[0] : D\} \end{aligned}$$

$$u = \text{alloc}([0, n+1)); \text{mutate}(n+1, u[0, n] < 5 @ u[n], u)$$

$$\tilde{\psi}' = \tilde{\psi} \cup \{u : [n+1, 2n+2]\}, \tilde{\varphi}' = \tilde{\varphi} \cup \{[n+1, 2n+2] : D\}$$

After the compilation, we create two local variables p and t to represent the loci x and y , mapping to sequences $[0, n]$ and $\{n\}$. We then add $u = \text{alloc}([0, n+1])$ allocating a new space $[n+1, 2n+2]$ to join the two loci. The post-state contains a new variable u , pointing to the concatenated new sequence $[n+1, 2n+2]$. The old arrays p and t are still in the stores, but we refer to the locus $x[0, n] \sqcup y[0]$ as the newly allocated space in the following computation by mapping the locus to the new space in θ' . As a future work, we will prove the proof system compilation correctness from QAFNY to SEP, proof strategy in Figure 15.

5.2 Implementation and Comparison to Existing Quantum Verifications

We have implemented a prototype QAFNY to Dafny compiler, which faithfully respects the presented QAFNY to SEP compilation algorithm. To validate the soundness of the compiler implementation, we create many test cases for the compiler. We then insert a number of bugs in these test cases; Qafny has been able to detect all of them. Dafny's proof engine cannot be used to verify arbitrary separation-logic assertions because it only has an implicit frame rule implementation that allows users to set up variables that can be modified in a function. However, QAFNY only requires a subset of separation logic, and the QAFNY loci disjoint property and non-aliasing guarantee ensures that the QAFNY separation conjunctions are captured by Dafny's implicit frames when we compile QAFNY to Dafny. We utilize the QAFNY to Dafny compiler as an automated verification framework to verify six quantum programs, shown in Section 6 and Figure 17.

There were two main approaches to verifying quantum programs: program and measurement-based. The former views quantum program transitions as a state machine and verifies the inductive relations among transitions, while the latter focuses on the relations between quantum program measurements and the post-processing classical components – they typically view quantum components as black boxes with specifications.

QAFNY is program-based and other program-based mechanized frameworks for formally verifying quantum programs, including Qwire [41], SQIR [16, 15] (an upgrade of Qwire), and QBricks [3], provide libraries in an interactive proof assistant to guide users for building inductive proofs for quantum programs; each has verified 7-10 quantum programs. The core of SQIR and QBricks, as well as other executable quantum verification platforms, is a circuit-description language. Verifying a program in these frameworks inductively builds a unitary or density matrix as the program's quantum circuit semantic interpretation. For example, to verify Shor's algorithm, both QBricks and SQIR require inductive proofs based on elementary circuit gates to derive the unitary or density matrix semantics of different sub-components, including state preparations, oracles, and QFT^{-1} gates. Additionally, program

verification in these frameworks requires the development of theories and tactics to capture program properties, which usually involves the proof of additional theorems. This approach is qualitatively different from QAFNY, where program verification involves embedding assertions in a program for completing a proof. QAFNY identifies a few program structures, such as oracles and quantum conditionals, and formulates inductive patterns involving these quantum components as proof rules. These rules interact with quantum program operations and states for deriving verification proofs, so proofs are largely automated based on this small set of structures.

Figure 16 shows a quantitative comparison of QAFNY, regarding theory/proof statement running time and numbers of lines (LOC), with respect to QBricks and SQIR for verifying several quantum programs. The results show that QAFNY has the shortest running time and LOCs for verifying programs with our automated proof engine. The QBricks verification has better LOCs but a similar running time compared to SQIR. SQIR provides a complete verification [38] by proving every mathematical theorem involved in the verification, so its verification proofs are longer than QBricks; QBricks performs better by providing some automatic tactics for sequence operations ($e ; e$) and taking many math theorems as assumptions without proof. In testing the two frameworks, we found that the previous claim [16, 15] that rigorous quantum proofs are one-time cost is problematic because inductive theorem provers update constantly. Once an update happens, users might need to fix the proofs (not programs or specifications) in their history code, e.g., our researcher spent three days fixing minor bugs in the proofs in SQIR and QBricks due to Coq and Why3 version issues. Moreover, a new program verification in SQIR typically required detailed proofs of additional theorems beyond the program specifications.

QAFNY provides fast prototyping, where we apply the automated verification mechanisms in many classical systems [40, 22] to verify quantum programs and save programmers' effort. Verifying programs in many inductive theorem provers takes weeks and months to finish, while the same tasks in QAFNY cost researchers a few days due to the QAFNY features mentioned above. The fast prototyping in QAFNY can also help users to explore and understand new quantum program patterns such as the two case studies in Section 6, whose running time and LOCs are shown in Figure 17. Compared to the data of well-known algorithms in Figure 16, the data for verifying the new programs do not show a significant difference, showing QAFNY's ability to explore new algorithm behaviors without proving many new theories, which usually appears in the above quantum verification frameworks.

6 Case Studies

With two examples, we show QAFNY as a rapid prototyping tool for quantum programs.

6.1 Controlled GHZ: Composing Quantum Algorithms from Others

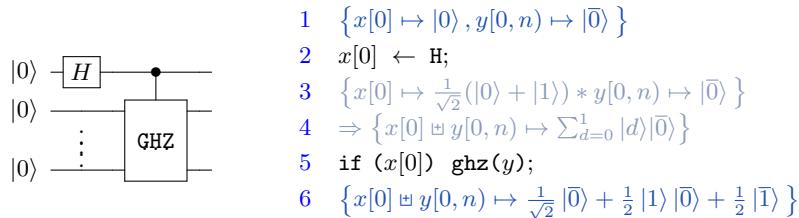

Figure 18 Controlled GHZ circuit and proof. $\text{ghz}(y)$ is in Fig. 3. Lines 3-4 automatically inferred.

Automated verification frameworks such as Dafny encourage programmers to build program proofs based on the reuse of subprogram proofs. However, this perspective is more or less overlooked in previous quantum proof systems. In SQIR, for example, verifying the correctness of a *controlled GHZ*, a simple circuit constructed by extending GHZ with an extra control qubit, requires generalizing the GHZ circuit to any arbitrary inputs. In QAFNY, users do not need to do this, as shown here.

Figure 18 provides a proof of the Controlled GHZ algorithm based on a proven GHZ method in Figure 3c. The focal point is the quantum conditional on line 5. For verifying a GHZ circuit, its input is an n -qubit `Nor`-typed value of all $|0\rangle$, but the given value, in line 4, is an `EN`-typed entanglement $\sum_{d=0}^1 |d\rangle|\bar{0}\rangle$. Here is where SQIR gets stuck. In QAFNY, we automatically verify the proof by rule P-IF and the equivalence relation to rewrite a singleton EN value to a `Nor` one, as $\sum_{j=0}^0 z_j|c_j\rangle \equiv z_0|c_0\rangle$. The detailed proof for the conditional is given below, where $U(b) = \mathcal{U}(b, x[0], \kappa)$ and $\kappa = x[0] \sqcup y[0, n]$.

$$\begin{array}{c}
 \Omega; \{y[0, n] : \text{Nor}\} \vdash_m \left\{ y[0, n] \mapsto |\bar{0}\rangle|\bar{1}\rangle \right\} \text{ghz}(y) \left\{ y[0, n] \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle|\bar{1}\rangle \right\} \\
 \hline
 \Omega; \{y[0, n] : \text{EN}\} \vdash_m \left\{ \mathcal{F}(x[0], y[0, n]) \mapsto \sum_{d=0}^1 |d\rangle|\bar{0}\rangle \right\} \text{ghz}(y) \left\{ y[0, n] \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle|\bar{1}\rangle \right\} \quad \text{EQ} \\
 \hline
 \Omega; \{\kappa : \text{EN}\} \vdash_c \left\{ \kappa \mapsto \sum_{d=0}^1 |d\rangle|\bar{0}\rangle \right\} \text{if } (x[0]) \text{ ghz}(y) \left\{ \mathcal{U}(\neg x[0]) \mapsto \sum_{d=0}^1 |d\rangle|\bar{0}\rangle * U(x[0]) \mapsto \sum_{d=0}^1 \frac{1}{\sqrt{2}} |\bar{d}\rangle|\bar{1}\rangle \right\} \quad \text{P-IF} \\
 \hline
 \Omega; \{\kappa : \text{EN}\} \vdash_c \left\{ \kappa \mapsto \sum_{d=0}^1 |d\rangle|\bar{0}\rangle \right\} \text{if } (x[0]) \text{ ghz}(y) \left\{ \kappa \mapsto \frac{1}{\sqrt{2}} |\bar{0}\rangle + \frac{1}{2} |1\rangle|\bar{0}\rangle + \frac{1}{2} |\bar{1}\rangle \right\}
 \end{array}$$

After rule P-IF is applied, locus $y[0, n]$'s value is rewritten to a `Nor` type value on the top as $|\bar{0}\rangle|\bar{1}\rangle$, where $|\bar{0}\rangle$ is n qubits and $|\bar{1}\rangle$ is frozen in the stack. Since two values are equivalent as QAFNY discards stacks, $|\bar{0}\rangle|\bar{1}\rangle$ is equivalent to $|\bar{0}\rangle$, which satisfies the input condition for GHZ, so all proof obligations introduced to invoke the `ghz` method are discharged.

6.2 Case Study: Understanding Quantum Walk

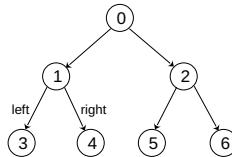

Figure 19 Tree Structure.

Quantum walk [54, 4, 53] is a quantum version of the classical random walk [36] and an important framework for developing quantum algorithms. However, most quantum walk analyses are based on Hamiltonian simulation, which deters many computer programmers from the quantum walk framework. Here, we show that the discrete-time quantum walk, at its very least, is a quantum version of breadth-first search; thus, many algorithms [4] based on Quantum walk can be understood as performing search algorithms in the quantum setting.

Figure 20 lists the proof outline for the core loop of a discrete-time quantum walk algorithm to traverse a complete binary tree (structure in Figure 19); each node has a unique key. The m -depth nodes in the tree have keys $j \in [2^m - 1, 2^{m+1} - 2]$, which form a sequence

```

 $q(j) \triangleq \sum_{i=0}^{2^{(j+1)}-3} z_i \langle \lfloor \log(i+1) \rfloor | \text{pat}(i, j) \rangle |i+1\rangle |d_i\rangle \text{ where } \text{pat}(i, j) \triangleq |0\rangle^{\otimes \lfloor \log(i+1) \rfloor} |1\rangle^{\otimes (j - \lfloor \log(i+1) \rfloor)}$ 
1  $\{x[0, t] \mapsto \frac{1}{\sqrt{2^t}} \otimes_{i=0}^{t-1} (|0\rangle + |1\rangle) * y[0, m] \mapsto |\bar{0}\rangle * h[0, n] \mapsto |\bar{0}\rangle * u[0] \mapsto |0\rangle * m = 2^t \cdot m < n\}$ 
2  $\Rightarrow \{x[0, t] \bowtie y[0, 0] \bowtie h[0, n] \bowtie u[0] \mapsto \sum_{k=0}^{2^t-1} \frac{1}{\sqrt{2^t}} |k\rangle |\bar{0}\rangle |0\rangle * y[0, m] \mapsto |\bar{0}\rangle * m = 2^t \cdot m < n\}$ 
3 for  $j \in [0, m)$  &&  $(x[0, t] < j+1) @ y[j]$ 
4  $\{x[0, t] \bowtie y[0, j] \bowtie h[0, n] \bowtie u[0] \mapsto q(j) + \sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} |k\rangle |\bar{0}\rangle |\bar{0}\rangle |0\rangle * y[j, m] \mapsto |\bar{0}\rangle\}$ 
5  $\{u[0] \leftarrow \text{H};$ 
6  $\text{if } (u[0]) \text{ left}(\lfloor \log(j+1) \rfloor, h[0, n]);$ 
7  $\text{if } (\neg u[0]) \text{ right}(\lfloor \log(j+1) \rfloor, h[0, n));\}$ 
8  $\{x[0, t] \bowtie y[0, m] \bowtie h[0, n] \bowtie u[0] \mapsto q(m)\}$ 

```

Figure 20 Quantum walk reachable node verification for a complete binary tree. **left** and **right** reach corresponding children. $q(j)$ is a quantum value with var j . $i+1$ is a node key in a tree.

from left to right in depth m -th, such as the sequence 3, 4, 5, 6 in depth 2 in Figure 19. Thus, a node (key j) has a depth $m = \lfloor \log(j+1) \rfloor$, and its **left** and **right** children have keys $2 \cdot j + 1$ and $2 \cdot j + 2$, respectively representing the **left** and **right** operation semantics in Figure 20, i.e., for any basis $|j\rangle$, with m being the depth and j a node key, the outputs of applying **left** and **right** are $|2 \cdot j + 1\rangle$ and $|2 \cdot j + 2\rangle$, respectively¹¹.

The algorithm in Figure 20 requires four quantum ranges: a t -qubit range x in superposition, an m -qubit range where $y[j]$'s position bases keep the result of evaluating $x[0, t] < j+1$ for j -th loop step, an n -qubit node register h storing the node keys, and a single qubit u acting as the random walk coin and determining the moving direction of the next step (1 for the left and 0 for the right). In line 2, we merge the ranges x , u , and h as the locus $x[0, t] \bowtie y[0, 0] \bowtie h[0, n] \bowtie u[0]$ ($y[0, 0]$ is empty); at each loop step (lines 3-7), we entangle a qubit in the range y into the locus. Finally, at line 8, the loop program entangles all these ranges together as a locus $x[0, t] \bowtie y[0, m] \bowtie h[0, n] \bowtie u[0]$.

In the j -th loop step, we abbreviate locus $x[0, t] \bowtie y[0, j] \bowtie h[0, n] \bowtie u[0]$ as $\kappa(j)$, and locus $\kappa(j)$'s state value is split into two basis-ket sets, separated by $+$ in Figure 20 line 4. To verify a step, we first split the $y[j]$ qubit, having position basis $|0\rangle$, from range $y[j, m]$, and merge the qubit into $\kappa(j)$. The split rewrites are given as:

$$\begin{aligned}
& \{ \kappa(j) \mapsto \sum_{i=0}^{2^{(j+1)}-3} z_i \langle \lfloor \log(i+1) \rfloor | \text{pat}(i, j) \rangle |i+1\rangle |d_i\rangle + \sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} |k\rangle |\bar{0}\rangle |\bar{0}\rangle |0\rangle * y[j, m] \mapsto |\bar{0}\rangle \} \\
& \equiv \{ \kappa(j+1) \mapsto \sum_{i=0}^{2^{(j+1)}-3} z_i \langle \lfloor \log(i+1) \rfloor | \text{pat}(i, j) \rangle |0\rangle |i+1\rangle |d_i\rangle + \sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} |k\rangle |\bar{0}\rangle |0\rangle |\bar{0}\rangle |0\rangle * y[j+1, m] \mapsto |\bar{0}\rangle \} \\
& \equiv \{ \kappa(j+1) \mapsto q'(|0\rangle) + \sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta(k, 0) * y[j+1, m] \mapsto |\bar{0}\rangle \}
\end{aligned}$$

At the last rewrite above, we abbreviate the first part of $\kappa(j+1)$'s value to be $q'(|0\rangle)$, and the second part to be $\sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta(k, 0)$ where $\delta(k, c) = |k\rangle |\bar{0}\rangle |c\rangle |\bar{0}\rangle |0\rangle$. Below, we show the proof steps (only the pre-condition transitions) for a conditional step in Figure 20 line 3, which can be divided into two small steps. Here, e is the conditional body in lines 5-7, and we apply P-FRAME to frame out locus $y[j+1, m]$ from the states, so the bottom state only refers to the locus $\kappa(j+1)$. We further split the second part above ($\sum_{k=j}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta(k, 0)$) into two basis-ket sets: $\frac{1}{\sqrt{2^t}} \delta(j, 0)$ and $\sum_{k=j+1}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta(k, 0)$.

¹¹The tree structure is a simplification; comprehensive implementations use Szegedy walk encoding [30].

$$\frac{\Omega; \{h[0, n] \sqsubseteq u[0] : \text{EN}\} \vdash_{\mathbb{M}} \left\{ h[0, n] \sqsubseteq u[0] \mapsto \sum_{i=0}^{2^{(j+1)-3}} z_i |i+1\rangle |d_i\rangle \widehat{\beta} + \frac{1}{\sqrt{2^t}} |\bar{0}\rangle |0\rangle \widehat{\beta}' \right\} e \{ \dots \}}{\Omega; \{\kappa\langle j+1 \rangle : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \kappa\langle j+1 \rangle \mapsto q'(|1\rangle) + \frac{1}{\sqrt{2^t}} \delta\langle j, 1 \rangle + \sum_{k=j+1}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta\langle k, 0 \rangle \right\} \text{ if } ((x[0, t) < j+1) @ y[j]) e \{ \dots \}}$$

$$\frac{\Omega; \{\kappa\langle j+1 \rangle : \text{EN}\} \vdash_{\mathbb{M}} \left\{ \kappa\langle j+1 \rangle \mapsto q'(|0\rangle) + \frac{1}{\sqrt{2^t}} \delta\langle j, 0 \rangle + \sum_{k=j+1}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta\langle k, 0 \rangle \right\} \text{ if } ((x[0, t) < j+1) @ y[j]) e \{ \dots \}}{\Omega; \{u[0] \sqsubseteq h[0, n] : \text{EN}\} \vdash_{\mathbb{M}} \left\{ u[0] \sqsubseteq h[0, n] \mapsto \sum_{i=0}^{2^{(j+1)-3}} \frac{1}{\sqrt{2}} z_i |d_i\rangle |i+1\rangle \widehat{\beta} + \sum_{i=0}^{2^{(j+1)-3}} \frac{1}{\sqrt{2}} z_i |d_i+1\rangle |i+1\rangle \widehat{\beta} + \frac{1}{\sqrt{2^{t+1}}} |\bar{0}\rangle |\bar{0}\rangle \widehat{\beta}' + \frac{1}{\sqrt{2^{t+1}}} |1\rangle |\bar{0}\rangle \widehat{\beta}' \right\}}$$

We split the P-If proof step (Line 3 in Figure 20) into two small steps above. The bottom step represents the first half of the \mathcal{F} transformer application (Figure 11) in P-If. It views the Boolean guard $(x[0, t) < j+1) @ y[j]$ as an oracle application and for every basis-ket in the locus $\kappa\langle j+1 \rangle$, we compute the Boolean value $x[0, t) < j+1$ and store it to $y[j]$'s position bases. Unlike the simple Boolean guards appearing in Figures 3c and 6, the Boolean guard here has side-effects that modify $y[j]$'s position bases. $\kappa\langle j+1 \rangle$'s value is split into three basis-ket sets separated by $+$. In the set $q(|0\rangle)$, range $x[0, t)$'s position bases have the form $|\lfloor \log(i+1) \rfloor\rangle$ (the depth of a node key $i+1$) and the bases' natural number interpretations are smaller than $j+1$; in the sets $\frac{1}{\sqrt{2^t}} \delta\langle j, 0 \rangle$ and $\sum_{k=j+1}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta\langle k, 0 \rangle$, range $x[0, t)$'s position bases are $|j\rangle$ and $|k\rangle$ ($j < k$). The former's natural number interpretation is less than $j+1$, while the latter is not. Thus, we flip $y[j]$'s position bases of the two sets after applying the bottom rule above while leaving the third set unchanged.

The middle step in the above P-If proof step rules out the basis-ket set $\sum_{k=j+1}^{2^t-1} \frac{1}{\sqrt{2^t}} \delta\langle k, 0 \rangle$, because the $y[j]$'s position bases are all 0; then, we push bases $|\lfloor \log(i+1) \rfloor\rangle |\text{pat}(i, j)\rangle |0\rangle$ and $|k\rangle |\bar{0}\rangle |0\rangle$ to the frozen stacks as $\widehat{\beta}$ and $\widehat{\beta}'$, respectively for the remaining two sets.

$$\frac{\Omega; \{u[0] \sqsubseteq h[0, n] : \text{EN}\} \vdash_{\mathbb{M}} \left\{ u[0] \sqsubseteq h[0, n] \mapsto \sum_{i=0}^{2^{(j+1)-3}} z_i |d_i\rangle |i+1\rangle \widehat{\beta} + \frac{1}{\sqrt{2^t}} |\bar{0}\rangle |\bar{0}\rangle \widehat{\beta}' \right\} u[0] \leftarrow \text{H} \quad \left\{ u[0] \sqsubseteq h[0, n] \mapsto \sum_{i=0}^{2^{(j+1)-3}} \frac{1}{\sqrt{2}} z_i |d_i\rangle |i+1\rangle \widehat{\beta} + \sum_{i=0}^{2^{(j+1)-3}} \frac{1}{\sqrt{2}} z_i |d_i+1\rangle |i+1\rangle \widehat{\beta} + \frac{1}{\sqrt{2^{t+1}}} |\bar{0}\rangle |\bar{0}\rangle \widehat{\beta}' + \frac{1}{\sqrt{2^{t+1}}} |1\rangle |\bar{0}\rangle \widehat{\beta}' \right\}}$$

For the H application in line 5 (Figure 20), we first rewrite the locus, in the pre- and post-states, from $h[0, n] \sqsubseteq u[0]$ to $u[0] \sqsubseteq h[0, n]$; shown as the proof triple above. There is a hidden uniqueness assumption ¹² for all basis-kets in $q(j)$ (Figure 20): $\forall z\beta |d_i\rangle \in q(j) \Rightarrow \forall z' . z'\beta |d_i+1\rangle \notin q(j)$, i.e., if we truncate the $u[0]$ qubit, every basis is still unique in $q(j)$. For each basis-ket, the H application duplicates the non- $u[0]$ part, with the flip of $u[0]$'s position bases. During the process, the amplitude of each basis-ket is reduced by $\frac{1}{\sqrt{2}}$. The **left** and **right** in lines 6 and 7 then move the node key (range $h[0, n]$'s position basis) of each basis-ket to its **left** and **right** child, depending on the coin bit stored as $u[0]$'s position basis; thus, the uniqueness property is preserved (left and right children always have different keys). Remember that the number of basis-kets is doubled in the H gate application; after the j -th loop step, all $(j-1)$ -th depth nodes become j -th depth and the two root node basis-kets ($\frac{1}{\sqrt{2^{t+1}}} |0\rangle |\bar{0}\rangle \widehat{\beta}'$ and $\frac{1}{\sqrt{2^{t+1}}} |1\rangle |\bar{0}\rangle \widehat{\beta}'$) become 1-st depth nodes; thus, the state, after j -th loop step, is in superposition containing all nodes up to j -th depth, except the root node.

The above applications also show the necessity of frozen basis stacks. When applying the conditional, we hide $x[0, t)$'s position bases to frozen basis stacks, and there are $2^{(j+1)-3}$ different such stacks. We need to record the position bases in the frozen basis stacks; so, 1) when we apply the H gate, we know which basis-kets are associated with a specific position basis; 2) once the conditional is over, the position bases can be retrieved.

The verification in Figure 20 describes the basic property of the quantum walk algorithm framework. The biggest advantage of the framework is to permit the manipulation of different quantum applications on different tree nodes in each loop step, which is why many algorithms [5, 4, 28, 1] have been developed based on it.

¹²In the Dafny implementation, this needs to be an explicit assumption given by the users.

7 Related Work

This section gives related work beyond the discussion in Section 5.2.

Measurement-based Quantum Proof Systems. Except for the works in Section 5.2, previous quantum proof systems are measurement-based, including quantum Hoare logic [56, 26, 10, 57], quantum separation logic (QSL) [20, 59], quantum relational logic [25, 52], and probabilistic Hoare logic for quantum programs [19], informed the QAFNY development. They differ from QAFNY in three main respects, however: 1) their conditionals are solely classical, while QAFNY has quantum conditionals; 2) they mainly focus on the probabilistic relations between the quantum measurement results and classical components and view quantum program components as black boxes specified by Hilbert spaces or density matrices; and 3) most of them have no mechanized implementations, and they do not have a quantum program compiler. The verification procedure in these frameworks, to some extent, shows the possibility of verifying mainly hybrid classical-quantum (HCQ) programs by requiring the input of black-boxed and verified quantum program components.

QSL [20] develops a new separation logic theory (with no executable proof examples, however) for Hilbert spaces and classical controls, mainly for verifying HCQ programs by black-boxing quantum components. This differs from the QAFNY system, based on classical separation logic for classical array operations. QSL is based on a notion of frame rules that split a tensor product state into two parts, similar to our `Had` typed state split equation. However, they do not specify when and how a quantum state separation may happen. As in Section 3, in many cases, quantum state separation is not trivial and might not be automatically inferred by a proof engine.

Liu et al. [26] contains an example verification for Grover’s search algorithm based on the SQIR inductive verification style, albeit with worse proof automation (3184 LOC vs. 1018 LOC in Figure 16). CoqQ [60] provides a mechanized automated verification framework for HCQ programs. However, their proof automation is to connect quantum and classical components, i.e., they view quantum circuit components as black-boxes. By giving pre- and post-conditions, they perform proof automation on verifying HCQ programs that view the quantum components as sub-procedures. There are some examples in CoqQ to verify quantum components, but they are handled in the same style as SQIR and QBricks above. See TR [24] D.

Classical Proof Systems. We are informed by separation logic, as articulated in the classic paper [42], and other papers as well [18, 50, 34, 58, 27, 46]. Primarily, we show a compilation from QAFNY to SEP, representing a subset of separation logic admitting sound and completeness [55], which was also studied by [51, 9]. The QAFNY implementation is compiled to Dafny [21], a language designed to simplify writing correct code. The natural proof methodology [27, 37, 29] informs the QAFNY development, where it embeds the proofs of data-structures to a recursive search problem.

8 Conclusion and Future Work

We present QAFNY, a system for expressing and automatically verifying quantum programs that can be compiled into quantum circuits. We develop a proof system that views quantum operations as classical array aggregate operations, e.g., viewing quantum measurements as array filters, so that we can map the proof system, which is sound and complete with respect

to the QAFNY semantics for well-typed programs, to classical verification infrastructure. We implement a prototype compiler in Dafny and use it to verify several quantum programs. We believe that programmers can utilize QAFNY to develop quantum algorithms and verify them through our automated verification engine with a significant saving of human effort, as demonstrated in Section 6. The QAFNY language is universal in terms of the power of expressing quantum programs since all gates in the universal RzQ gate set {H, X, RZ, CNOT} [33] are definable. However, being able to define all possible quantum programs does not mean that we can utilize QAFNY to verify all quantum programs, especially HCQ programs, automatically. Verifying HCQ programs requires the full power of quantum mixed states, i.e., users might want to know the probabilistic output of executing a quantum program with a quantum input state being associated with a probability. Verifying all such programs requires a powerful classical probability distribution library beyond the current scope of QAFNY, although the existing QAFNY implementation does include a restricted library for reasoning about probability distributions [32] that can verify some HCQ programs.

In future work, we plan to build and verify a complete QAFNY implementation in Dafny; especially, we intend to enhance the probability distribution libraries to automatically verify more HCQ programs. We also want to show the soundness proof of the implementation as well as the circuit compilation correctness from QAFNY to SQIR (TR [24] C.6). We will further investigate integrating QAFNY with other tools, such as CoqQ [60], to verify HCQ programs automatically.

Abstract

The introduction of separation logic has led to the development of symbolic execution techniques and tools that are (functionally) compositional with function specifications that can be used in broader calling contexts. Many of the compositional symbolic execution tools developed in academia and industry have been grounded on a formal foundation, but either the function specifications are not validated with respect to the underlying separation logic of the theory, or there is a large gulf between the theory and the implementation of the tool.

We introduce a formal compositional symbolic execution engine which creates and uses function specifications from an underlying separation logic and provides a sound theoretical foundation for, and indeed was partially inspired by, the Gillian symbolic execution platform. This is achieved by providing an axiomatic interface which describes the properties of the consume and produce operations used in the engine to update compositionally the symbolic state, for example when calling function specifications. This consume-produce technique is used by VeriFast, Viper, and Gillian, but has not been previously characterised independently of the tool. As part of our result, we give consume and produce operations inspired by the Gillian implementation that satisfy the properties described by our axiomatic interface. A surprising property is that our engine semantics provides a common foundation for both correctness and incorrectness reasoning, with the difference in the underlying engine only amounting to the choice to use satisfiability or validity. We use this property to extend the Gillian platform, which previously only supported correctness reasoning, with incorrectness reasoning and automatic true bug-finding using incorrectness bi-abduction. We evaluate our new Gillian platform by using the Gillian instantiation to C. This instantiation is the first tool grounded on a common formal compositional symbolic execution engine to support both correctness and incorrectness reasoning.

2012 ACM Subject Classification Theory of computation → Program verification; Theory of computation → Program analysis; Theory of computation → Separation logic; Theory of computation → Automated reasoning

Keywords and phrases separation logic, incorrectness logic, symbolic execution, bi-abduction

1 Introduction

One of the main challenges that modern program analysis tools based on static symbolic execution [1] must face is *scalability*, that is, the ability to tractably analyse large, dynamically changing codebases. Such scalability requires symbolic techniques and tools that are *functionally compositional* (or simply compositional) where the analysis works on functions in isolation, at any point in the codebase, and then records the results in simple function specifications that can be used in broader calling contexts. However, the traditional symbolic execution tools and frameworks based on first-order logic, such as CBMC [16] and Rosette [32], can only be compositional for functions that manipulate the variable store, but not for functions that manipulate the heap, limiting their usability.

A key insight is that, to obtain compositionality, the analysis should work with function specifications that are *local*, in that they should describe the function behaviour only on the *partial* states or resources that the function accesses or manipulates, and a mechanism for using such specifications when the function is called by code working on a larger state. This insight was first introduced in separation logic (SL) [24, 29], a modern over-approximating (OX) program logic for compositional verification of correctness properties, which features local function specifications that can be called on larger state with the help of the *frame rule*. Recently, these ideas have been adapted to under-approximate (UX) reasoning in the context of incorrectness separation logic (ISL) [28] for compositional true bug-finding.

Ideas from SL and ISL have led to the development of efficient compositional symbolic execution tools in academia and industry, such as the tool VeriFast [14] and the multi-language platforms Viper [23] and Gillian [21] for semi-automatic OX verification based on SL, and Meta’s multi-language platform Infer-Pulse [17] for automatic UX true bug-finding based on ISL. However, there are issues with the associated formalisms of the tools: either the function specifications created and used by the tool are not validated with respect to the underlying separation logic; or there is a large gulf between the formalism and the implementation of the tool. VeriFast, Viper, and Gillian, on the one hand, all come with a sound compositional symbolic operational semantics that closely model the tools. These tools handle the creation and use of function specifications (and the folding and unfolding of predicates) using two operations, called *consume* and *produce*, which, respectively, removes from and adds to a given symbolic state the symbolic state corresponding to a given assertion. The formalisms accompanying the tools, however, do not properly connect their function specifications to the underlying separation logics. Thus, function specifications created by the tools cannot soundly be used by other tools, and vice versa. On the other hand, the formalism of Infer-Pulse describes compositional symbolic execution as proof search in ISL, and similarly with its SL-predecessor Infer [4], thereby making the connection to its separation logic direct. However, the gap between the formalism and the tool is considerable.

In this paper, inspired by the Gillian platform [11, 21], we formally define a compositional symbolic execution (CSE) engine that provides a sound theoretical foundation for building compositional OX and UX analysis tools. Our engine is described by a compositional symbolic operational semantics using the consume and produce operations to interface with function

specifications valid in either SL or ISL. A surprising property of our semantics is that it is simple to switch between OX and UX reasoning. In more detail, our CSE engine features the following theoretical contributions:

1. *specification interoperability*, in the sense that it can both create and use function specifications validated in an underlying separation logic, allowing for a mix-and-match of specifications validated in various ways from various sources;
2. *an axiomatic approach to compositionality*, in that we provide an axiomatic description of properties for the consume and produce operations, which have not been previously characterised axiomatically;
3. *a general soundness result*, which states that, assuming the axiomatic properties of the consume and produce operations and the validity of function specifications that are used with respect to the underlying separation logic, the CSE engine is sound and creates function specifications that are valid with respect to the said logic;
4. *a unified semantics*, which captures the essence of *both* the OX reasoning of VeriFast, Viper, and Gillian, and the UX reasoning in Infer-Pulse, with the difference amounting *only* to the choice of using satisfiability or validity, and different axiomatic properties of the consume and produce operations.

We instantiate our general soundness result by giving example implementations of the consume and produce operations, inspired by those found in Gillian, which we prove satisfy the properties laid out by the axiomatic interface. For clarity of presentation, although both our CSE engine and our consume and produce operations are inspired by Gillian, we have opted to work with a fixed, linear memory model and a simple while language instead of the parametric memory model approach of Gillian and its goto-based intermediate language GIL. The move from a fixed to a parametric memory model is straightforward and planned future work.

In addition, this paper brings the following practical contributions:

1. a demonstrator Haskell implementation of our CSE engine with example implementations of the consume and produce operations;
2. an extension of the Gillian platform with automatic compositional UX true bug-finding using UX bi-abduction in the style of Infer-Pulse, making Gillian the first unified tool for OX and UX compositional reasoning about real-world code.

The Gillian platform already supported whole-program symbolic testing as found in, for example, CBMC, and semi-automatic OX compositional verification underpinned by SL as in, for example, VeriFast. Because our CSE engine has pinpointed the small differences required for the switch between OX and UX reasoning, we were able to simply extend Gillian with automatic compositional UX true-bug finding without affecting its other analyses. Interestingly, UX true bug-finding has not been implemented in a consume-produce engine before. We demonstrate the additional UX reasoning by extending the CSE engine with UX bi-abductive reasoning [5, 6, 28, 17], an automatic technique which has enabled compositional reasoning to scale to industry-grade codebases, and which works by generating function specifications from their implementations by incrementally constructing the calling context. We implement this technique following the approach pioneered by OX tool JaVerT 2.0 [10], where missing-resource errors are used to generate fixes that drive the specification construction. We evaluate this extension of Gillian using its Gillian-C instantiation, on a real-world Collections-C data-structure library [25], obtaining promising initial results and performance.

An extended version of this paper is available on arXiv [18], which includes additional definitions and proofs of the theorems discussed in this paper.

2 Overview: Compositional Symbolic Execution

We give an overview of our CSE engine, together with example analyses that we show can be hosted on top of this engine. Our CSE engine consists of three engines built on top of each other, labelled by different reasoning modes, OX and UX, that are appropriate for different types of analyses. In short, the reasoning modes can be characterised as follows:

Mode	Guarantee	Consequence rule	Analysis
OX	Full path coverage	Forward logical consequence	Full verification in SL
UX	Path reachability	Backward logical consequence	True bug-finding in ISL

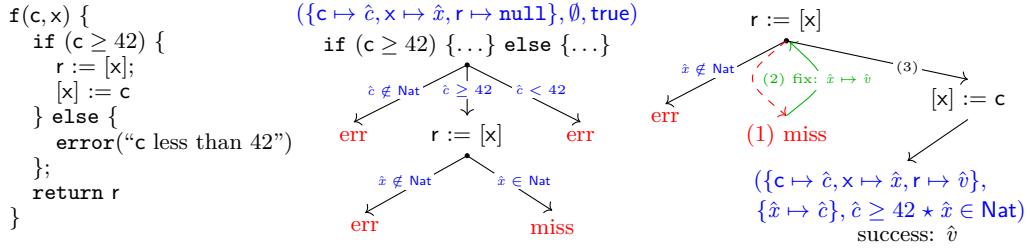

The *core engine* (§4) is a simple symbolic execution engine for our demonstrator programming language (§3). It does not use assertions to update symbolic state and is hence compatible with both OX and UX reasoning. It is sufficient to capture whole-program symbolic testing found in, e.g., CMBC and Gillian. The *compositional engine* (§5, §6) is built on top of this core engine. It can switch between either the OX or UX mode of reasoning, providing support for the use of SL and ISL function specifications by extending the core engine with consume and produce operations for updating the symbolic state. In OX mode, it captures the full verification found in e.g. VeriFast and Gillian, soundly underpinned by SL. For the first time, in UX mode it also captures ISL analysis, not previously found in a symbolic execution tool. We demonstrate this by building the UX *bi-abductive engine* (§7) on top of the UX compositional engine to automatically fix missing-resource errors (e.g., a missing heap cell) using the UX bi-abductive technique from Infer-Pulse, to capture automatic true bug-finding underpinned by ISL.

2.1 Core Engine

The core symbolic execution engine provides a foundation on top of which the other components are built. It is essentially a standard symbolic execution engine that is slightly adapted to handle both usual language errors and the missing-resource errors, which can occur now that we are working with partial state.

Our engine operates over partial symbolic states $\hat{\sigma} = (\hat{s}, \hat{h}, \hat{\pi})$ comprising: a symbolic variable store \hat{s} , holding symbolic values for the program variables; a partial symbolic heap \hat{h} , representing the memory on which programs operate; and a symbolic path condition $\hat{\pi}$, holding constraints accumulated during symbolic execution. We work with a simple demonstrator programming language (cf. §3) and linear heaps: that is, partial-finite maps from natural numbers to values. The core engine is both OX- and UX-sound, also referred to as exact (EX) [20], as established by Thm. 1.

Example. In Fig. 1 (left), we define a simple function f . In Fig. 1 (middle), we illustrate its symbolic execution, which starts from $\hat{\sigma} = (\{c \mapsto \hat{c}, x \mapsto \hat{x}, r \mapsto \text{null}\}, \emptyset, \text{true})$, with the function parameters (c and x) initialised with some symbolic variables (\hat{c} and \hat{x}), the local function variables (r) initialised to null , the heap set to empty and the path condition set to true . Next, executing the if-statement with condition $c \geq 42$ yields three branches: one in which c is not a natural number, in which the execution fails with an evaluation error; one in which $c \geq 42$, in which the execution continues; and one in which $c < 42$, in which the program throws a user-defined error. Next, executing the lookup $r := [x]$ results in two more branches: one in which x is not a heap address (natural number), yielding a type error and one in which x is a heap address. In that branch, the lookup fails with a missing-resource error as the heap is empty.

■ **Figure 1** Definition and symbolic execution of function f .

Analysis: EX Whole-program Symbolic Testing. The core engine can be used to perform whole-program symbolic testing in the style of CBMC [16] and Gillian [11], in which the user creates symbolic variables, imposes some initial constraints on them, runs the symbolic execution to completion, and asserts that some final constraints hold.

2.2 Compositional Engine

Our compositional engine extends the core engine to support calling, in its respective OX and UX mode, SL and ISL function specifications, denoted $\{\vec{x} = \vec{x} \star P\} f(\vec{x}) \{ok : Q_{ok}\} \{err : Q_{err}\}$ and $[\vec{x} = \vec{x} \star P] f(\vec{x}) [ok : Q_{ok}] [err : Q_{err}]$,¹ respectively, where P is a pre-condition and Q_{ok} and Q_{err} are success and error post-conditions. A SL specification gives an OX description of the function behaviour whereas an ISL specification gives a UX description:

- (SL) All terminating executions of the function f starting in a state satisfying P either end successfully in a state that satisfies Q_{ok} or fault in a state that satisfies Q_{err} .
- (ISL) Any state satisfying either the success Q_{ok} or error post-conditions Q_{err} is reachable from some state satisfying the pre-condition P by executing the function f .

The engine also adds support, in both OX and UX mode, for folding and unfolding of user-defined predicates, describing inductive data-structures such as linked lists.

In both cases, the call to function specifications and the folding and unfolding of predicates are implemented following the consume-produce engine style, underpinned by `consume` and `produce` operations, which, in essence, remove (consume) and add (produce) the symbolic state corresponding to a given assertion from and to the current symbolic state. For example, in Fig. 2, the symbolic execution is in a symbolic state $\hat{\sigma}$ and calls a function $f(\vec{x})$ by its specification in ISL mode. The (successful) function call is implemented by first consuming the symbolic state $\hat{\sigma}_P$ corresponding to the pre-condition P , leaving the symbolic frame $\hat{\sigma}_f$, and then producing into $\hat{\sigma}_f$ the symbolic state $\hat{\sigma}_{Q_{ok}}$ corresponding to the post-condition Q_{ok} .

Our approach is novel in two ways: (1) we provide an axiomatic interface that captures the sufficient properties of the consume and produce operations for the engine to be sound; and (2) we provide example implementations (in the same style as the rest of the engine, that is, using inference rules) for the consume and produce operations that we prove satisfy the axiomatic interface. Moreover, our consume and produce operations switch their behaviour between the mode of reasoning (OX/UX), as described next.

¹ UX quadruples can be split into two triples, but OX quadruples cannot. To unify our presentation, we consider both types of specifications in quadruple form.

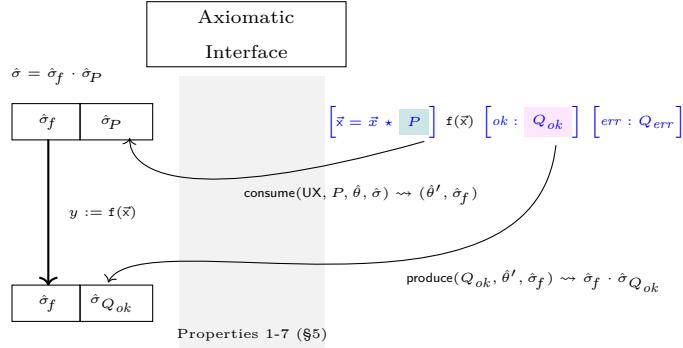

Figure 2 UX function-call rule: successful case.

Axiomatic Interface. We have identified sufficient properties for the consume and produce operations to be OX or UX sound (cf. Thm. 3). Here we will describe a general idea of the consume operation, the more complex of the two operations, the signature of which is:

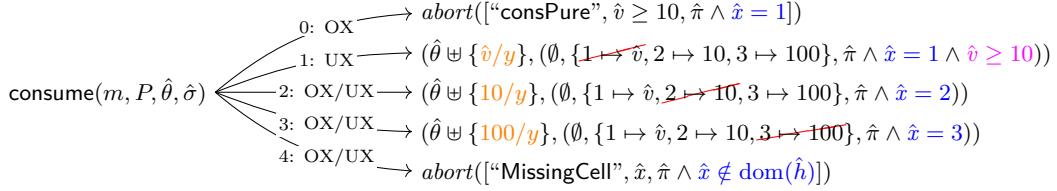

$$\text{consume}(m, P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow (\hat{\theta}', \hat{\sigma}_f) \mid \text{abort}(\hat{v})$$

The consume operation takes a mode m (OX or UX), an assertion P , a substitution $\hat{\theta}$, and a symbolic state $\hat{\sigma}$, where the substitution $\hat{\theta}$ links known logical variables in P to symbolic values in $\hat{\sigma}$. The operation finds which part of $\hat{\sigma}$ could match P , resulting in potentially multiple successful or unsuccessful matches, and then, per match, returns either the pair $(\hat{\theta}', \hat{\sigma}_f)$, which comprises a substitution $\hat{\theta}'$ and a resulting symbolic state $\hat{\sigma}_f$, or it aborts with error information \hat{v} . Some properties the interface of `consume` mandates are the following:

1. In successful consumption, there exists a symbolic state $\hat{\sigma}_P$ such that $\hat{\sigma} = \hat{\sigma}_f \cdot \hat{\sigma}_P$ (where \cdot denotes state composition, which composes the corresponding components of the two states together) and that every concrete state described by $\hat{\sigma}_P$ satisfies P . This tells us that the matched part of $\hat{\sigma}$ does correspond to P , that the effect of `consume` is its removal from $\hat{\sigma}$, and that consumption can be viewed as the frame inference problem [3], with the resulting state $\hat{\sigma}_f$ constituting the frame;
2. In OX mode, `consume` does not drop paths; in UX mode, it does not drop information. The interface allows, e.g., tool developers to design an OX-consume that (soundly) drops certain information deemed unneeded or a UX-consume that (soundly) drops paths according to a tool-specific criteria (e.g., as in UX bi-abduction in Infer-Pulse).

Example Implementation: Consume. We provide example implementations for the consume and produce operations (§6) that explore the similarities between OX and UX reasoning, and allow us to maintain unified implementations across both reasoning modes. Our consume operation has a mode switch m , allowing for OX- or UX-specific behaviour, which we use to control the *only difference* in our implementation between the two modes: the consumption of pure (non-spatial) information (cf. Fig. 7, left). For soundness, our implementation of the consume operation has to be compatible with the SL and ISL guarantees: in OX mode, `consume` requires full path coverage, and in UX, it requires path reachability.

We illustrate our `consume` implementation by example. Consider the symbolic state $\hat{\sigma} \triangleq (\emptyset, \hat{h}, \hat{\pi})$, where $\hat{h} \triangleq \{1 \mapsto \hat{v}, 2 \mapsto 10, 3 \mapsto 100\}$ and $\hat{\pi} \triangleq \hat{x} > 0 \wedge \hat{v} > 5$, and let us consume the assertion $P \triangleq x \mapsto y * y \geq 10$ from $\hat{\sigma}$ knowing that $\hat{\theta} = \{\hat{x}/x\}$, meaning that the logical variable x of P is mapped to the symbolic variable \hat{x} of $\hat{\sigma}$. This consumption is presented in the diagram below:

- the arrows are labelled with the mode m of operation of `consume`, being either only OX, or only UX, or OX/UX when the consumption has the same behaviour in both modes;
- both our OX and UX consumption branch on all possible matches: in this case, the cell assertion $x \mapsto y$ can be matched to any of the three cells in the heap (branches 0–3), but it could also refer to a cell that is outside of the heap (branch 4);
- when branching occurs, then the branching condition is added to the path condition of the resulting state (the constraints in blue), ensuring information is not dropped;
- the heap cell corresponding to $x \mapsto y$ is removed when matched successfully (branches 1, 2, 3), and in those cases we learn the value corresponding to y (substitution extension in orange where \uplus denotes disjoint union);
- for the heap cell $\{1 \mapsto \hat{v}\}$, our OX consumption (branch 0) must abort since the $\hat{\pi}$ does not imply $y \geq 10$ when $y = \hat{v}$, whereas UX consumption (branch 1) can proceed by restricting the path condition (constraint in magenta), since dropping paths is sound in UX; this allows our UX consumption to successfully consume more assertions; OX consumption cannot do the same since that would render e.g. the function-call rule, which is implemented in terms of `consume`, unsound in OX mode;
- our UX consumption could alternatively drop the missing-cell abort outcome (branch 4), however, some analyses, such as bi-abduction, have use for this error information so we do not drop it.

Analysis: Verification. We use our compositional engine to provide semi-automatic OX verification: that is, given a function implementation and an OX function specification, the engine checks if the implementation satisfies the specification. This analysis is semi-automatic in that the user may have to provide loop invariants as well as ghost commands for, e.g., predicate manipulation and lemma application. It is implemented in the standard way for consume-produce tools.

2.3 Bi-abductive Engine

Bi-abduction is a technique that enables automatic compositional analysis by allowing incremental discovery of resources needed to execute a given piece of code. It was introduced in the OX verification setting [5, 6], later forming the basis of the bug-finding tool Infer [4], and was recently ported to the UX setting of true bug-finding, underpinning Infer-Pulse [17].

Our UX bi-abduction advances the state of the art in two ways. Firstly, UX bi-abduction has thus far been intertwined with the proof search of the symbolic execution tool it has formulated for [28, 17]. Inspired by an approach developed in the OX tool JaVerT 2.0 [10], we add UX bi-abduction as a layer on top of CSE by generating fixes from missing-resource errors. This covers both missing-resource errors from the execution of the commands of the language (e.g., in heap lookup, the looked-up cell might not be in the heap) as well as invocations of `consume` (e.g., if the resource required by a function pre-condition is not in the heap). In more detail, when a missing-resource error occurs, a fix is generated and applied to

the current symbolic state, allowing the execution to continue. Secondly, our UX bi-abduction is able to reason about predicates, allowing us to synthesise and soundly use a broader range of function specifications from other formalisms and tools, in particular specifications that capture unbounded behaviour rather than bounded or single-path behaviour.

Analysis: Specification Synthesis and True Bug-finding. We use bi-abduction to power automatic synthesis of UX function specifications, obtaining one specification per each constructed execution path. Such function specification synthesis forms the back-end of Pulse-style true bug-finding, where specifications describing erroneous executions, after appropriate filtering, can be reported as bugs. Given the guarantees of UX reasoning, any bug (represented by a synthesised erroneous function specification) found during this process will be a true bug.

Example: Specification Synthesis. We illustrate how bi-abduction can be used for the synthesis of UX function specifications, using again the simple function $f(c, x)$ from Fig. 1 (left). The first and the third branches of Fig. 1 (middle) yield the following specifications:

$$\begin{aligned} [c = c \star x = x] \ f(c, x) \ [err : err = ["ExprEval", "c \geq 42"] \star c \notin \text{Nat}] \\ [c = c \star x = x] \ f(c, x) \ [err : err = ["Error", "c \text{ less than } 42"] \star c < 42] \end{aligned}$$

noting that information about local variables is discarded, the error value is returned in the dedicated program variable err , and symbolic variables are replaced with logical variables.

Using bi-abduction, the second branch of Fig. 1 (middle) now becomes Fig. 1 (right). The second branch of Fig. 1 (middle) has one branch in which x is not a heap address (natural number), yielding a type error and the following specification

$$[c = c \star x = x] \ f(c, x) \ [err : err = ["Type", "x", x, "Nat"] \star c \geq 42 \star x \notin \text{Nat}]$$

and one branch in which x is a heap address. In that branch, the lookup fails with a missing-resource error as the heap is empty, but in bi-abductive execution, that is, Fig. 1 (right), instead of failing we first generate the fix $\hat{x} \mapsto \hat{v}$, where \hat{v} is a fresh symbolic variable, and then add it to the heap and re-execute the lookup, which now succeeds. The rest of the function is executed without branching or errors, the function terminates and returns the value of r , which is \hat{v} . This branch results in the following specification:

$$[c = c \star x = x \star x \mapsto v] \ f(c, x) \ [ok : x \mapsto c \star c \geq 42 \star \text{ret} = v]$$

which illustrates an essential principle of bi-abduction, which is to add the fixes applied during execution (also known as *anti-frame*, highlighted in red) to the specification pre-condition.

Example: Specification Synthesis with Predicates. To exemplify how predicates can be useful during specification synthesis, consider the following variant of the standard singly-linked list predicate: $\text{list}(x; xs, vs)$, where x denotes the starting address of the list, and xs and vs denote node addresses and node values, respectively.² Both addresses and values are exposed in the predicate to ensure that no information is lost when the predicate is folded, making it suitable for UX reasoning. The predicate is defined as follows:

$$\begin{aligned} \text{list}(x; xs, vs) \triangleq (x = \text{null} \star xs = [] \star vs = []) \vee \\ (\exists v, x', xs', vs'. x \mapsto v, x' \star \text{list}(x'; xs', vs') \star xs = x : xs' \star vs = v : vs') \end{aligned}$$

² We use the semicolon notation for predicates to be consistent with the main text, where the notation is used for automation – for the purpose of this section, these semicolons can be read as commas.

Further, consider the predicate $\text{listHead}(x; xs)$, which tells us that x is the head of the list xs if xs is not empty and null otherwise, defined as

$$\text{listHead}(x; xs) \triangleq (xs = [] \star x = \text{null}) \vee (\exists xs'. xs = x : xs'),$$

and the following specifications of two list-manipulating functions (e.g., proven using pen-and-paper), which capture the exact behaviour of inserting a value in the front of a list (LInsert) and swapping of the first two values in a list (LSwapFirstTwo):

$$\begin{aligned} [x = x \star v = v \star \text{list}(x; xs, vs)] \text{ LInsert}(x, v) & [ok : \text{list}(\text{ret}; \text{ret}:xs, v:vs) \star \text{listHead}(x; xs)] \\ [x = x \star \text{list}(x; xs, vs)] \text{ LSwapFirstTwo}(x) & [err : \text{list}(x; xs, vs) \star |vs| < 2 \star \text{err} = \text{"List too short!"}] \end{aligned}$$

Using these specifications, we can bi-abduce the following UX true-bug specification of client code calling these functions, where the discovered anti-frame is again highlighted in red, but this time contains a predicate:

$$\begin{aligned} & [x = x \star \text{list}(x; xs, vs)] \\ & x := \text{LInsert}(x, 42); y := \text{LSwapFirstTwo}(x) \\ & [err : \exists x'. \text{list}(x'; x':xs, 42:vs) \star \text{listHead}(x; xs) \star |42:vs| < 2 \star \text{err} = \text{"List too short!"}] \end{aligned}$$

3 Programming Language

We present a simple imperative heap language with function calls on which our analysis engine operates. The language is standard, except that, in line with previous work on compositional reasoning and incorrectness [8, 9, 10, 12, 28], we track freed cells in the heap, and separate language errors and missing-resource errors to preserve the compositionality of the semantics. We sometimes refer to the definitions of this section as *concrete* to differentiate them from the *symbolic* definitions used in the symbolic engine introduced in subsequent sections.

Syntax. The values are given by: $v \in \text{Val} ::= n \in \text{Nat} \mid b \in \text{Bool} \mid s \in \text{Str} \mid \text{null} \mid [\vec{v}]$, where \vec{v} denotes a vector of values. The types are given by: $\tau \in \text{Type} ::= \text{Val} \mid \text{Nat} \mid \text{Bool} \mid \text{Str} \mid \text{List}$. The types are used to define the semantics of the language; the language itself is dynamically typed. The expressions, $E \in \text{PExp}$, comprise the values, program variables $x, y, z, \dots \in \text{PVar}$, and expressions formed using the standard operators for numerical and Boolean expressions. The commands are given by the grammar:

$$\begin{aligned} C \in \text{Cmd} ::= & \text{skip} \mid x := E \mid x := \text{nondet} \mid \text{error}(E) \mid x := [E] \mid [E] := E \mid x := \text{new} \mid \\ & \text{free}(E) \mid \text{if } (E) C \text{ else } C \mid C; C \mid y := f(\vec{E}) \end{aligned}$$

comprising the variable assignment, variable assignment of a non-deterministically chosen natural number, user-thrown error, heap lookup, heap mutation, allocation, deallocation, command sequencing, conditional control-flow and function call. Our results extend to other control-flow commands, e.g. loops, since these can be implemented using conditionals and recursive functions. The sets of program variables for expressions $\text{pv}(E)$ and commands $\text{pv}(C)$ are standard.

Functions and Function Implementation Contexts. A function implementation, denoted $f(\vec{x}) \{ C; \text{return } E \}$, comprises: an identifier, $f \in \text{Fid} \subseteq \text{Str}$; the parameters, given by a list of distinct program variables \vec{x} ; a body, $C \in \text{Cmd}$; and a return expression, $E \in \text{PExp}$, with $\text{pv}(E) \subseteq \{\vec{x}\} \cup \text{pv}(C)$. A function implementation context, γ , maps function identifiers to their implementations: $\gamma : \text{Fid} \rightarrow_{\text{fin}} \text{PVar List} \times \text{Cmd} \times \text{PExp}$, where \rightarrow_{fin} denotes that the function is a finite partial function. We often write $f(\vec{x}) \{ C; \text{return } E \} \in \gamma$ for $\gamma(f) = (\vec{x}, C, E)$.

Stores, Heaps and States. A variable store, $s : \text{PVar} \rightarrow_{\text{fin}} \text{Val}$, is a function from program variables to values. A *partial* heap, $h : \text{Nat} \rightarrow_{\text{fin}} (\text{Val} \uplus \{\emptyset\})$, is a function from natural numbers to values extended with a dedicated symbol $\emptyset \notin \text{Val}$ recording that a heap cell has been freed. Two heaps are disjoint, denoted $h_1 \# h_2$, when their domains are disjoint. Heap composition, denoted $h_1 \uplus h_2$, is given by the disjoint union of partial functions which is only defined when the domains are disjoint. A *partial* program state, $\sigma = (s, h)$, is a pair comprising a store and a heap. State composition, denoted $\sigma_1 \cdot \sigma_2$, is given by $(s_1, h_1) \cdot (s_2, h_2) \triangleq (s_1 \cup s_2, h_1 \uplus h_2)$ for $\sigma_1 = (s_1, h_1)$ and $\sigma_2 = (s_2, h_2)$, which is only defined when variable stores are equal on their intersection and the heap composition is defined.

Operational Semantics. We use a standard expression evaluation function, $\llbracket E \rrbracket_s$, which evaluates an expression E with respect to a store s , assuming that expressions do not affect the heap. It results in either a value or a dedicated symbol $\notin \text{Val}$, denoting, an evaluation error, such as a variable not being in the store or a mathematical error. The operational semantics of commands is a big-step semantics using judgements of the form $\sigma, C \Downarrow_\gamma o : \sigma'$ which reads “the execution of command C in state σ and function implementation context γ results in a state σ' with outcome o ”, where $o ::= \text{ok} \mid \text{err} \mid \text{miss}$ denotes, respectively, a successful execution, a language error, and a missing-resource error due to the absence of a required cell in the partial heap. The separation of the missing-resource errors from the language errors is important for compositional reasoning, since the language satisfies both the standard OX and UX frame properties when the outcome is not missing. The semantics is standard and given in full in [18], along with the frame properties it satisfies.

4 Compositional Symbolic Execution: Core Engine

We present our CSE engine in two stages. In this section, we present the core CSE engine, given by a standard compositional symbolic operational semantics presented here to establish notation and introduce key concepts to the non-specialist reader: the definitions are similar to those for whole-program symbolic execution; the difference is with the use of partial state which has the effect that we have the distinction between language errors and missing-resource errors. In §5.3, we extend the core engine with our semantic rules for function calls and folding/unfolding predicates, using an axiomatic description of the consume and produce operations given in §5.2.

4.1 Symbolic States

Let $S\text{Var}$ be a set of symbolic variables, disjoint from the set of program variables, PVar , and values, Val . Symbolic values are defined as follows:

$$\hat{v} \in S\text{Val} ::= v \mid \hat{x} \mid \hat{v} + \hat{v} \mid \dots \mid \hat{v} = \hat{v} \mid \neg \hat{v} \mid \hat{v} \wedge \hat{v} \mid \hat{v} \in \tau$$

A symbolic store, $\hat{s} : \text{PVar} \rightarrow_{\text{fin}} S\text{Val}$, is a function from program variables to symbolic values. A partial symbolic heap, $\hat{h} : S\text{Val} \rightarrow_{\text{fin}} (S\text{Val} \uplus \{\emptyset\})$, is a function from symbolic values to symbolic values extended with \emptyset . A path condition, $\hat{\pi} \in S\text{Val}$, is a symbolic Boolean expression that captures constraints imposed on symbolic variables during execution. A (partial) symbolic state is a triple of the form $\hat{\sigma} = (\hat{s}, \hat{h}, \hat{\pi})$. Throughout the paper, we only work with well-formed states $\hat{\sigma}$, denoted $\mathcal{Wf}(\hat{\sigma})$, the definition is uninformative (it ensures, e.g., that the addresses of the symbolic heap are interpreted as natural numbers), see [18]. We write $\hat{\sigma}.\text{pc}$ and $\hat{\sigma}[\text{pc} := \hat{\pi}']$ to denote, respectively, access and update the state path condition. We write $\text{sv}(X)$ to denote the set of symbolic variables of a given construct X : e.g., $\text{sv}(\hat{s})$ for symbolic stores, $\text{sv}(\hat{h})$ for symbolic heaps, etc.

$$\begin{array}{c}
\text{LOOKUP} \\
\frac{\begin{array}{c} \llbracket E \rrbracket_{\hat{s}}^{\hat{\pi}} \Downarrow (\hat{v}, \hat{\pi}') \quad \hat{h}(\hat{v}_l) = \hat{v}_m \\ \hat{\pi}'' \triangleq (\hat{v}_l = \hat{v}) \wedge \hat{\pi}' \quad \text{SAT}(\hat{\pi}'') \end{array}}{(\hat{s}, \hat{h}, \hat{\pi}), x := [E] \Downarrow_{\Gamma} ok : (\hat{s}[x \mapsto \hat{v}_m], \hat{h}, \hat{\pi}'')} \\
\\
\text{LOOKUP-ERR-VAL} \\
\frac{\begin{array}{c} \llbracket E \rrbracket_{\hat{s}}^{\hat{\pi}} \Downarrow (\hat{v}, \hat{\pi}') \\ \hat{v}_{err} \triangleq [\text{"ExprEval"}, \text{str}(E)] \end{array}}{(\hat{s}, \hat{h}, \hat{\pi}), x := [E] \Downarrow_{\Gamma} err : (\hat{s}_{err}, \hat{h}, \hat{\pi}')} \\
\\
\text{LOOKUP-ERR-MISSING} \\
\frac{\begin{array}{c} \llbracket E \rrbracket_{\hat{s}}^{\hat{\pi}} \Downarrow (\hat{v}, \hat{\pi}') \quad \text{SAT}(\hat{\pi}') \wedge \hat{v} \in \text{Nat} \wedge \hat{v} \notin \text{dom}(\hat{h}) \\ \hat{v}_{err} \triangleq [\text{"MissingCell"}, \text{str}(E), \hat{v}] \end{array}}{(\hat{s}, \hat{h}, \hat{\pi}), x := [E] \Downarrow_{\Gamma} miss : (\hat{s}_{err}, \hat{h}, \hat{\pi}' \wedge \hat{v} \in \text{Nat} \wedge \hat{v} \notin \text{dom}(\hat{h}))}
\end{array}$$

■ **Figure 3** Excerpt of symbolic execution rules, where $\hat{s}_{err} = \hat{s}[\text{err} \mapsto v_{err}]$.

Symbolic Interpretations. A symbolic interpretation, $\varepsilon : \text{SVar} \rightarrow_{fin} \text{Val}$ maps symbolic variables to concrete values, and is used to define the meaning of symbolic states and state the soundness results of the engine. We lift interpretations to symbolic values, $\varepsilon : \text{SVal} \rightarrow_{fin} \text{Val}$, with the property that it is undefined if the resulting concrete evaluation faults. Satisfiability of symbolic values is defined as usual, i.e., $\text{SAT}(\hat{\pi}) \triangleq \exists \varepsilon. \varepsilon(\hat{\pi}) = \text{true}$. We further lift symbolic interpretations to stores, heaps, and states, overloading the ε notation.

4.2 Core Engine

The symbolic expression evaluation relation, $\llbracket E \rrbracket_{\hat{s}}^{\hat{\pi}} \Downarrow (\hat{w}, \hat{\pi}')$, evaluates a program expression E with respect to a symbolic store \hat{s} and path condition $\hat{\pi}$. It results in either a symbolic value or an evaluation error, $\hat{w} \triangleq \hat{v} \mid \not{f}$, and a satisfiable path condition $\hat{\pi}' \Rightarrow \pi$, which may contain additional constraints arising from the evaluation (e.g., to prevent branching on division by zero). The core CSE semantics is described using the usual single-trace semantic judgement (below, left) which is used to state UX properties. It also induces the collecting semantic judgement (below, right), which is used to state OX properties.

$$\hat{\sigma}, C \Downarrow_{\gamma} o : \hat{\sigma}' \quad \hat{\sigma}, C \Downarrow_{\gamma} \hat{\Sigma}' \iff \hat{\Sigma}' = \{(o, \hat{\sigma}') \mid \hat{\sigma}, C \Downarrow_{\gamma} o : \hat{\sigma}'\}$$

We give the lookup rules for illustration in Fig. 3: for example, the rule LOOKUP branches over all possible addresses in the heap that can match the given address.

Our CSE semantics is both OX- and UX-sound, which we call exact: OX soundness captures that no paths are dropped by stating that the symbolic semantics includes all behaviour w.r.t. the concrete semantics; UX soundness captures that no information is dropped by stating that the symbolic semantics does not add behaviour w.r.t. the concrete semantics.

► **Theorem 1** (OX and UX soundness).

$$\begin{array}{ll}
(OX) & \hat{\sigma}, C \Downarrow_{\gamma} \hat{\Sigma}' \wedge \varepsilon(\hat{\sigma}), C \Downarrow_{\gamma} o : \sigma' \implies \exists \hat{\sigma}', \varepsilon' \geq \varepsilon. (o, \hat{\sigma}') \in \hat{\Sigma}' \wedge \sigma' = \varepsilon'(\hat{\sigma}') \\
(UX) & \hat{\sigma}, C \Downarrow_{\gamma} o : \hat{\sigma}' \wedge \varepsilon(\hat{\sigma}') = \sigma' \implies \varepsilon(\hat{\sigma}), C \Downarrow_{\gamma} o : \sigma'
\end{array}$$

where $\varepsilon' \geq \varepsilon$ denotes that ε' extends ε , i.e., $\varepsilon'(\hat{x}) = \varepsilon(\hat{x})$ for all $\hat{x} \in \text{dom}(\varepsilon)$.

5 Compositional Symbolic Execution: Full Engine

Our core CSE engine is limited in that it does not call function specifications written in a program logic, and it cannot fold and unfold user-defined predicates to verify, e.g., specifications of list algorithms. What is missing is a general description of how to update symbolic state using assertions from the function specifications and predicate definitions. In

VeriFast, Viper and Gillian, this symbolic-state update is given by their implementations of the consume and produce operations. We instead give an *axiomatic interface* for describing such symbolic-state update by providing a general characterisation of these consume and produce operations (§5.2). Using this interface, we are able to give general definitions of the function-call rule (§5.3) and the folding and unfolding of predicates that are independent of the underlying tool implementation. Assuming the appropriate properties stated in the axiomatic interface, we prove that the resulting CSE engine is either OX sound or UX sound. Moreover, because the axiomatic interface relates the behaviour of the consume and produce operations to the standard satisfaction relation of SL and ISL, our function-call rule is able to use any function specification proven correct with respect to the standard function specification validity of SL and ISL, including functions specification proven outside our engine. In the next section (§6), we demonstrate that the Gillian implementation of the consume and produce operations are correct with respect to our axiomatic interface.³

5.1 Assertions and Extended Symbolic States

We present assertions suitable for both SL and ISL reasoning, and also extend our symbolic states to account for predicates. It is helpful to make a clear distinction between the logical assertions and symbolic states: since we work with the linear heap, the gap between assertions and symbolic states is quite small; with more complex memory models and optimised symbolic representations of memory, the gap is larger and this distinction becomes essential.

Assertions. Let $x, y, z \in \text{LVar}$ denote logical variables, distinct from program and symbolic variables. The set of logical expressions, $E \in \text{LExp}$, extends program expressions to include logical variables. We work with the following set of assertions (other assertions are derivable):

$$\begin{aligned} \pi \in \text{BAsrt} &\triangleq E \mid E \in \tau \mid \neg\pi \mid \dots \mid \pi_1 \wedge \pi_2 \\ P \in \text{Asrt} &\triangleq \pi \mid \text{False} \mid P_1 \Rightarrow P_2 \mid P_1 \vee P_2 \mid \exists x. P \mid \\ &\quad \text{emp} \mid E_1 \mapsto E_2 \mid E \mapsto \emptyset \mid P_1 \star P_2 \mid p(\vec{E}_1; \vec{E}_2) \end{aligned}$$

where $E, E_1, E_2 \in \text{LExp}$, $x \in \text{LVar}$, and $p \in \text{Str}$. The assertions should by now be familiar from separation logic. They comprise the lift of the usual first-order Boolean assertions π , assertions built from the usual first-order connectives and quantifiers, and assertions well-known from separation logic: the empty assertion `emp`, the cell assertion $E_1 \mapsto E_2$ describing a heap cell at an address given by E_1 with value given by E_2 , the less well-known assertion $E \mapsto \emptyset$ describing a heap cell at address E that has been freed, the separating conjunction $P_1 \star P_2$, and the predicate assertions $p(\vec{E}_1; \vec{E}_2)$. The parameters of predicate assertions $p(\vec{E}_1; \vec{E}_2)$ are separated into in-parameters \vec{E}_1 (“ins”) and out-parameters \vec{E}_2 (“outs”) for automation purposes, as we discuss in §6; this separation does not affect the logical meaning of the predicate assertions. We write $\text{1v}(X)$ to denote free logical variables of a construct X : e.g., $\text{1v}(E)$ for logical expressions, $\text{1v}(P)$ for assertions, etc. We say that an assertion P is *simple* if it does not syntactically feature the separating conjunction; simple assertions are used in the definition of matching plans (§6.1).

Predicates. Predicate definitions are given by a set Preds containing elements of type $\text{Str} \times \text{LVar} \times \text{LVar} \times \text{Asrt}$, with the notation $p(\vec{x}_{\text{in}}; \vec{x}_{\text{out}}) \{P\} \in \text{Preds}$, where the string p denotes the predicate name, the lists of disjoint parameters $\vec{x}_{\text{in}}, \vec{x}_{\text{out}}$ denote the predicate

³ To our best understanding, there is a large overlap between Gillian’s consume and produce operations and those of Viper and VeriFast. We therefore expect them to also satisfy the OX properties of our interface (we have however not proven this fact).

ins and outs respectively, and the assertion $P = \bigvee_i (\exists \vec{y}_i. P_i)$ denotes the predicate body, which does not contain program variables and whose free logical variables are contained in $\{\vec{x}_{\text{in}}\} \cup \{\vec{x}_{\text{out}}\}$ which are disjoint from the bound variables \vec{y}_i , and where the P_i 's (denoting the assertions of the predicate definition) do not contain disjunctions or existential quantifiers.

Satisfiability. The meaning of an assertion P is defined by capturing the models of P using the standard satisfaction relation $\theta, \sigma \models P$ where $\theta : \text{LVar} \rightarrow_{\text{fin}} \text{Val}$ is a logical interpretation represented by a function from logical variables to values and σ is a program state (as defined in §3). The formal definition is included in the extended version of this paper [18].

Function Specifications. The quadruples $\langle \vec{x} = \vec{x} \star P \rangle f(\vec{x}) \langle \text{ok} : Q_{\text{ok}} \rangle \langle \text{err} : Q_{\text{err}} \rangle$ and $\langle \vec{x} = \vec{x} \star P \rangle f(\vec{x}) \langle \text{ok} : Q_{\text{ok}} \rangle \langle \text{err} : Q_{\text{err}} \rangle$ denote, respectively, a SL and an ISL function specification, as explained in §2.2. We write $\langle \vec{x} = \vec{x} \star P \rangle f(\vec{x}) \langle \text{ok} : Q_{\text{ok}} \rangle \langle \text{err} : Q_{\text{err}} \rangle$ to refer to either. Both quadruples record successful executions and language errors. They are unable to record missing-resource errors, as these errors do not satisfy the OX and UX frame properties. Missing errors can be removed automatically via UX bi-abduction (see §7).

Formally, we define function specifications using internalisation [20]. In short, internalisation relates internal specifications, which describe the internal behaviour of functions, to external specifications, which describe the external behaviour of functions. Internalisation is needed for ISL to allow the logic to drop information about function-local program variables at function boundaries, since dropping information is in general not allowed in ISL. The full definitions of function specifications and internalisation are included in [18].

A function specification context, $\Gamma \in \text{Fid} \rightarrow_{\text{fin}} \mathcal{P}(\mathcal{E}\text{Spec})$, maps function identifiers to a finite set of external specifications $\mathcal{E}\text{Spec}$. To simplify the presentation of the paper, we assume existential quantifiers only occur at the top level of external specifications. We denote the validity of Γ with respect to γ by $\models (\gamma, \Gamma)$, and validity of a function specification with respect to Γ by $\Gamma \models \langle \vec{x} = \vec{x} \star P \rangle f(\vec{x}) \langle \text{ok} : Q_{\text{ok}} \rangle \langle \text{err} : Q_{\text{err}} \rangle$.

Extended Symbolic States. To reason about unbounded execution to verify, for example, specifications of list algorithms, we extend the partial symbolic states defined in §4.1 with symbolic predicates of the form $p(\vec{v}_1; \vec{v}_2)$, with $p \in \text{Str}$ and $\vec{v}_1, \vec{v}_2 \in \text{SVal}$. An extended symbolic state \hat{s} is a tuple $(\hat{s}, \hat{H}, \hat{\pi})$ comprising a partial symbolic state \hat{s} , a symbolic resource $\hat{H} = (\hat{h}, \hat{\mathcal{P}})$ with symbolic heap \hat{h} and multiset of symbolic predicates $\hat{\mathcal{P}}$, and a symbolic path condition $\hat{\pi}$. Definitions of well-formedness of symbolic state and symbolic interpretations are extended as expected. We define $\varepsilon, \sigma \models (\hat{s}, \hat{H}, \hat{\pi})$ analogously to assertion satisfaction since the interpretation of a symbolic state with respect to symbolic interpretation $\varepsilon : \text{SVar} \rightarrow_{\text{fin}} \text{Val}$ is a relation and not a function (cf. §4) due to the presence of symbolic predicates.

The composition of two extended symbolic states is defined by:

$$(\hat{s}_1, \hat{H}_1, \hat{\pi}_1) \cdot (\hat{s}_2, \hat{H}_2, \hat{\pi}_2) \triangleq (\hat{s}_1 \cup \hat{s}_2, \hat{H}_1 \cup \hat{H}_2, \hat{\pi}_1 \wedge \hat{\pi}_2 \wedge \mathcal{Wfc}(\hat{H}_1 \cup \hat{H}_2))$$

where $\hat{H}_1 \cup \hat{H}_2$ denotes the pairwise union of the components of the symbolic resource and $\mathcal{Wfc}(\hat{H}_1 \cup \hat{H}_2)$ ensures that the composition is well-formed.

5.2 Axiomatic Interface for Consume and Produce

We present our axiomatic interface for the consume and produce operations, used to update the symbolic state during function call and to fold and unfold the predicates. Given the substitution $\hat{\theta} : \text{LVar} \rightarrow_{\text{fin}} \text{SVal}$, the consume and produce operations have the signatures:

$$\text{consume}(m, P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow (\hat{\theta}', \hat{\sigma}_f) \mid \text{abort}(\hat{v}) \quad \text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}'$$

We assume the following holds initially: state $\hat{\sigma}$ and substitution $\hat{\theta}$ are well-formed; and $\hat{\theta}$ covers P for produce, that is, $\text{lv}(P) \subseteq \text{dom}(\hat{\theta})$. For properties 1–4 below, consider the following executions:

$$\begin{array}{ll} \text{consume}(m, P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow (\hat{\theta}', \hat{\sigma}_f) & \text{where } \hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi}) \text{ and } \hat{\sigma}_f = (\hat{s}', \hat{H}_f, \hat{\pi}') \\ \text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}' & \text{where } \hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi}) \text{ and } \hat{\sigma}' = (\hat{s}', \hat{H}', \hat{\pi}') \end{array}$$

► **Property 1** (Well-formedness). *The variable store is not altered: that is, $\hat{s}' = \hat{s}$ and*

$$(\text{consume}) \quad \mathcal{Wf}(\hat{\sigma}_f) \text{ and } \mathcal{Wf}(\hat{\theta}', \hat{\pi}') \quad (\text{produce}) \quad \mathcal{Wf}(\hat{\sigma}')$$

► **Property 2** (Path Strengthening). $\hat{\pi}' \Rightarrow \hat{\pi}$

► **Property 3** (Consume Covers P). $\hat{\theta}' \geq \hat{\theta}$ and $\text{dom}(\hat{\theta}') \supseteq \text{lv}(P)$

► **Property 4** (Soundness).

$$(\text{consume}) \quad \exists \hat{H}_P. \quad \hat{H} = \hat{H}_f \cup \hat{H}_P \wedge (\forall \varepsilon, \sigma. \varepsilon, \sigma \models \hat{\sigma}_P \implies \varepsilon(\hat{\theta}'), \sigma \models P) \quad \text{where } \hat{\sigma}_P \triangleq (\emptyset, \hat{H}_P, \hat{\pi}')^a$$

$$(\text{produce}) \quad \exists \hat{H}_P. \quad \hat{H}' = \hat{H} \cup \hat{H}_P \wedge (\forall \varepsilon, \sigma. \varepsilon, \sigma \models \hat{\sigma}_P \implies \varepsilon(\hat{\theta}), \sigma \models P) \quad \text{where } \hat{\sigma}_P \triangleq (\emptyset, \hat{H}_P, \hat{\pi}')$$

► **Property 5** (Completeness: OX consume). *If $\text{abort} \notin \text{consume(OX, } P, \hat{\theta}, \hat{\sigma})$ and $\varepsilon, \sigma \models \hat{\sigma}$, then*

$$\exists \hat{\theta}', \sigma_f, \hat{\sigma}_f. \quad \text{consume(OX, } P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow (\hat{\theta}', \hat{\sigma}_f) \wedge \varepsilon, \sigma_f \models \hat{\sigma}_f$$

► **Property 6** (Completeness: UX consume). *If $\text{consume(UX, } P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow (\hat{\theta}', \hat{\sigma}_f)$, $\varepsilon(\hat{\pi}') = \text{true}$ and $\varepsilon(\hat{\theta}'), (\emptyset, h_P) \models P$, then*

$$\varepsilon, (\emptyset, h_P) \models \hat{\sigma}_P \wedge (\forall h_f. \varepsilon, (s, h_f) \models \hat{\sigma}_f \wedge h_P \# h_f \implies \varepsilon, (s, h_f \uplus h_P) \models \hat{\sigma})$$

► **Property 7** (Completeness: produce). *If $\varepsilon, (s, h) \models \hat{\sigma}$ and $\varepsilon(\hat{\theta}), (\emptyset, h_P) \models P$ and $h \# h_P$, then*

$$\exists \hat{\sigma}_P. \quad \text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma} \cdot \hat{\sigma}_P \wedge \varepsilon, (\emptyset, h_P) \models \hat{\sigma}_P$$

^a We choose the empty symbolic store for $\hat{\sigma}_P$; P does not have program variables so this choice is arbitrary. The symbolic state $\hat{\sigma}_P$ is the one used in Prop. 6.

■ **Figure 4** The axiomatic interface for the consume and produce operations.

Recall the use of the consume and produce operations in the function call illustrated in Fig. 2 of §2.2. For $\text{consume}(m, P, \hat{\theta}, \hat{\sigma})$, the initial substitution $\hat{\theta}$ comes from replacing the function parameters with symbolic values given by the arguments in the function call; consume matches the precondition P and substitution $\hat{\theta}$ against part of $\hat{\sigma}$, removing the appropriate resource $\hat{\sigma}_P$ and returning the frame $\hat{\sigma}_f$ and the substitution $\hat{\theta}'$ which extends $\hat{\theta}$ with further information given by the match. For $\text{produce}(Q_{ok}, \hat{\theta}', \hat{\sigma}_f)$, the produce takes the postcondition Q_{ok} and this resulting substitution $\hat{\theta}'$ and creates a symbolic state which is composed with $\hat{\sigma}_f$ to obtain $\hat{\sigma}'$. Notice that the consume operation can abort with error information if no match is found. The produce operation does not abort, but it may render states unsatisfiable, in which case the branch is cut.

In Fig. 4, we present the axiomatic interface of the consume and produce operations, identifying sufficient properties to prove OX and UX soundness for the function-call rule and the folding and unfolding of predicates, as we demonstrate in the next section (§5.3). Properties 1–3 ensure that the operations are compatible with the expected properties of symbolic execution, including well-formedness $\mathcal{Wf}(\hat{\theta}', \hat{\pi}')$ of the symbolic substitutions with respect to path conditions. This property guarantees that the $\hat{\pi}'$ implies that $\hat{\theta}'$ does not map logical variables into \perp , that is, $\hat{\pi}' \models \text{codom}(\hat{\theta}') \subseteq \text{Val}$.

Properties 4–7 give conditions for `consume` and `produce` to soundly decompose and compose symbolic states respectively, while being compatible with symbolic and logical interpretations. These properties will come as no surprise to those with a formal knowledge of symbolic execution. However, their identification was not easy, requiring a considerable amount of back and forth between the soundness proof and the properties to pin them down properly. We describe the more interesting of the properties described in Fig. 4:

- Prop. 2 states that path conditions may only get strengthened: OX and UX `consume` may strengthen $\hat{\pi}$ to due to branching; additionally UX `consume` may strengthen $\hat{\pi}$ arbitrarily due to cutting; and `produce` may add constraints to $\hat{\pi}$ arising from P .
- Prop. 4, for `consume` (and similarly for `produce`), states that the operation is sound: the symbolic resource of $\hat{\sigma}$ can be decomposed as $\hat{H} = \hat{H}_f \cup \hat{H}_P$, i.e., it consists of the symbolic resources of $\hat{\sigma}_P$ and $\hat{\sigma}_f$, respectively, and $\forall \varepsilon, \sigma. \varepsilon, \sigma \models \hat{\sigma}_P \implies \varepsilon(\hat{\theta}''), \sigma \models P$ states that all models of $\hat{\sigma}_P$ are models of P .
- Prop. 5 captures that successful OX consumptions do not drop paths: if no branch aborts, and we have a model $\varepsilon, \sigma \models \hat{\sigma}$, then there exists a branch $\hat{\sigma}_f$ with a model using the same ε , i.e., there exist σ_f such that $\varepsilon, \sigma_f \models \hat{\sigma}_f$.
- Prop. 6 is as follows: in successful UX `consume`, any model of the consumed assertion P must also model the consumed state $\hat{\sigma}_P$ (obtained from Prop. 4), and when extended with a compatible model of the output state $\hat{\sigma}_f$ it must model the input state $\hat{\sigma}$.

Assuming these properties of the `consume` and `produce` operations, we are able to prove that the function-call rule and the predicate folding and unfolding are sound, and thus that our whole CSE engine is sound (Thm. 3). In §5.3, we give an example (Ex. 2) illustrating some of the properties in action during a function call.

5.3 Full CSE Engine

We introduce our full CSE engine, extending the core CSE engine (§4) with the ability to soundly call valid SL and ISL function specifications (§5.1), and to fold/unfold predicates. We extend and adapt the compositional symbolic operational semantics to carry a specification context Γ and the mode of execution m (OX or UX), obtaining the judgement $\hat{\sigma}, \mathsf{C} \Downarrow_{\Gamma}^m o : \hat{\sigma}'$, and extend the possible outcomes with *abort*, as `consume` can abort. The rules are analogous except for the rules for function calls and predicate folding/unfolding, as detailed below.⁴

Function-Call Rule. The unified success rule for a function call is in Fig. 5, using the notation $\Gamma(f)|_m$ to isolate the m -mode specifications of f . A description of each step is included in the rule itself. In short, given an initial state $\hat{\sigma}$, the rule selects a function specification, consumes the specification pre-condition from $\hat{\sigma}$, resulting in $\hat{\sigma}'$, and produces the post-condition of the specification into $\hat{\sigma}'$, resulting in the final state $\hat{\sigma}''$. The steps in grey are uninteresting (about renamings and fresh variables) and can be ignored on a first reading.

► **Example 2.** We show a possible execution of a function call using a function specification, where we assume we have been given `consume` and `produce` example implementations that satisfy the axiomatic interface. Consider the function f given in §2.1 and the ISL specification given in §2.3: $[c = c * x = x * P] f(c, x) [ok : x \mapsto c * c \geq 42 * \text{ret} = v]$ where P is $x \mapsto v$,

⁴ The satisfiability check $\mathbf{SAT}(\hat{\pi})$ used by the rules over-approximates the existence of a model for $(\hat{s}, \hat{H}, \hat{\pi})$, due to the presence of symbolic predicates; for sound reasoning in UX mode, our engine addresses this source of over-approximation by under-approximating the satisfiability check once by bounded unfolding of predicates at the end of execution.

(1) $\langle\!\langle \vec{x} = \vec{x} * P \rangle\!\rangle f(\vec{x}) \langle\!\langle ok : Q_{ok} \rangle\!\rangle \langle\!\langle err : Q_{err} \rangle\!\rangle \in \Gamma(f) _m$	get function specification
(2) $\llbracket \vec{E} \rrbracket_{\hat{s}}^{\hat{\pi}} \Downarrow (\vec{\theta}, \hat{\pi}')$ and $\hat{\theta} \triangleq \{\vec{v}/\vec{x}\}$	evaluate function parameters
(3) $\text{consume}(m, P, \hat{\theta}, \hat{\sigma}[\text{pc} := \hat{\pi}']) \rightsquigarrow (\hat{\theta}', \hat{\sigma}')$	consume pre-condition as Q_{ok} is a post-condition
(4) $Q_{ok} = \exists \vec{y}. Q'_{ok}$	extend substitution to cover Q_{ok}
(5) $\hat{\theta}'' \triangleq \hat{\theta}' \cup \{\vec{z}/\vec{y}\}$	fresh variables
(6) \vec{z}, r, \hat{r} fresh	
(7) $Q''_{ok} = Q'_{ok}\{r/\text{ret}\}$ and $\hat{\theta}''' = \hat{\theta}'' \cup \{\hat{r}/r\}$	set up return value
(8) $\text{produce}(Q''_{ok}, \hat{\theta}''', \hat{\sigma}') \rightsquigarrow \hat{\sigma}''$	produce post-condition
$\hat{\sigma}, y := f(\vec{E}) \Downarrow_{\Gamma}^m ok : \hat{\sigma}''[\text{sto} := \hat{s}[y \mapsto \hat{r}]]$	

Figure 5 Unified function-call rule for CSE: success case, where $\hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi})$.

here assumed to be in the function specification context Γ . Suppose the symbolic execution is in a state $\hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi})$ and that the next step is $\hat{\sigma}, y := f(50, 1) \Downarrow_{\Gamma}^{\text{UX}} ok : \hat{\sigma}'$. Let $\hat{H} = (\{\hat{x} \mapsto \hat{c}, \hat{y} \mapsto 1, 3 \mapsto 5\}, \emptyset)$ be the symbolic resource, and $\hat{\pi} = \hat{c} \geq 42 \wedge \hat{x} \neq \hat{y} \wedge \hat{x}, \hat{y} \in \text{Nat}$ be the symbolic path condition (the symbolic store \hat{s} is irrelevant to this computation and left opaque). We now follow the steps (1) - (8) described in the function-call rule in Fig. 5.

Step (1) is above. Step (2) evaluates the parameters of the function call which in this case yields the initial substitution is $\hat{\theta} = \{50/c, 1/x\}$. Step (3) is to consume the pre-condition of f : $\hat{\theta}$ identifies the logical variable x with 1, and thus, this $\hat{\theta}$ maps P into $1 \mapsto v$; now we check whether there exists a resource in \hat{H} that matches this. There are two possibilities: either $\hat{x} = 1$ and $v = \hat{c}$; or $\hat{y} = 1$ and $v = 1$. Let us choose the first match. Thus, with our axiomatic description of a consume operation, $\text{consume}(\text{UX}, x \mapsto v, \hat{\theta}, \hat{\sigma})$ gives the pair $(\hat{\theta}', \hat{\sigma}_f)$, with substitution $\hat{\theta}' = \{50/c, 1/x, \hat{c}/v\}$ and symbolic frame $\hat{\sigma}_f = (\hat{s}, (\{\hat{y} \mapsto 1, 3 \mapsto 5\}, \emptyset), \hat{\pi} \wedge \hat{x} = 1)$. Here $\hat{\theta}' \geq \hat{\theta}$ as described by Prop. 3 of Fig. 4, the new path condition $\hat{\pi} \wedge \hat{x} = 1$ is stronger than the initial $\hat{\pi}$, as required by Prop. 2.

Steps (4) - (5) are straightforward: Q_{ok} is not existentially quantified and the domain of $\hat{\theta}'$ covers $Q_{ok} = x \mapsto c * c \geq 42 * \text{ret} = v$. Steps (6) - (7) set up the return value by renaming ret with a fresh logical variable r as in $Q''_{ok} = Q_{ok}\{r/\text{ret}\}$ and defining the substitution $\hat{\theta}'' = \hat{\theta}' \uplus \{\hat{r}/r\}$, with \hat{r} a fresh symbolic variable. Step (8) produces the post-condition which results in $(\hat{s}, (\{\hat{y} \mapsto 1, 3 \mapsto 5, 1 \mapsto 50\}, \emptyset), \hat{\pi}')$, for some $\hat{\pi}'$ that is satisfiable.

We illustrate the general execution of the function-call rule in Fig. 6. Successful `consume` may branch (in the figure: $\hat{\sigma}_{f_1}, \dots, \hat{\sigma}_{f_k}$) due to different ways of matching with the symbolic state $\hat{\sigma}$, and the function call will branch accordingly. In both modes, in each successful branch, say with frame state $\hat{\sigma}_{f_i}$, the function-call rule will call `produce`, which will produce both Q_{ok} and Q_{err} postconditions of the function specification. The function call propagates errors from `consume`, whose error handling can depend on the mode of reasoning. In OX mode, all errors must be reported; the figure shows an example with two *abort* outcomes, one with a symbolic value $\hat{\sigma}_{miss}$, representing a missing outcome, and another abort $\hat{\sigma}_{\hat{v}}$. In UX mode, in contrast, errors can be cut: e.g., a `consume` implementation may choose to report missing errors (to be used in e.g. bi-abduction, see §7), but cut other errors, as illustrated in the figure. Lastly, note that `consume` implementations must represent missing-resource errors as abort errors. To see why, consider the function `do_nothing() { skip; return null }` and the (nonsensical but valid) specification `[5 ↦ 0] do_nothing() [ok : 5 ↦ 0 * ret = null]`. Of course, in the concrete semantics, calling the function will never result in a miss. Now, say the symbolic engine calls the function using the provided function specification. If the the resource of the pre-condition is not available in the current symbolic heap, then the consumption of the pre-condition will fail. Because no concrete execution of the function results in a miss, it would be unsound for the consumption to report a missing-resource error in this case.

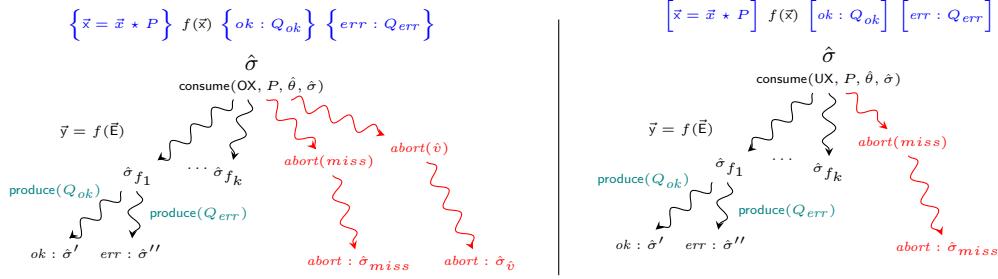

Figure 6 Branching in OX and UX function calls.

Predicate Rules. To handle the folding and unfolding of predicates in symbolic states, we extend the language syntax with the following two ghost commands (also known as tactic commands): $C \in \text{Cmd} ::= \dots \mid \text{fold } p(\vec{E}) \mid \text{unfold } p(\vec{E})$, where $\vec{E} \in \text{PExp}$ specifies the values of the in-parameters of the predicate p . In the concrete semantics, these commands are no-ops, as they are ghost commands. The symbolic-semantics rules are similar to the function-call rule: in short, a fold of a predicate consumes the body of the predicate, learns the out-parameters of the predicate, and adds the predicate (with the specified in-parameters and learnt out-parameters) to the symbolic state; and an unfold of a predicate finds a corresponding predicate in the symbolic state, learns the out-parameters of the predicate, and produces the body of the predicate.

Soundness. Our CSE engine is sound: OX soundness, expectedly, has no restrictions on the predicates; UX soundness, on the other hand, allows only strictly exact predicates (i.e., predicates whose bodies are satisfiable by at most one heap [33]) to be folded to ensure that no information is dropped.

► **Theorem 3** (Compositional OX and UX soundness). *If all UX predicate foldings are limited to strictly exact predicates, then the following hold:*

$$\begin{aligned} &\models (\gamma, \Gamma) \wedge \hat{\sigma}, C \Downarrow_{\Gamma}^{OX} \hat{\Sigma}' \wedge \text{abort} \notin \hat{\Sigma}' \wedge \varepsilon, \sigma \models \hat{\sigma} \wedge \sigma, C \Downarrow_{\gamma} o : \sigma' \implies \\ &\quad \exists \hat{\sigma}', \varepsilon' \geq \varepsilon. (o, \hat{\sigma}') \in \hat{\Sigma}' \wedge \varepsilon', \sigma' \models \hat{\sigma}' \\ &\models (\gamma, \Gamma) \wedge \hat{\sigma}, C \Downarrow_{\Gamma}^{UX} o : \hat{\sigma}' \wedge \varepsilon, \sigma' \models \hat{\sigma}' \implies \exists \sigma. \varepsilon, \sigma \models \hat{\sigma} \wedge \sigma, C \Downarrow_{\gamma} o : \sigma' \end{aligned}$$

Proof. Proofs of rules not related to function calls and predicates are the same as for Thm. 1. OX soundness of function call follows from soundness of `consume` (Prop. 4), OX completeness of `consume` (Prop. 5), and completeness of `produce` (Prop. 7). UX soundness of function call follows from the soundness of `consume` and `produce` (Prop. 4) and UX completeness of `consume` (Prop. 6). Full details are given in the extended version of this paper [18]. ◀

6 Consume and Produce Implementations

We provide implementations for the `consume` and `produce` operations and prove that they satisfy the properties 1–7 of the axiomatic interface (§5.2). We give the complete set of rules implementing these operations in the extended version [18] and only discuss the interesting rules here. Our implementations are inspired by the Gillian OX implementations, although previous work has only given a brief informal sketch of these implementations [10].

6.1 Implementations

Consume Implementation. As is typical for SL-based analysis tools, our *consume* operation works with a fragment of the assertions with no implications, disjunctions, or existentials (which are handled outside consumption, see, e.g., the function-call rule); which means that input assertions for consumption are \star -separated lists of simple assertions. Following the implementation of Gillian, our *consume* operation works by consuming one simple assertion at a time and is split into two phases, a planning phase and a consumption phase:

$$\text{consume}(m, P, \hat{\theta}, \hat{\sigma}) \triangleq \text{let } mp = \text{plan}(\text{dom}(\hat{\theta}), P) \text{ in } \text{consume}_{\text{MP}}(m, mp, \hat{\theta}, \hat{\sigma})$$

Here our interest lies in the consumption phase: the planning phase of Gillian has been formalised and discussed by Lööw et al. [19]. We, however, repeat the necessary background of the planning phase here to keep this paper self-contained.

Consumption Planning. The *plan* operation has two responsibilities: to resolve the order of consumption and the unknown variables. The operation takes a set of known logical variables (above, $\text{dom}(\hat{\theta})$) and an assertion P to plan and returns a *matching plan* (*MP*) of the form $[(\text{Asrt}, [(\text{LVar}, \text{LExp})])]$. An MP for an assertion $P = P_1 \star \dots \star P_n$ ensures that (1) the simple assertions P_i of P are consumed in an order such that the *in-parameters* (*ins*) of each simple assertion, i.e., the parameters (logical variables) that must be known to consume the simple assertion, have been learnt during previous consumption; (2) specifies how *out-parameters* (*outs*) are learnt during consumption, i.e., the remaining parameters (logical variables). For instance, the in-parameter of the cell-assertion $x \mapsto z + 1$ is x and the out-parameter is z , where the value of z can be learnt by inspecting the heap and subtracting 1. Another example is given by the pure assertion $x + 1 = y + 3$: here, what the in- and out-parameters are depend on what variables are known, e.g., if we know x we can learn y and vice versa.

► **Example 4.** Say we are to plan the assertion $x \leq 10 \star x \mapsto y \star y = z - 10$ knowing that $\hat{\theta} = \{\hat{x}/x\}$, that is, x is known but y and z are not. One MP for this assertion is $[(x \leq 10, []), (x \mapsto y, [(y, O)]), (y = z - 10, [(z, y + 10)])]$, where O is used to refer to the value of the consumed heap cell. First, by consuming $x \leq 10$ we learn nothing (x is already known); second, when consuming $x \mapsto y$ we learn y (from the consumed heap cell); third, since we learn y in the previous step, we can learn z by manipulating the assertion to $z = y + 10$. Another MP is $[(x \mapsto y, [(y, O)]), (x \leq 10, []), (y = z - 10, [(z, y + 10)])]$. Note that there is no MP starting with assertion $y = z - 10$, because y and z are not known initially.

Consuming Assertions. Having discussed the planning phase, we now discuss how pure assertions, cell assertions, and predicate assertions are consumed.

Consuming Pure Assertions. Fig. 7 contains the $\text{consume}_{\text{MP}}$ rules for consuming pure assertions. The rules are defined in terms of the helper operation $\text{consPure}(m, \hat{\pi}, \hat{\pi}') = \hat{\pi}'' \mid \text{abort}$ which depends on the current reasoning mode m :

- (i) for $m = \text{OX}$, we check $\neg \text{SAT}(\hat{\pi} \wedge \neg \hat{\pi}')$ which is equivalent to $\hat{\pi} \Rightarrow \hat{\pi}'$, hence, the SAT check corresponds to the entailment check seen in traditional OX reasoning;
- (ii) for $m = \text{OX}$, if $\text{SAT}(\hat{\pi} \wedge \neg \hat{\pi}')$, that is, $\neg(\hat{\pi} \Rightarrow \hat{\pi}')$, consumption, of course, must abort;
- (iii) for $m = \text{UX}$, consPure instead cuts all paths of $\hat{\pi}$ that are not compatible with the input pure assertion $\hat{\pi}'$, i.e., forms $\hat{\pi} \wedge \hat{\pi}'$, and then checks if there are any paths left after the cut, i.e., checks $\text{SAT}(\hat{\pi} \wedge \hat{\pi}')$.

$$\begin{aligned}
 \text{consPure}(m, \hat{\pi}, \hat{\pi}') = & \\
 \begin{cases} \hat{\pi} \wedge \hat{\pi}', & \text{if } m = \text{UX and } \text{SAT}(\hat{\pi} \wedge \hat{\pi}') \\ \hat{\pi}, & \text{if } m = \text{OX and } \neg \text{SAT}(\hat{\pi} \wedge \neg \hat{\pi}') \\ \text{abort}, & \text{if } m = \text{OX and } \text{SAT}(\hat{\pi} \wedge \neg \hat{\pi}') \end{cases} &

 \end{aligned}$$

■ **Figure 8** Rules for `consCell` and `consumeMP` (excerpt), where $\hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi})$.

► **Example 5.** To exemplify the difference between OX and UX consume, consider calling a function `foo(y)` with the precondition $y = y \star y \geq 0$. The first step of calling a function using its function specification is to consume its precondition, which we now illustrate. Say we are in a symbolic state with path condition $\hat{\pi} = \hat{v} > 5$ and are calling the function with an argument that symbolically evaluates to \hat{v} , i.e., we know $\hat{\theta}(y) = \hat{v}$. In OX mode, the function call aborts: `consumeMP`'s pure consumption error rule is applicable because $\text{consPure(OX, } \hat{\pi}, \hat{\theta}(y) \geq 10) = \text{abort}$ since $\text{SAT}(\hat{\pi} \wedge \neg(\hat{v} \geq 10))$. Intuitively, this means that not all paths described by $\hat{\pi}$ are described by $y \geq 10$, i.e., we are “outside” the precondition of the function. Differently, in UX mode, a call to `consPure(UX, } \hat{\pi}, \hat{\theta}(y) \geq 10)` cuts the incompatible paths by strengthen the path condition to $\hat{\pi} \wedge \hat{v} \geq 10$. That is, instead of as in OX mode where execution must abort, in UX mode the execution can continue.

Consuming Cell Assertions. Fig. 8 contains some of the `consumeMP` rules for consuming a cell assertion. The rules are defined using the helper operation $\text{consCell}(\hat{v}, \hat{\sigma}) \rightsquigarrow (\hat{v}', \hat{\sigma}') \mid \text{abort}$, which tries to consume the cell at address \hat{v} in mode m by branching over all possible addresses in the heap, returning the corresponding value in the heap, \hat{v}' , and the rest of the state, $\hat{\sigma}'$, and returns *abort* if it is possible for the address \hat{v} to point outside of heap. In the successful `consumeMP` rule (featured in Fig. 8), the operation `consPure` is used to consume the contents of the matched cells. The erroneous `consumeMP` rules are available in [18].

Consuming Predicate Assertions. The `consumeMP` rules for predicate assertions are generalisations of the rules for cell assertions, with two main differences: predicates may have multiple *ins* and *outs* whereas cells have a single *in* and single *out*, and predicate assertions refers to symbolic predicates whereas cell assertions refer to the symbolic heap.

$$\begin{array}{c}
 \frac{\hat{h}' \triangleq \hat{h} \uplus \{\hat{l} \mapsto \hat{v}_\emptyset\} \quad \hat{\pi}' \triangleq \hat{\pi} \wedge \hat{l} \notin \text{dom}(\hat{h}) \quad \text{SAT}(\hat{\pi}') \quad \hat{\sigma}' \triangleq \hat{\sigma}[\text{heap} := \hat{h}', \text{pc} := \hat{\pi}']}{\text{prodCell}(\hat{l}, \hat{v}_\emptyset, \hat{\sigma}) = \hat{\sigma}'} \quad \frac{P \text{ pure} \quad \hat{\pi}' \triangleq \hat{\pi} \wedge \hat{\theta}(P) \quad \text{SAT}(\hat{\pi}') \quad \hat{\sigma}' \triangleq \hat{\sigma}[\text{pc} := \hat{\pi}']}{\text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}'} \quad \frac{\hat{\pi}' \triangleq \hat{\pi} \wedge \hat{\theta}(E_a) \in \text{Nat} \wedge \hat{\theta}(E_v) \in \text{Val} \quad \text{prodCell}(\hat{\theta}(E_a), \hat{\theta}(E_v), \hat{\sigma}[\text{pc} := \hat{\pi}']) = \hat{\sigma}'}{\text{produce}(E_a \mapsto E_v, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}'}
 \end{array}$$

Figure 9 Rules for `prodCell` and `produce` (excerpt), where $\hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi})$ and \hat{v}_\emptyset denotes a symbolic value or \emptyset .

Produce Implementation. The implementation of $\text{produce}(Q, \hat{\theta}, \hat{\sigma})$ is straightforward: it extends $\hat{\sigma}$ with the symbolic state corresponding to Q given $\hat{\theta}$, ensuring well-formedness. Unlike `consume`, `produce` does not require planning and is not dependent on the mode of execution. An excerpt of rules for `produce` is given in Fig. 9. Like `consume`, `produce` does not support assertion-level implications, which are usually not found in function specifications or predicate definitions. However, `produce`, unlike `consume`, supports assertion-level disjunctions since the function specification we synthesise using bi-abduction contains disjunctions (cf. §8).

6.2 Correctness of Implementations

The correctness of the `consume` and `produce` implementations amount to showing that they satisfy properties of the axiomatic interface for `consume` and `produce`.

► **Theorem 6** (Correctness). *The `consume` and `produce` operations satisfy properties 1-7 (§5.2).*

7 Bi-abduction

To enable hosting Pulse-style true bug-finding on top of our CSE engine, it must support UX bi-abduction. In this section, we show how the engine presented in §5 can be extended to support UX bi-abduction by catching missing-resource errors that happen during execution and applying *fixes* to enable uninterrupted execution instead of faulting. These fixes, stored in an *anti-frame*, add the missing resource to the current state and allow execution to continue. This style of bi-abduction was introduced in the OX setting by JaVert 2.0 [10]. Here we show that it can also be applied to the UX setting. We focus on UX bi-abduction for true bug-finding, but also discuss in §8 how the obtained UX results can be used in an OX setting.

We introduce the judgement for the bi-abductive symbolic engine, $\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}', \hat{H})$, with outcomes $o ::= ok \mid err$, and the anti-frame $\hat{H} = (\hat{h}, \hat{P})$ containing the anti-heap \hat{h} and the anti-predicates \hat{P} . We do not need *miss* or *abort* as possible outcomes since if they happen during execution they will be either fixed by bi-abduction or cut if not. The new judgement is defined in terms of the judgement $\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{UX}} o : \hat{\sigma}'$ and a partial function `fix` as:

$$\begin{array}{c}
 \text{BIAB} \\
 \frac{\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{UX}} o : \hat{\sigma}' \quad \text{not_Seq}(C) \quad o \notin \{miss, abort\}}{\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}', (\emptyset, \emptyset))} \quad \text{BIAB-MISS} \\
 \frac{\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{UX}} o : \hat{\sigma}' \quad \text{not_Seq}(C) \quad o \in \{miss, abort\} \quad \text{fix}(\hat{\sigma}') = (\hat{H}, \hat{\pi}) \quad \hat{\sigma} \cdot (\hat{H}, \hat{\pi}), C \Downarrow_{\Gamma}^{\text{bi}} o' : (\hat{\sigma}'', \hat{H}')} {\hat{\sigma}, C \Downarrow_{\Gamma}^{\text{bi}} o' : (\hat{\sigma}'', \hat{H} \cup \hat{H}')}
 \end{array}$$

$$\begin{array}{c}
 \text{BIAB-SEQ-ERR} \\
 \frac{\hat{\sigma}, C_1 \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}', \hat{H}) \quad o \neq ok}{\hat{\sigma}, C_1; C_2 \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}', \hat{H})}
 \end{array}
 \quad
 \begin{array}{c}
 \text{BIAB-SEQ} \\
 \frac{\hat{\sigma}, C_1 \Downarrow_{\Gamma}^{\text{bi}} ok : (\hat{\sigma}', \hat{H}_1) \quad \hat{\sigma}', C_2 \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}'', \hat{H}_2) \quad \text{sv}(\text{dom}(\hat{H}_2)) \cap (\text{sv}(\hat{\sigma}') \setminus \text{sv}(\hat{\sigma})) = \emptyset}{\hat{\sigma}, C_1; C_2 \Downarrow_{\Gamma}^{\text{bi}} o : (\hat{\sigma}'', \hat{H}_1 \cup \hat{H}_2)}
 \end{array}$$

where `not_Seq(C)` denotes that C is not a sequence command (i.e., does not have the form $C_1; C_2$), $\hat{\sigma} \cdot (\hat{H}, \hat{\pi})$ denotes $\hat{\sigma} \cdot (\emptyset, \hat{H}, \hat{\pi} \wedge \mathcal{Wfc}(\hat{H}))$, $\text{dom}(\hat{H}_2) = \text{sv}(\text{dom}(\hat{h}_2)) \cup \text{sv}(\text{dom}(\hat{P}_2))$, and $\text{dom}(\hat{P})$ denotes all symbolic variables of the `ins` of the predicates in \hat{P} . The rule BIAB states that for non-erroneous outcomes, the bi-abductive engine has the same semantics as the underlying UX engine it is built on top of. The rule BIAB-MISS, which is the most interesting rule, catches missing-resource errors from the underlying UX engine and uses the `fix` function to add the missing resource to the current symbolic state and anti-frame, such that execution can continue. The two rules BIAB-SEQ-ERR and BIAB-SEQ are two straightforward sequencing rules for the engine, where the symbolic-variable condition of BIAB-SEQ ensures that the anti-frame \hat{H}_2 does not clash with resource allocated by C_1 .

To exemplify, say the engine is in symbolic state $(\{v \mapsto 0, a \mapsto 13\}, (\emptyset, \emptyset), \text{true})$ and is about execute $v := [a]$, i.e., about to retrieve the value of the heap cell with address a . Since this cell is not in the heap, the rule LOOKUP-ERR-MISSING from Fig. 3 is applicable, which sets the variable `err` to `[“MissingCell”, “a”, 13]` and gives outcome `miss`. Now, in the rule BIAB-MISS, given the data in the `err` variable, the `fix` function constructs a fix $((\{13 \mapsto \hat{v}\}, \emptyset), \text{true})$ where \hat{v} is a fresh variable. The rule adds this fix to both the current symbolic state and the anti-frame, resulting in the symbolic state $(\{v \mapsto \hat{v}, a \mapsto 13\}, (\{13 \mapsto \hat{v}\}, \emptyset), \text{true})$ and outcome `ok`. Other cases are similar. E.g., when abort outcomes from `consume` represent missing resource (e.g., when invoked in a function call), `fix` returns the resources needed for the execution to continue. The following theorem captures the essence of bi-abduction:

► **Theorem 7** (CSE with Bi-Abduction: UX Soundness).

$$\hat{\sigma}, C \Downarrow_{\Gamma}^{bi} o : (\hat{\sigma}', \hat{H}) \implies \hat{\sigma} \cdot (\hat{H}, \text{true}), C \Downarrow_{\Gamma}^{UX} o : \hat{\sigma}'$$

8 Analysis Applications

We discuss the three analysis applications we have built on top of our unified CSE engine, to demonstrate its wide applicability: EX whole-program automatic symbolic testing (§8.1); OX semi-automatic verification (§8.2); and UX automatic true bug-finding (§8.3).

We have gathered these three analyses from different corners of the literature. EX symbolic testing is well understood in the first-order symbolic execution literature. OX verification is well understood in the consume-produce symbolic execution literature. However, one novelty here is that the correctness proof of the analysis is established with respect to our axiomatic interface rather than the consume/produce operations directly, allowing us to show that function specifications are valid w.r.t. the standard SL definition of validity. In contrast to the other two analyses, UX bug-finding has not previously been implemented in consume-produce style, making this a novel contribution. To simplify the presentation, we consider only non-recursive functions. All applications can be extended to handle bounded recursion by adding a fuel parameter. Unbounded recursion can be handled in verification via user-provided annotations, but is not a good fit for automatic bug-finding.

8.1 EX Whole-program Symbolic Testing

Our EX core engine allows us to implement simple non-compositional analyses, such as whole-program symbolic testing, in the style of CBMC [16] and Gillian [11]. For this analysis, we augment the input language with three additional commands: `x := sym`, for creating symbolic variables; `assume(E)`, for imposing a constraint E on the current state; and `assert(E)`, for checking that E is true in the current state. The operational semantics for these commands is given in the extended version of this paper [18].

The testing algorithm is as follows. Given a command C and implementation context γ , the analysis starts from the state $\hat{\sigma} \triangleq (\{x \mapsto \text{null} \mid x \in \text{pv}(C)\}, \emptyset, \text{true})$, and executes C to completion. The analysis reports back any violations of the `assert` commands encountered during execution. Given the core engine is UX sound, any bug found will be a true bug. Moreover, if the analysed code contains no unbounded recursion, given the core engine is OX sound, all existing bugs will be found modulo the ability of the underlying SMT solver.

8.2 OX Verification

We formalise an OX verification procedure, `verifyOX`, on top of our CSE engine. Given a specification context Γ , a function $f(\vec{x}) \{ C; \text{return } E \}$ with $f \notin \text{dom}(\Gamma)$, and an OX specification $t_f = \{\vec{x} = \vec{x} \star P\} \{ok : Q_{ok}\} \{err : Q_{err}\}$, if $\text{verifyOX}(\Gamma, f, t_f)$ terminates successfully, then we can soundly extend Γ to $\Gamma' = \Gamma[f \mapsto t_f]$. The algorithm is given below:

1. Let $\hat{\theta} \triangleq \{\hat{x}/x \mid x \in \text{lv}(\vec{x} = \vec{x} \star P)\}$, $\hat{s} \triangleq \{x \mapsto \hat{x} \mid x \in \vec{x}\} \cup \{x \mapsto \text{null} \mid x \in \text{pv}(C) \setminus \vec{x}\}$, and $\hat{\sigma} = (\hat{s}, \emptyset, \text{true})$.
2. Set up symbolic state corresponding to pre-condition: $\text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}'$.
3. Execute the function to completion: $\hat{\sigma}', C; \text{ret} := E \Downarrow_{\Gamma}^{\text{OX}} \hat{\Sigma}'$. Then, for every $(o, \hat{\sigma}'') \in \hat{\Sigma}'$:
 - (a) If $o = \text{miss}$ or $o = \text{abort}$, abort with an error.
 - (b) If $o = ok$, then let $\hat{\theta}' = \hat{\theta} \uplus \{(\hat{\sigma}''.\text{sto})(\text{ret})/r\}$ for a fresh r and let $Q' = Q_{ok}\{r/\text{ret}\}$. Otherwise, $o = err$, in which case let $\hat{\theta}' = \hat{\theta}$ and $Q' = Q_{err}$.
 - (c) Consume the post-condition: $\text{consume(OX, } Q'', \hat{\theta}', \hat{\sigma}'') \rightsquigarrow (\hat{\theta}'', \hat{\sigma}''')$, where $Q' = \exists \vec{y}. Q''$.
 - (d) If consumption fails or the final heap is not empty, abort with an error.⁵

8.3 UX Specification Synthesis and True Bug-finding

Recall that Pulse-style UX bug-finding is powered by UX specification synthesis, where, after appropriate filtering, synthesised erroneous specification can be reported as bugs. UX specification synthesis, in turn, is powered by UX bi-abduction (as introduced in §7).

To formalise the specification synthesis procedure, we first define the `toAsrt` function, which takes a symbolic state $\hat{\sigma} = (\hat{s}, \hat{H}, \hat{\pi})$, where $\hat{H} = (\hat{h}, \hat{P})$, and returns the corresponding assertion. The function is simple to implement: \hat{s} becomes a series of equalities, \hat{h} becomes a series of cell assertions, \hat{P} are lifted to predicate assertions and $\hat{\pi}$ is lifted to a pure assertion. Using `toAsrt`, we can also transform multiple symbolic states into an assertion by transforming them individually and gluing together the obtained assertions using disjunction.

We generate UX function specifications using the `synthesise` (Γ, f, P) algorithm, which takes a specification context Γ , a function $f(\vec{x}) \{ C; \text{return } E \}$ and its candidate pre-condition, $\vec{x} = \vec{x} \star P$, and uses bi-abduction to generate a set of UX specifications describing the behaviour of f starting from P . As $P = \text{emp}$ is a valid starting point, `synthesise` can be applied to any function without a priori knowledge. The `synthesise` algorithm is as follows:

1. Let $\hat{\theta} \triangleq \{\hat{x}/x \mid x \in \text{lv}(\vec{x} = \vec{x} \star P)\}$, $\hat{s} \triangleq \{x \mapsto \hat{x} \mid x \in \vec{x}\} \cup \{x \mapsto \text{null} \mid x \in \text{pv}(C) \setminus \vec{x}\}$, and $\hat{\sigma} = (\hat{s}, \emptyset, \text{true})$.
2. Add the symbolic representation of P to $\hat{\sigma}$: $\text{produce}(P, \hat{\theta}, \hat{\sigma}) \rightsquigarrow \hat{\sigma}'$
3. Execute the function, obtaining a set of traces: $\hat{\sigma}', C, \text{ret} := E \Downarrow_{\Gamma}^{\text{bi}} \{(o_i, (\hat{\sigma}'_i, \hat{H}_i)) \mid i \in I\}$.
4. Then, for every obtained $(o_i, ((\hat{s}'_i, \hat{H}'_i, \hat{\pi}'_i), \hat{H}_i))$:
 - a. Complete the candidate pre-condition: $P_i \triangleq P \star \text{toAsrt}((\emptyset, \hat{H}_i, \text{true}))$.

⁵ This check is required due to our classical (linear) treatment of resource, appropriate for languages with explicit deallocation rather than garbage collection.

- b. Restrict the final store to the return/error variable: $\hat{s}_i'' \triangleq \hat{s}_i'|_{\{x\}}$, where $x = \text{ret}$ if $o_i = \text{ok}$ and $x = \text{err}$ otherwise.
- c. Create the post-condition: $Q_i \triangleq \text{toAsrt}(\hat{s}_i'', \hat{H}_i', \hat{\pi}_i')$.
- d. Return $[P_i] f(\vec{x}) [o_i : \exists \vec{y}. Q_i]$, where $\vec{y} \triangleq \text{lv}(Q_i) \setminus \text{lv}(P_i)$.

► **Theorem 8** (Correctness of synthesise).

$$[P'] f(\vec{x}) [o : \exists \vec{y}. Q] \in \text{synthesise}(\Gamma, f, P) \implies \Gamma \models [P'] f(\vec{x}) [o : \exists \vec{y}. Q]$$

► **Remark 9.** Step 4b corresponds to forgetting the local variables when moving from internal to external post-condition since symbolic states only have program variables in the store.

► **Remark 10.** Front-end heuristics to filter out “interesting” bugs, i.e., synthesised erroneous specification, can be easily implemented on top of our bi-abduction (e.g., filtering for manifest bugs as per Lee et al. [17]); for this paper, however, we are foremost interested in back-end engine development and therefore consider such front-end issues out of scope.

► **Remark 11.** Specifications with the same anti-frame can be coalesced into one via disjunction of their post-conditions. Moreover, if a specification does not branch on symbolic variables created by the execution of C , the pure part of the post-condition can be lifted to the precondition to create an EX specification [20], which can then be used both in OX verification and UX true bug-finding.

► **Remark 12.** Automatic predicate folding and unfolding may be required in some cases to prevent redundant fixes: e.g., if $y := g(); x := [y]$ and g has post-condition $\text{list}(\text{ret}, vs)$, the list predicate should be unfolded for the lookup to access the first value in the list. Gillian has heuristics-based automatic folding and unfolding, but we leave its description and the evaluation of its compatibility with bi-abduction for future work. Without automatic folding and unfolding, code must not break the interface barrier of the data structures it uses.

9 Evaluation

We have evaluated our CSE engine in the following two practical ways.

9.1 Companion Haskell Implementation

With our engine formalism, we have developed a companion Haskell implementation to demonstrate that the formalism is implementable (and to catch errors early by executing simple examples). The Haskell implementation follows the inference rules of $\hat{\sigma}, C \Downarrow_{\Gamma}^m o : \hat{\sigma}'$ given in §5, and the specific `consume` and `produce` operations in §6. We have implemented the search through the inference rules inside a symbolic execution monad, similar to other monads in the literature [7, 22]; the monad handles, e.g., demonic non-determinism (branching), angelic non-determinism (backtracking), per-branch state and global state.

9.2 Gillian OX and UX Compositional Analysis Platform

Our unified CSE engine took direct inspiration from the Gillian compositional OX platform. Using the ideas presented here, we returned to Gillian and adapted its CSE engine to handle both SL and ISL function specifications with real-world consume-produce implementations. Leveraging the identified difference between OX and UX reasoning, we were able to introduce UX reasoning to Gillian by adding, in essence, a OX/UX flag to the corresponding function. As these changes were isolated, existing analyses implemented in Gillian remain unaffected, including Gillian’s whole-program symbolic testing, previously evaluated on the Collections-C library [11], and Gillian’s compositional OX verification, previously evaluated on AWS

Table 1 Aggregated results of synthesising function specifications for the Collections-C library (commit 584e113). Results were obtained by setting the loop and recursive call unrolling limit to 3, on a MacBook Pro 2019 laptop with 16 GB memory and a 2.3 GHz Intel Core i9 CPU.

code [21]. In addition, we have implemented UX bi-abduction in Gillian, following the fixes-from-errors approach presented in §7, where functions are evaluated bottom-up along the call graph and previously generated specifications are used at call sites.

To evaluate Gillian’s new support for UX reasoning, we have tested its new UX bi-abduction analysis on real-world code, specifically, the Collections-C [25] data-structure library for C. As discussed in §8, specification synthesis using UX bi-abduction constitutes the back-end of Pulse-style bug-finding and is its most time-consuming part. The Collections-C library has 2.6K stars on GitHub and approximately 5.2K lines of code, and it uses many C constructs and idioms such as structures and pointer arithmetic. The data structures it provides include, e.g., dynamic arrays, linked lists, and hash tables. To carry out the evaluation, we extended previous work where the Gillian platform has been instantiated to the C programming language, called Gillian-C. Tbl. 1 presents the results of our new UX bi-abduction analysis, grouped by the data structures of the library: the numbers of associated functions; number of corresponding GIL instructions (GIL is the intermediate language used by Gillian); the number of success and error specifications; and the analysis time. Since one specification is synthesised per execution path, the number of specifications reflect the number of execution paths the Gillian engine was able to construct using bi-abduction. In summary, Gillian-C synthesises specifications for 364 functions of the Collections-C library, producing 5693 specifications in 66.92 seconds. We believe the results are promising both in terms of performance and number of specifications synthesised. One anomaly is that 58% of the execution time is spent on 3 of the 343 functions, leading to the creation of 1640 specifications. This anomaly arises because of the memory model currently in use by Gillian-C and not from a limitation of our formalisation or of the Gillian engine. More detailed analysis and a selection of generated specifications are available in [18].

10 Related Work

First-order Compositional Symbolic Execution. Static symbolic execution tools and frameworks based on first-order logic, such as CBMC [16] and Rosette [32, 27], can be made functionally compositional with respect to the variable store but not with respect to arbitrary state because they are not able to specify functions that manipulate memory in a way that would make the reasoning scalable.

Compositional Symbolic Execution. We work with a CSE engine with consume and produce operations, as found in, e.g., the OX tools VeriFast [14], Viper [23], and Gillian [11, 21]. In contrast, an alternative approach is to describe CSE inside a separation logic using proof search, as found in, e.g., Smallfoot [2, 3], Infer [4], and Infer-Pulse [17].

Here, we focus on formalising a CSE engine with consumers and producers, which more accurately models tool implementations. All the current consume-produce tools are based on OX reasoning. Some have detailed work on formalisation: Featherweight VeriFast [15] provides a Coq mechanisation inspired by VeriFast; Schwerhoff’s PhD thesis [30] and Zimmerman et al. [35] provide detailed accounts of Viper’s symbolic execution backend. Previous work has not, like us, introduced an axiomatic interface for their consume and produce operations. Because of the interface, our results are established using function specifications whose meaning is defined in standard SL/ISL-style, in particular, using the standard satisfaction relation for assertions defined independent of the choice of our CSE engine. This means that we can use specifications developed outside of our engine, e.g., using theorem provers, and vice versa. In contrast, the work on Featherweight VeriFast does not define an assertion satisfaction relation independent of their consume and produce operations. Schwerhoff does not give a soundness theorem at all. Lastly, Zimmerman et al. give a standard satisfaction relation (for implicit dynamic frames [31], a variant of SL [26]) but only embed this relation inside their concrete semantics instead of working with the standard definitions of function specifications (see Fig. 11 of their paper). Finally, we have demonstrated that our engine semantics provides a common foundation for OX and UX reasoning, with the difference in the underlying engine only amounting to the choice to use satisfiability or validity. This allows a straightforward extension of Gillian to support UX reasoning.

Bi-abduction. Bi-abduction was originally introduced for OX reasoning [5, 6] and led to Meta’s automatic Infer tool for bug-finding [4]. Recently, it was reworked for UX reasoning and led to Meta’s Infer-Pulse for true bug-finding [28, 17]. In these works, compositional symbolic execution is formalised using proof search, in the style of the Smallfoot description of symbolic execution [2, 3], with bi-abduction embedded into that proof search. In contrast, our UX bi-abduction is formulated as a separate layer on top of our CSE engine, establishing fixes from missing-resource errors using an idea introduced for OX bi-abduction by JaVerT 2.0 [10].

Alternating between OX and UX Reasoning. Smash by Godefroid et al. [13] is the most well-known tool to combine OX and UX reasoning. It is a first-order tool which “alternates” between OX and UX reasoning to speed up the program analysis implemented by the tool. However, citing Le et al. [17], who in turn report on personal communication with Godefroid, Smash-style analyses seem to have faced obstacles when put into practice in that they were “used in production at Microsoft, but are not used by default widely in their deployments, because other techniques were found which were better for fighting path explosion.” Our CSE engine, in contrast, has a completely different motivation in that its purpose is to host different types of OX and UX analyses.

Program Correctness and Incorrectness. We know of two program logics that work with both program correctness and incorrectness. Exact separation logic (ESL) [20] combines the guarantees of both SL and ISL, providing exact function specifications compatible with both OX verification and UX true bug-finding. Exact specifications are compatible with our CSE engine, e.g., in UX mode the engine can call exact unbounded function specifications of list algorithms and still preserve true bug-finding. Outcome logic (OL) [34] is based on OX

Hoare logic with a different approach to handling incorrectness based on the reachability of sets of states. No tool is currently based on OL; in the future, we hope to be able to extend straightforwardly our unified approach to incorporate OL.

11 Conclusions

We have introduced a compositional symbolic execution engine capable of creating and using function specifications arising from an underlying separation logic. Our engine is formally defined using a novel axiomatic interface which ensures a sound link between the execution engine and the function specifications using consume and produce operations. Thus, our engine creates function specifications usable by other tools, and uses function specifications from various sources, including theorem provers and pen-and-paper proofs. Additionally, we have captured the essence of the Gillian consume and produce implementations both operationally, using inference rules, and via an accompanying Haskell implementation, and shown that our operational description satisfies the properties of the axiomatic interface. In this way, we offer a degree of assurance that the real-world, heavily-optimised Gillian implementation is correct.

A surprising property of our semantics is that it provides a common foundation for both OX reasoning based on SL, and UX reasoning based on ISL. By leveraging the minimal differences between the OX and UX engines, we have extended the OX Gillian platform to support UX reasoning. This extension includes function specifications underpinned by ISL, enabling automatic true bug-finding using UX bi-abduction which our engine incorporates by creating fixes from missing-resource errors. We evaluate our extension using the Gillian instantiation to C, the first real-world tool to support both compositional correctness and incorrectness reasoning, grounded on a common formal compositional symbolic execution engine. Our instantiation preserves the previous OX verification evaluated on AWS code [21] and now automatically synthesises UX function specifications for the real-world Collections-C library using our UX bi-abduction technique.

We believe that our axiomatic interface and formalisation of UX bi-abduction serve as re-usable techniques, which we hope will provide valuable guidance for the implementation of the next-generation compositional symbolic execution engines.

Abstract

The use of function specifications to reason about function calls and the manipulation of user-defined predicates are two essential ingredients of modern compositional verification tools based on separation logic. To execute these operations successfully, these tools must be able to solve the frame inference problem, that is, to understand which parts of the state are relevant for the operation at hand. We introduce *matching plans*, a concept that is used in the Gillian verification platform to automate frame inference efficiently. We extract matching plans and their automation machinery from the Gillian implementation and present them in a tool-agnostic way, making the Gillian approach available to the broader verification community as a verification-tool design pattern.

2012 ACM Subject Classification Theory of computation → Logic and verification; Theory of computation → Separation logic; Theory of computation → Automated reasoning

Keywords and phrases Compositional reasoning, separation logic, frame inference

Funding This work was supported by the EPSRC Fellowship “VetSpec: Verified Trustworthy Software Specification” (EP/R034567/1).

Acknowledgements We would like to thank José Fragoso Santos, who conceived the idea of matching plans (which we formalise in this work) as part of the work on JaVerT [6] and did their original implementation in Gillian. We would also like to thank the anonymous reviewers for their comments.

1 Introduction

Separation logic [18, 21] has enabled the verification community to develop analyses and tools that are *compositional* in the sense that they are able to analyse parts of the program in isolation and reuse the obtained results in broader contexts. Currently, some of the most prominent such tools are VeriFast [7], Viper [16], Gillian [13], and CN [20]. These tools achieve compositionality by being able to use function specifications at call sites instead of executing function bodies. In addition, to be able to reason about data structures such as lists and trees, the tools include support for user-defined inductive predicates that describe these data structures. When using function specifications and manipulating predicates, the tools have to be able to solve the *frame inference problem* [3], that is, understand which part of the state is relevant for the operation that is being performed. The ability to handle this problem efficiently is essential for their scalability and usability.

As part of building tools for compositional analysis, it is up to the tool designers to choose how to tackle frame inference, and the implications of the associated decisions should be understood closely as they affect both the tool implementation and the user experience. For example, two important tool-design questions are: “Which specification language should the tool use?” and “Is there a particular style in which the specifications should be written?”. Expectedly, the approaches in the literature are many and varied (which we discuss further in §7).

In this paper, we present the approach of the Gillian verification tool to the frame inference problem and show how the choices made allow for *efficient and predictable automation*. The approach captures and automates the *assertion-adaptation workflow* that users must follow to facilitate frame inference when working with tools that offer less automation, such as VeriFast and Viper. In more detail, for the assertions of function specifications and predicate definitions, Gillian automatically constructs a *matching plan* (MP), which provides:

1. (*efficiency*) an ordering of the subcomponents of each assertion (technically: the simple assertions) that guarantees that the associated frame inference will not backtrack, together with a description of how all associated free and existentially quantified variables can be learnt; and
2. (*predictability*) a clean separation between the structural and computational portions of frame inference.

MPs and their construction have not been described in depth before; we formalise both in a tool-agnostic way, thereby making the Gillian approach available to the broader verification community as a verification-tool design pattern.

The paper is structured as follows. We first introduce MPs informally using examples and discuss the key insights in §2. We then establish the required preliminaries in §3 and introduce MPs formally in §4, focusing on a core illustrative fragment of MPs as implemented in Gillian. Next, in §5, we show how to extend the MPs of §4 with more complex features that are available in Gillian. Finally, we conclude by evaluating the scalability and performance of the MP-based automation of Gillian (§6) and giving a detailed comparison with related work (§7).

2 Overview

We give an informal overview of *matching plans* (MPs), the key new concept we introduce in this paper. We first introduce the required background, which is the *consume/produce engine architecture* utilised by modern compositional symbolic execution tools, including VeriFast, Viper, and Gillian. Then, with the background in place, we introduce MPs using examples.

2.1 Background: Symbolic Execution Based on Consume and Produce

We place ourselves in the setting of semi-automated compositional verification tools based on symbolic execution [1] and separation logic (SL) and are underpinned by SMT solvers. In this context, the frame inference problem amounts to, given an assertion and a symbolic state, understanding which part of the symbolic state corresponds to the assertion. In particular, we are interested in tools such as VeriFast, Viper, and Gillian, implemented using *consumers and producers*, which are spatial variants of the, possibly more familiar, assert and assume, respectively. To *consume/produce* an assertion is to remove/add the corresponding spatial state from/to the current symbolic state and to assert/assume the pure constraints of the assertion. Our presentation focuses on consumption, as production does not require performing frame inference, and is therefore not of immediate interest. The two main use cases for frame inference in our setting are the following:

Use of function specifications to reason about function calls. Given a function specification $\{P\} f(\vec{x}) \{Q\}$, the verification tool *consumes* the part of the symbolic state that corresponds to the function pre-condition P (performing frame inference for P) and in its place *produces* a symbolic state that corresponds to the function post-condition Q .

Folding user-defined predicates. Given a predicate definition, folding a predicate consists of consuming the part of the symbolic state that corresponds to (a disjunct of) the definition and in its place producing the folded predicate, as discussed in more detail shortly.

Other use cases are similar. For example, reasoning about loops using loop invariants is largely similar to reasoning about function calls using function specifications.

2.2 Running Example: Folding a List Predicate

MPs help address two problems that arise during consumption and are related to frame inference: *the order of consumption* and *the learning of variables not given by context*, which we also refer to as *learning unknown variables*. We illustrate these problems using the example of folding the standard $\text{list}(x, vs)$ predicate that describes a singly-linked list starting at address x and carrying values vs . It is defined as follows, using standard SL notation, where “ \star ” denotes the separating conjunction and “ \mapsto ” denotes the cell assertion:

$$\begin{aligned} \text{list}(x, vs) \triangleq & (x = \text{null} \star vs = []) \vee \\ & (\exists v, x', vs'. x \mapsto v \star x + 1 \mapsto x' \star \text{list}(x', vs') \star vs = v : vs') \end{aligned}$$

This predicate has two disjuncts. The first disjunct states that the list is empty ($x = \text{null}$) and carries no values ($vs = []$). The second disjunct states that the list is non-empty, consisting of the list head node ($x \mapsto v \star x + 1 \mapsto x'$), which contains the node value, v , and the pointer to the next node, x' , and the tail of the list ($\text{list}(x', vs')$), while connecting the values appropriately ($vs = v : vs'$, meaning that vs is the result of prepending v to vs').

Let us now attempt to fold the predicate $\text{list}(x, vs)$ in the symbolic heap $\{1 \mapsto 1, 2 \mapsto 3, 3 \mapsto 2, 4 \mapsto \text{null}, 5 \mapsto 0, 6 \mapsto 1, 7 \mapsto 42\}$, knowing that $x = 5$.¹ As mentioned above, folding this list means performing frame inference by pinpointing a part of the symbolic state that corresponds to one of the predicate disjuncts. In consume/produce-based tools, this is done one *simple assertion* at a time, where an assertion is defined to be simple iff it does not contain the separating conjunction. Carving off the existential quantifiers, the first and second disjunct of the definition of $\text{list}(x, vs)$, respectively, have the following simple assertions:

$(\mathbf{A1}) \quad x = \text{null}$ $(\mathbf{A2}) \quad vs = []$	$(\mathbf{B1}) \quad x \mapsto v$ $(\mathbf{B2}) \quad x + 1 \mapsto x'$ $(\mathbf{B3}) \quad \text{list}(x', vs')$ $(\mathbf{B4}) \quad vs = v : vs'$
---	---

The first disjunct is relatively straightforward: to consume it means to check if it is possible for x to equal null and for vs to equal the empty list, which it is not since we know that $x = 5$. For the second disjunct, we additionally have to *learn* the values of the existentially quantified variables v , x' , and vs' . This can be more or less complex, depending on the *order* in which we process the assertions. For example, if we start with (B3), we will have to perform proof search, trying to guess the values of x' and vs' as they are not known, likely needing to backtrack and make different choices, which can be computationally expensive.

¹ For simplicity, in this example we describe symbolic heaps using cell assertions. In practice, one could choose to represent symbolic heaps differently for the purpose of, for example, efficient symbolic reasoning.

On the other hand, if we choose (B1) and (B2) first, given that we know $x = 5$, we could learn that $v = 0$ and $x' = 1$ trivially by inspecting the heap. From there, we can tackle (B3) by recursively folding the list $\text{list}(x', vs')$, ultimately learning $vs' = [1, 2]$, from which we can then process (B4), learning that $vs = [0, 1, 2]$. After having folded the predicate, the remaining frame is only the single heap cell $\{7 \mapsto 42\}$.

2.3 MPs for Predicate Folding and Function Calls

MPs provide a solution to the two problems illustrated in the previous section: given an assertion P , an MP for P provides an *ordering of the simple assertions of P* so that the consumption of P is guaranteed to not backtrack, as well as a *description of how free and existentially quantified variables of P can be learnt* during this consumption.

MPs are based on dividing parameters of assertions and predicates into *input parameters* (*ins*) and *output parameters* (*outs*). Intuitively, the *ins* of an assertion/predicate are the parameters that are sufficient to be provided so that the rest of the parameters, the *outs*, can be learned. For example, for the cell assertion $x \mapsto y$, if we know x we can learn y by looking it up in the heap: therefore, the *in* of the cell assertion is x and the *out* is y . For the $\text{list}(x, vs)$ predicate, on the other hand, the *in* is x and the *out* is vs .

Folding predicate example (running example). To give an example of an MP, consider again the second disjunct of the definition of the $\text{list}(x, vs)$ predicate:

$$x \mapsto v \star x + 1 \mapsto x' \star \text{list}(x', vs') \star vs = v : vs'$$

Assuming that only x is known before consumption, the MP for this disjunct is as follows (we give a formal definition of MPs in §4):

$$\begin{aligned} & [(x \mapsto v, [(v, O_1)]), \\ & (x + 1 \mapsto x', [(x', O_1)]), \\ & (\text{list}(x', vs'), [(vs', O_1)]), \\ & (vs = v : vs', [(vs, v : vs')])] \end{aligned}$$

which captures the following order of the simple assertions and ways of learning variables:

1. $x \mapsto v$ comes first, and from it we learn v as the cell assertion *out* by looking up the value corresponding to address x (which we know) in the heap, which is expressed using the placeholder variable O_1 ;
2. $x + 1 \mapsto x'$ comes next, and from it we learn x' again as the cell assertion *out*, noting that we know the assertion *in* $x + 1$ given that we know x ;
3. $\text{list}(x', vs')$ comes next, and from it we learn vs' as the predicate *out*, which can be done either by recursively folding as described above, or by matching against a predicate already existing in the symbolic state; and
4. $vs = v : vs'$ comes last, and from it we learn that vs equals $v : vs'$.

Function call example. We have exemplified MPs for folding predicate definitions. MPs are equally useful to handle function specifications. Creating an MP for a function specification amounts to creating an MP for the function pre-condition, which is effectively the same as creating an MP for a disjunct of a predicate. Interestingly, the use of *ins* and *outs* has as a consequence that MPs can be created only for function pre-conditions P in which all of the variables of P can be learnt if the function parameters are known. We have observed that this is not a restriction in practice, as the parameters are the only means that a function

can use to access or modify the state. In fact, a specification not obeying this property is likely either incorrect or contains resources not relevant for the function, which we can easily signal to the tool user.

2.4 MP-based Automation for Frame Inference

Gillian provides *predictable automation* for frame inference by providing machinery for automatically constructing MPs. This automation works by splitting the consumption process into two phases: a planning phase and a consumption phase – i.e., what we in the introduction of the paper referred to as “the structural and computational portions of frame inference” before having introduced consumption. An MP is automatically constructed in the planning phase. The consumption phase then follows the plan provided by the MP, which dictates consumption order and how variables are learnt. Because the planning phase is separate from the rest of consumption, planning is *predictable*. In particular, whereas the consumption phase relies on an unpredictable underlying SMT solver, the planning phase does not. The construction of MPs can therefore be understood (and, in particular, debugged) without having to take into consideration the more complicated consumption phase.

To compare Gillian with verification tools with no or little automation support for frame inference, e.g., the VeriFast tool: MPs can be said to capture the *assertion-adaptation workflow* tool users must follow when adapting assertions for such tools. Specifically, MPs capture this workflow by making clear the relationship between *ins* and *outs*. E.g., in VeriFast, the tool essentially requires that the MP can be directly “read off” assertions: the tool leaves it to the tool user to find both the consumption order and to “factor out” the *outs*, i.e., the parameters that will be learned during consumption given the *ins*. To exemplify, consider the simple assertion $x = 5$. Say x is unknown, an MP for this assertion can be directly read off the assertion: $[(x = 5, [(x, 5)])]$. Now, consider instead the simple assertion $y = x + z$ and say that y and z are known. An MP for this assertion is $[(y = x + z, [(x, y - z)])]$. In a tool without automation, the assertion would have to be adapted to $x = y - z$ such that how to learn the unknown variable x could be read off directly from the assertion. A slightly more complicated example is given by the simple assertion $x \mapsto x' + 1$ where x is known and x' is unknown. An MP for this assertion is $[(x \mapsto x' + 1, [(x', O_1 - 1)])]$, meaning that to adapt the assertion to a tool without automation, a user would have to introduce an intermediate variable as follows: $x \mapsto x'' \star x' = x'' - 1$. Similarly, in tools without automation, the consumption order must be specified by the user as well. E.g., in VeriFast assertions are consumed in left-to-right order. For example, consider the (contrived but simple) assertion $x > 5 \star x = 6$. Say that x is unknown, then there is no MP where $x > 5$ is consumed first, because x cannot be learnt from $x > 5$ without guessing. Instead, the only MP for the assertion is $[(x = 6, [(x, 6)]), (x > 5, [])]$. That is, without automation support, the user would have to switch the order of the simple assertions.

Gillian automates this workflow by automatically constructing MPs, thereby automating away assertion adaptations such as the adaptations exemplified above. Moreover, the automation helps in using assertions generated by other tools (which do not necessarily generate assertions in the style verification tools expect). In §4, we provide a formal description of a simple planning algorithm that is able to construct MPs for assertions with unknown variables embedded inside simple arithmetic expressions. This simple planning algorithm is the theoretical core of the MPs and the MP-based automation of Gillian. This simple core provides a foundation that can be extended in multiple directions. We discuss some of those extensions in §5, including an example of extending the learning algorithm to handle an instance of list-based learning, which originates from a large verification case study that has been carried out in Gillian where the automation eased the amount of assertion adaptation needed.

3 Preliminaries: Assertion Language

As mentioned in the introduction, we introduce the formal description of MPs in two steps. First, in §4, we formalise a simple version of MPs, which we call core MPs. Second, in §5, we discuss extensions of core MPs that widen their applicability. In this section, we formally define the simple assertion language we use to formalise core MPs. In particular, the simple assertion language we introduce here is for the simple memory model commonly used in theoretical investigations into separation logic. When we discuss extensions of core MPs in §5, we show that core MPs are easily extended to other memory models.

Given a set of logical variables $x, y, z, \dots \in \text{LVar}$, the syntax of our assertion language is as follows:

► **Definition 1** (Syntax of Assertions).

$$\begin{aligned} v \in \text{Val} &\triangleq n \in \text{Int} \mid b \in \text{Bool} \mid \text{null} \mid [\vec{v}] \\ E \in \text{Exp} &\triangleq v \mid x \mid \neg E \mid E_1 \wedge E_2 \mid E_1 + E_2 \mid E_1 - E_2 \mid E_1 : E_2 \mid E_1 < E_2 \mid E_1 = E_2 \\ P \in \text{Asrt} &\triangleq E \mid \text{emp} \mid E_1 \mapsto E_2 \mid P_1 \star P_2 \mid p(\vec{E}_1; \vec{E}_2) \end{aligned}$$

The values, Val , consist of integers, Booleans, null values, and lists of values. (Note that we will use the notation $[x]$ to denote *both* lists with elements x and the type of lists with elements of type x . E.g., $[\text{LVar}]$ denotes the type of lists of LVar s.) The expressions, Exp , are standard, including a representative selection of operators. We do not include program variables, as they are not needed for our discussion here; they can be treated straightforwardly. The assertions, Asrt , are also standard, except that predicate assertions, $p(\vec{E}_1; \vec{E}_2)$, have their arguments separated into *ins* and *outs*, which are used to construct MPs for predicates.

Definitions of predicates (e.g., list from the overview section) come from a set Preds :

► **Definition 2** (Syntax of Predicates). *We describe the predicate definitions of Preds using the following syntax:*

$$p(\vec{x}_{in}; \vec{x}_{out}) = \bigvee_{i=1}^n (\exists \vec{x}_i. P_i)$$

where $p \in \text{Str}$ (strings), $\vec{x}_{in}, \vec{x}_{out}, \vec{x}_i \in [\text{LVar}]$, and $P_i \in \text{Asrt}$.² Predicates abide by the following restrictions: \vec{x}_{in} and \vec{x}_{out} have no duplicates; \vec{x}_{in} and \vec{x}_{out} are disjoint and for every $i \in [1, n]$, $\vec{x}_{in} \cup \vec{x}_{out}$ and \vec{x}_i are disjoint; and P_i only has logical variables from $\vec{x}_{in} \cup \vec{x}_{out} \cup \vec{x}_i$.

The semantics of assertions is standard. Let $h : \text{Nat} \rightarrow_{fin} \text{Val}$ (with $\text{Nat} \subset \text{Int}$) denote a heap and $\theta : \text{LVar} \rightarrow_{fin} \text{Val}$ a logical interpretation, and let $\llbracket E \rrbracket_\theta$ be the standard expression evaluation function. With these in place, the semantics of assertions is as follows:

► **Definition 3** (Semantics of Assertions). *The satisfaction relation for assertions, denoted by $\theta, h \models P$, is defined as follows:*

$$\begin{aligned} \theta, h \models E &\Leftrightarrow \llbracket E \rrbracket_\theta = \text{true} \wedge h = \emptyset \\ \text{emp} &\Leftrightarrow h = \emptyset \\ E_1 \mapsto E_2 &\Leftrightarrow h = \{\llbracket E_1 \rrbracket_\theta \mapsto \llbracket E_2 \rrbracket_\theta\} \\ P_1 \star P_2 &\Leftrightarrow \exists h_1, h_2. h = h_1 \uplus h_2 \wedge \theta, h_1 \models P_1 \wedge \theta, h_2 \models P_2 \\ p(\vec{E}_1; \vec{E}_2) &\Leftrightarrow \exists i. \exists \vec{v}_i. \theta[\vec{x}_{in} \mapsto \llbracket \vec{E}_1 \rrbracket_\theta, \vec{x}_{out} \mapsto \llbracket \vec{E}_2 \rrbracket_\theta, \vec{x}_i \mapsto \vec{v}_i], h \models P_i \\ &\quad \text{for } p(\vec{x}_{in}; \vec{x}_{out}) = \bigvee_{i=1}^n (\exists \vec{x}_i. P_i) \in \text{Preds} \end{aligned}$$

² Formally, Preds is a set with elements of type $(\text{Str}, [\text{LVar}], [\text{LVar}], ([\text{LVar}], \text{Asrt}))$, but this is not important for our development.

We need the following definitions in our discussion on MPs. As discussed in the overview, MPs are defined over collections of *simple assertions*:

► **Definition 4** (Simple Assertion). *An assertion P is simple iff it syntactically contains no separating conjunction: e.g., $x \mapsto 5$ is simple, and so is $\text{foo}(x; y, z)$ regardless of how foo is defined, but $x \mapsto 0 \star y \mapsto 0$ is not simple.*

We will also need to talk about the *free logical variables of expressions and assertions*:

► **Definition 5** (Free Logical Variables of Expressions and Assertions). *We write $\text{lv}(E)$ to denote the free logical variables of an expression E and extend this notation to lists of expressions, writing $\text{lv}(\vec{E})$. The function lv naturally extends to assertions.*

4 Formalisation of Core MPs

We now formally describe a simple version of MPs, which we call core MPs, for the assertion language introduced in the previous section. We discuss extensions of core MPs in the next section.

4.1 Formal Definition of MPs

MPs are defined w.r.t. a given *knowledge base* KB and an assertion P . A knowledge base is a set of the currently known logical variables, which grows during planning. MPs have type $[(\text{Asrt}, [(\text{LVar}, \text{Exp})])]$ and are defined as follows:

► **Definition 6** (Matching Plans (MPs)). *Given a knowledge base KB and an assertion P of the form $P_1 \star \dots \star P_n$ where $P_i|_{i=1}^n$ are simple assertions, MP is a matching plan for P with respect to KB iff $\text{plan}(KB, [P_1, \dots, P_n], MP)$, as per the rules in Fig. 1 and Fig. 2.*

As a shorthand, we sometimes say that an assertion that has an MP is “plannable” (where the KB is usually left to be implied by context).

The rules in Fig. 1 and Fig. 2 are designed to ensure that if the simple assertions of P are consumed in the order specified by an MP of P , then the *ins* of each simple assertion P will be known before the simple assertion is consumed. To say this more formally, let us denote by $\text{ins}(KB, P)$ the *ins* of the assertion P under the knowledge base KB . Now, if $\text{plan}(KB, [P_1, \dots, P_n], [(P_{m_i}, _)|_{i=1}^n])$ holds, then $[P_{m_i}|_{i=1}^n]$ is a permutation of $[P_i|_{i=1}^n]$, and if we let KB_i denote the knowledge base before the i -th iteration of the planning, then for every $1 \leq i \leq n$, it holds that $\text{ins}(KB_i, P_{m_i}) \subseteq KB_i$.

We now explain the rules in Fig. 1 and Fig. 2. We go by bottom-up order, starting with the rules for expressions.

Explanation of expression planning rules. Fig. 1 contains the rules for expression planning. The entry point into expression planning is the `planExps` relation. Here we discuss planning of a single expression, that is, the relation `planExp`, and return to the non-single case when discussing assertion planning. For core MPs, we only include a few basic learning rules for `planExp` to illustrate the basic idea. The rule (`PURE`) state that expressions where all variables are known are trivially plannable. The rule (`PURE-EQ`) is more interesting. It says, given an equality expression where all variables of one side are known, the expression is plannable if the unknown variables of the other side of the expression can be factored out. The factoring is done by the `learnEq(KB, Ek, Eu)` function, where E_k is known and E_u is unknown. This function, at a high level, tries to move known parts of E_u to E_k until only a

$$\begin{array}{c}
 (\text{LIST-BASE}) \frac{}{\text{planExps}(KB, [], [])} \\
 \\
 (\text{LIST-IND}) \frac{1 \leq i \leq n \quad \text{planExp}(KB, E_i, [(x_j, E_{i_j})|_{j=1}^k]) \quad \text{planExps}(KB', [E_1, \dots, E_{i-1}, E_{i+1}, \dots, E_n], res')}{\text{planExps}(KB, [E_1, \dots, E_n], [(x_j, E_{i_j})|_{j=1}^k] ++ res')}
 \end{array}$$

$$\begin{array}{c}
 (\text{PURE}) \frac{1v(E) \subseteq KB}{\text{planExp}(KB, E, [])} \quad (\text{PURE-EQ}) \frac{1v(E_i) \subseteq KB \quad 1v(E_j) \not\subseteq KB \quad \{i, j\} = \{1, 2\} \quad \text{learnEq}(KB, E_i, E_j) = res}{\text{planExp}(KB, E_1 = E_2, res)}
 \end{array}$$

$$\begin{aligned}
 \text{learnEq}(KB, E_k, x) &\triangleq [(x, E_k)] \\
 \text{learnEq}(KB, E_k, \neg E) &\triangleq \text{learnEq}(KB, \neg E_k, E) \\
 \text{learnEq}(KB, E_k, E_1 + E_2) &\triangleq \begin{cases} \text{learnEq}(KB, E_k - E_1, E_2), & \text{if } 1v(E_1) \subseteq KB, 1v(E_2) \not\subseteq KB \\ \text{learnEq}(KB, E_k - E_2, E_1), & \text{if } 1v(E_1) \not\subseteq KB, 1v(E_2) \subseteq KB \end{cases} \\
 \text{learnEq}(KB, E_k, E_1 - E_2) &\triangleq \begin{cases} \text{learnEq}(KB, E_1 - E_k, E_2), & \text{if } 1v(E_1) \subseteq KB, 1v(E_2) \not\subseteq KB \\ \text{learnEq}(KB, E_k + E_2, E_1), & \text{if } 1v(E_1) \not\subseteq KB, 1v(E_2) \subseteq KB \end{cases}
 \end{aligned}$$

 **Figure 1** Rules: `planExps`, `planExp`, and `learnEq` for expressions.

logical variable is left, which can then be learnt. The function `learnEq` returns a list since with support for lists in the expression language it is possible to learn multiple variables from one expression. We do not include learning rules for lists here but discuss a list-related extension in §5. Note that including learning rules for different operators is always optional: learning rules are only required to use operators in learning (i.e., to enable more automation), operators without special learning rules can still be planned as long as all unknown variables of the input assertion can be learnt elsewhere.

► **Example 7.** Say, $KB = \{x, y\}$. Some simple examples include

- $\text{learnEq}(KB, x, z) = [(z, x)]$,
- $\text{learnEq}(KB, x, z + 5) = \text{learnEq}(KB, x - 5, z) = [(z, x - 5)]$,
- $\text{planExp}(KB, x = z, [(z, x)])$,
- $\text{planExp}(KB, x = \neg z, [(z, \neg x)])$, and
- $\text{planExp}(KB, x = z + 5 - y, [(z, x + y - 5)])$.

Explanation of assertion planning rules. Fig. 2 contains the rules for assertion planning. We first discuss `planSimple`, which is the planning relation for simple assertions. Pure simple assertions are handled by the (`CONJ`) rule. The rule takes a list of expressions formed by the conjuncts of the input expression. It does so by relying on the `planExps` relation for planning of lists of expressions: the relation specifies expression orders for which all `outs` can be learned (its definition is similar to the definition of `plan`, which we discuss shortly). Non-conjunct pure simple assertions are covered by the degenerate case of the (`CONJ`) rule when $n = 1$. The (`EMP`) rule is trivial since `emp` is always plannable. The (`HEAP`) rule for cell assertions $E_1 \mapsto E_2$ states that a cell assertion is plannable if we (at least) know its `ins`, that is, the

$$\begin{array}{c}
 (\text{PLAN-BASE}) \frac{}{\text{plan}(KB, [], [])} \\
 \\
 (\text{PLAN-IND}) \frac{1 \leq i \leq n \quad \text{planSimple}(KB, P_i, [(x_j, E_j)|_{j=1}^k])}{\begin{array}{l} KB' \triangleq KB \cup \{x_j|_{j=1}^k\} \\ \text{plan}(KB', [P_1, \dots, P_{i-1}, P_{i+1}, \dots, P_n], MP) \end{array}} \frac{}{\text{plan}(KB, [P_1, \dots, P_n], (P_i, [(x_j, E_j)|_{j=1}^k]): MP)} \\
 \\
 \hline
 \\
 (\text{CONJ}) \frac{n \geq 1 \quad \text{planExps}(KB, [E_1, \dots, E_n], res)}{\text{planSimple}(KB, \wedge_{i=1}^n E_i, res)} \\
 \\
 (\text{EMP}) \frac{}{\text{planSimple}(KB, \text{emp}, [])} \quad (\text{HEAP}) \frac{\text{planExps}(KB \cup \{O_1\}, [E_2 = O_1], res)}{\text{planSimple}(KB, E_1 \mapsto E_2, res)} \\
 \\
 (\text{PRED}) \frac{\begin{array}{l} \text{lv}(E_1) \subseteq KB \\ \vec{E}_2 = [E_{2i}|_{i=1}^n] \\ \text{planExps}(KB \cup \{O_1, \dots, O_n\}, [E_{21} = O_1, \dots, E_{2n} = O_n], res) \end{array}}{\text{planSimple}(KB, p(\vec{E}_1; \vec{E}_2), res)}
 \end{array}$$

■ **Figure 2** Rules: `plan` and `planSimple` for assertions.

logical variables of E_1 , and E_2 is plannable according to `planExps`. We also need to record that the *out* of the cell assertion, that is, E_2 , equals the contents of the cell at E_1 in memory, and from this equality we may be able to learn further information. Note, however, that the heap is not available during the planning process, and we therefore use a placeholder variable O_1 , which is a reserved logical variable that is not allowed to occur in assertions, that will be instantiated to the actual heap contents at runtime (see Ex. 8). Finally, the (PRED) rule generalises the planning of cell assertions to predicates by abstracting all of the predicate *outs* using placeholder variables O_1, \dots, O_n to then be instantiated and linked to $E_{2i}|_{i=1}^n$ appropriately.

► **Example 8.** To illustrate how placeholder variables work in practice, consider consuming $x \mapsto y$ knowing that $x = 41$. An MP for this assertion, by (HEAP), is $[(x \mapsto y, [(y, O_1)])]$. Say the current heap has a cell $41 \mapsto 42$. In this case, at the time of consumption the placeholder variable O_1 will be instantiated with the contents of the cell at x , which equals 42, yielding $y = 42$.

We now turn to the main entry point: the `plan` relation. The main rule of `plan`, the (PLAN-IND) rule, specifies valid orders of the simple assertions of P that guarantee the learning of all their *outs*, extending the knowledge base as the *outs* of each simple assertion are learnt. At each choice point, the rule is applicable for a simple assertion P_i whose *ins* are all known using the `planSimple` relation, together with all the logical variables $x_j|_{j=1}^k$ that can be learnt from P_i and expressions $E_j|_{j=1}^k$ describing how they can be learnt. The rule then extends the knowledge base with learnt variables, inductively repeats the planning for the remaining simple assertions, and finally adds the result of `planSimple`, $(P_i, [(x_j, E_j)|_{j=1}^k])$, to the full MP.

► **Example 9.** Let $P = \text{list}(w; vs) \star x \mapsto y \star z \mapsto w \star z = y + 21$ and $KB = \{x\}$, and let us use the provided rules to construct an MP for P . Branching on the (PLAN-IND) rule, we have that for $i = 1$ and $i = 3$ we cannot apply (PRED) and (HEAP) as we do not know all the

corresponding ins (in particular, w and z), and for $i = 4$ we cannot apply (PURE-EQ) as we do not know all of the variables on either side of the equality. For $i = 2$, however, we can apply (HEAP) as we know x and we have $\text{planExps}(KB \cup \{O_1\}, [y = O_1], [(y, O_1)])$, which follows from $\text{planExp}(KB \cup \{O_1\}, y = O_1, [(y, O_1)])$, which in turn follows from $\text{learnEq}(KB \cup \{O_1\}, O_1, y) = [(y, O_1)]$. Returning to (PLAN-IND) and continuing until the end, we obtain the following MP for P :

$$[(x \mapsto y, [(y, O_1)]), (z = y + 21, [(z, y + 21)]), (z \mapsto w, [(w, O_1)]), (\text{list}(w; vs), [(vs, O_1)])]$$

4.2 Computing MPs

Given the inference-rule formalisation of MPs in the previous section, it is easy to construct an algorithm for automatically constructing MPs: a simple greedy algorithm searching through the `plan` relation is sufficient to find an MP for a given assertion. We can greedily pick the first valid choice we find at each choice point of the rules of the `plan` relation and its auxiliary relations. That is, no backtracking is needed to explore multiple choice points (note that here we are referring to backtracking during the construction of MPs, not the backtracking during consumption that MPs help to avoid as discussed earlier). This is because *outs* are only learnt by equality reasoning and therefore learning only happens when forced, so the order in which *outs* are learnt does not matter. In §6, we report performance numbers of this simple greedy algorithm as implemented in Gillian.

Note that no soundness result is needed for MPs to ensure soundness for the verification tool as a whole: as long as no simple assertions are dropped from a given input assertion, it is not possible to construct an “incorrect” MP that leads to an unsoundness bug in the verification tool. This is because an incorrectly constructed MP will simply make the consumption following the MP to fail and force the verification process to abort. To exemplify, consider the assertion $x = 1$ with an empty knowledge base. Say we construct the incorrect MP $[(x = 1, [(x, 0)])]$, suggesting to instantiate x to 0. During consumption, this MP will lead to $0 = 1$ being consumed, which will of course fail. Similarly, an MP missing one or more *outs* will cause the consumption to fail as well. E.g., an incorrect MP $[(x = 1, [])]$ for the same assertion, where the x variable is missing, will be caught during consumption as well since x will be left uninstantiated.

4.3 MPs for Function Specifications and Predicates

Given the definition of an MP for an assertion, we can easily define MPs for function specifications and predicates, as we now explain and exemplify.

MPs for function specifications are defined as follows:

- ▶ **Definition 10** (Matching Plans: Function Specification). *An MP for a function specification $\{\vec{x} = \vec{x} \star P\} f(\vec{x}) \{Q\}$ is an MP for P with knowledge base $\{\vec{x}\}$.*

For function specifications of the above form, where the function parameters \vec{x} are bound to logical variables \vec{x} , when symbolically executing a function call, the values of \vec{x} are given by the arguments provided in the call, and \vec{x} can therefore be assumed to be known at the start of the planning.³

MPs for predicates are defined as follows:

³ As we do not include program variables in assertions, pre-conditions are formally pairs of the form (\vec{x}, P) , but we stylise them to remain in line with the usual SL syntax.

► **Definition 11** (Matching Plans: Predicates). An MP for a predicate $p(\vec{x}_{in}; \vec{x}_{out}) = \bigvee_{i=1}^n (\exists \vec{x}_i. P_i)$, is a list of MPs, $[mp_i]_{i=1}^n$, such that mp_i is an MP for P_i with knowledge base $\{\vec{x}_{in}\}$.

Recall that the use case for MPs for predicates is predicate folding: to fold a predicate $p(\vec{x}_{in}; \vec{x}_{out})$ we have to know its *ins* \vec{x}_{in} , whereas the existentials from the predicate body disjuncts need to be inferable from these *ins* and the *outs* \vec{x}_{out} can be either provided or optionally left to be inferred from the *ins*. Also note that how MPs are defined for predicates does not depend on how much folding automation the verification tool provides: from the perspective of planning, it does not matter if the fold was requested manually or automatically. Lastly note that because the *ins* and *outs* of a predicate are given at the time of definition, failure to construct an MP can be reported early, i.e., at the time of definition, rather than when the predicate is used in folding.

Examples of plannable predicates include all predicates for standard data structures. We discuss some data-structure examples in more detail below.

► **Example 12.** We return to the standard SL predicate $list(x; vs)$ from our running example, where we now have separated the *ins* and *outs*. Recall, the predicate is defined as follows:

$$\begin{aligned} list(x; vs) \triangleq & (x = \text{null} \star vs = []) \vee \\ & (\exists v, x', vs'. list(x'; vs') \star x \mapsto v \star x + 1 \mapsto x' \star vs = v : vs') \end{aligned}$$

Importantly, despite the fact that the definition of the *list* predicate is recursive, no recursion is needed to express (or compute) the MP for the predicate. Per Def. 11, the predicate is plannable since the following is an MP for the predicate:

$$\begin{aligned} [[(x = \text{null}, & [(x, \text{null})])], \\ & (vs = [], & [(vs, [])])], \\ & [(x \mapsto v, & [(v, O_1)])], \\ & (x + 1 \mapsto x', & [(x', O_1)])], \\ & (list(x'; vs'), & [(vs', O_1)])], \\ & (vs = v : vs', & [(vs, v : vs')])]] \end{aligned}$$

where the first element of the list is an MP for the first disjunct of the predicate body (the null disjunct) and the second element of the list is an MP for the second disjunct of the predicate body (the non-null disjunct).

► **Example 13.** We easily see that the following two variants of the singly-linked list predicate *list* and the doubly-linked list predicate *dlist* are plannable:

$$\begin{aligned} list(x) \triangleq & (x = \text{null}) \vee (\exists v, x'. x \mapsto v, x' \star list(x')) \\ list(x; n) \triangleq & (x = \text{null} \star n = 0) \vee (\exists v, x'. x \mapsto v, x' \star list(x'; n - 1)) \\ \text{dlseg}(x, x', y, y'; vs) \triangleq & (vs = [] \star x = x' \star y = y') \vee \\ & (\exists x'', v, vs'. vs = v : vs' \star x \mapsto v, x'', y' \star \text{dlseg}(x'', x', y, x; vs')) \\ \text{dlist}(x, y; vs) \triangleq & \text{dlseg}(x, \text{null}, y, \text{null}; vs) \end{aligned}$$

► **Example 14.** For a non-list example of a plannable data-structure predicate, we turn to binary search trees (extending our simple assertion language's values and expressions with support for sets):

$$\begin{aligned} bst(x; vs) \triangleq & (x = \text{null} \star vs = \emptyset) \vee \\ & (\exists v, l, r, vs_l, vs_r. x \mapsto v, l, r \star bst(r; vs_r) \star bst(l; vs_l) \star \\ & vs = vs_l \uplus \{v\} \uplus vs_r \star vs_l < v \star v < vs_r) \end{aligned}$$

► **Example 15.** Finally, we highlight that it is up to the tool user to make sensible choices for *ins* and *outs*, as not all plannable choices need be equally useful in practice. Note that this is not a requirement introduced by MPs, rather, MPs simply make this requirement explicit by separating *ins* from *outs*. To illustrate, consider the standard acyclic- and cyclic-list-segment predicates:

$$\begin{aligned}\text{lseg}(x, y, vs) &\triangleq (x = y \star vs = []) \vee \\ &\quad (\exists x', v, vs'. x \neq y \star x \mapsto v, x' \star vs = v : vs' \star \text{lseg}(x', y, vs')) \\ \text{cseg}(x, y, vs) &\triangleq (x = y \star vs = []) \vee \\ &\quad (\exists x', v, vs'. x \mapsto v, x' \star vs = v : vs' \star \text{cseg}(x', y, vs'))\end{aligned}$$

where the only difference between the two is in that the former does not allow the start and the end pointers to be equal in the second disjunct of its definition (specified by $x \neq y$) and the latter does not have this constraint, and consider the various choices of *ins* and *outs*, with the goal being that the *ins* should uniquely determine the *outs*, minimising potential branching coming from folding. For both *lseg* and *cseg*, x has to be an *in*, as otherwise, given that the list is singly-linked (forward-pointing), we would have no way of determining where the list segment starts. Observe that only having x as an *in* is enough for both disjuncts in both predicate definitions to be plannable. However, without additional *ins*, we do not know where the list segment ends, and folding the predicate would yield up to n branches, where n is the length of the maximal list segment in the heap starting from x . Adding y as an *in* solves this issue for *lseg*, since then we fix the list segment by knowing both the start and its end; similarly, we could add vs as an *in* and then we would know the length of the list segment, which, together with its start, would also uniquely determine it. Interestingly, adding y as an *in* for *cseg* still does not uniquely determine the cyclic list segment, as its two disjuncts are not disjoint: for example, in the heap $\{42 \mapsto 0, 42\}$, we could fold both *cseg*(42, 42; []) and *cseg*(42, 42; [0]). Adding vs as an *in* of *cseg*, however, does solve the issue, as the length of the list segment then becomes unambiguous. The same situation would come up with any predicate whose disjuncts are not disjoint.

5 Extensions

Having formalised core MPs in the previous section, we now discuss important MP extensions that widen the applicability and usefulness of MPs. The extensions we discuss here are from the implementation of MPs in the Gillian tool.

Parametric matching plans. To support multiple programming languages (e.g., C and JavaScript), Gillian is parametric on the memory model used for analysis. In supporting parametricity, Gillian's implementation of MPs is parametric as well, which we now show is a simple extension of core MPs.

Memory models in Gillian are described in terms of *core predicates*, which represent the fundamental units of the memory model. Core predicates are described using core-predicate assertions with syntax $c(\vec{E}_1; \vec{E}_2)$, where $c \in \text{Str}$ is the name of the core predicate and \vec{E}_1 and \vec{E}_2 are the *ins* and *outs* of the core predicate. Each memory model instance must provide a set of core predicates and the *ins* and *outs* of each core predicate. For example, for the simple memory model we used for core MPs, the only core predicate is the cell assertion, $E_1 \mapsto E_2$, which has E_1 as an *in* and E_2 as an *out* – or, more formally: $\mapsto(E_1; E_2)$. Another example is given by the Gillian C memory model, whose core predicates include a cell core predicate of the form $(E_b, E_o) \mapsto E_v$, which states that the cell at offset E_o in the block at location E_b has contents E_v , where E_b and E_o are the *ins* and E_v is an *out*, and a block-bound predicate $\text{bound}(E_b; n)$, which states that the block at location E_b has length n .

From the discussion above, it is straightforward to generalise planning to parametric planning since core-predicate assertions $c(\vec{E}_1; \vec{E}_2)$ share syntax with user-defined-predicate assertions $p(\vec{E}_1; \vec{E}_2)$ and therefore for the purpose of planning are the same. That is, the (PRED) rule of Fig. 2 can be used to plan core-predicate assertions. Indeed, recall that for the simple memory model we used for core MPs, the (HEAP) rule is indeed a special case of the (PRED) rule (see Fig. 2).

Extending learning capabilities. In some large verification projects, it might be desirable to extend the learning capabilities of the core MP algorithm with project-custom learning rules: for example, to avoid repetitive manual project-specific massage of assertions to make them plannable with respect to the simple learning rules of core MPs.

We discuss one such learning extension that has been implemented in Gillian, specifically, a list-related extension that was added for the largest case study carried out in Gillian: the verification of C and JavaScript implementations of the deserialisation module of the AWS Encryption SDK message header [13]. To illustrate, consider the assertion $P \triangleq a = a_l ++ a_r \star \text{len}(a_l) = l$ with $KB = \{a, l\}$, where $++$ denotes list concatenation and len denotes list length. P is not plannable using the core MP algorithm, because the algorithm can only learn logical variables: as list length is not injective, a_l cannot be learned from l and planning is stuck. However, P becomes plannable if knowledge bases are allowed to also contain expressions of the form $\text{len}(x)$: $\text{len}(a_l)$ can then be learnt from $\text{len}(a_l) = l$, and both a_l and a_r can be learnt, respectively, as $a_l = a[0 : \text{len}(a_l)]$ and $a_r = a[\text{len}(a_l) : \text{len}(a)]$ from $a = a_l ++ a_r$, where $E_1[E_2 : E_3]$ denotes list slicing from index E_2 inclusive to index E_3 exclusive.

The above example may look simple but was essential for creating MPs of predicates describing the data structures used in the AWS case study. At a high level, AWS Encryption SDK message headers are buffers (arrays of bytes) that comprise a number of sections, with each section having either a static length described by the standard or a dynamic length derived from content appearing in the earlier sections of the buffer. In that context, the list-length extension allowed for clear definitions that follow the descriptions in their official documentation. Otherwise, the predicates would have to be stated using more complex operators. Specifically, using Gillian notation, (part of) the predicate describing the message header is as follows:⁴

```
pred Header(+rawHeader, ver, type, sId, msgId, ECLen, ECKs, ...) :
  rawHeader == ([ver, type] ++ #rawSId ++ msgId ++ #rawECLen ++ #EC ++ ...) *
  len(#rawSId) == 2 * UInt16(#rawSId, suiteId) * len(msgId) == 16 *
  len(#rawECLen) == 2 * UInt16(#rawECLen, ECLEN) *
  len(#EC) == ECLEN * EncryptionContext(#EC, ECKs) * ...
```

while without the list-length extension its definition would be as follows:

```
pred Header(+rawHeader, ver, type, sId, msgId, ECLen, ECKs, ...) :
  [ver, type] == rawHeader[0, 2] * #rawSId == rawHeader[2, 4] *
  UInt16(#rawSId, suiteId) * msgId == rawHeader[4, 16] *
  #rawECLen = rawHeader[20, 22] * UInt16(#rawECLen, ECLEN) *
  #EC == rawHeader[22, 22 + ECLEN] * EncryptionContext(#EC, ECKs) * ...
```

⁴ In Gillian notation, the `+` symbol denotes a predicate `in`, and the `#` symbol denotes existential quantification. The `UInt16(+x, y)` predicate states that the two bytes given by `x` can be viewed as an unsigned 16-bit integer `y`, while the `EncryptionContext` predicates is specific to the AWS case study and its meaning is not relevant here.

By comparing these two definitions, we can see that not only is the latter more difficult to read and understand, but is also more error-prone, as the list-slicing indices get progressively more complicated.

This extension approach is not limited to the above list-length example and can be applied for other expressions: e.g., we might choose to keep $a + b$ in the KB if we know it but do not know either a or b . These further extensions can be added on an as-needed basis straightforwardly by modifying the OCaml code of Gillian. An interesting direction for the future is to develop a small domain-specific language for MP rules (i.e., rules like those in e.g. Fig. 1) to simplify extending Gillian’s MP algorithm with new rules for extended learning capabilities.

Support for magic wands. MPs can easily be extended to support the magic wand operator $\rightarrow*$. Formally, $\theta, h \models P_1 \rightarrow* P_2 \Leftrightarrow (\forall h'. h' \# h \wedge \theta, h' \models P_1 \Rightarrow \theta, (h' \uplus h) \models P_2)$ where $h' \# h$ denotes that the heaps are disjoint. Practically, magic wands are helpful to reason about “the rest” of a structure. For example, iterating over a linked list often requires the introduction of the list-segment predicate `1seg`, presented in Ex. 15, in order to specify the beginning of the list that has already been visited. Instead, the list segment `1seg(x, y, vs)` can be replaced by the magic wand `list(y, vs') →* list(x, vs ++ vs')`, meaning that the total list can be recovered by combining this resource with the rest of the list.

To add support for magic wands, we extend the assertion language with magic wand assertions of the form $p(\vec{E}_1; \vec{E}_2) \rightarrow* q(\vec{E}_3; \vec{E}_4)$, where p and q are user-defined predicates. We chose this syntax as to syntactically capture the in-parameters and out-parameters for each side of the operator. Such a magic wand assertion forms a simple assertion with \vec{E}_1 , \vec{E}_2 and \vec{E}_3 as in-parameters, and \vec{E}_4 as out-parameters. To explain the division of in-parameters and out-parameters, we give a summary of the underlying algorithm for performing consumption of magic wands as implemented in Gillian. The algorithm is originally from Viper [23, 5]:⁵

To consume a magic wand assertion $p(\vec{E}_1; \vec{E}_2) \rightarrow* q(\vec{E}_3; \vec{E}_4)$ from state σ :

1. Create a state σ_p by producing the definition of $p(\vec{E}_1; \vec{E}_2)$ in the empty state.
2. For each simple assertion Q in the definition of $q(\vec{E}_3; \vec{E}_4)$:
 - a. Try consuming Q in σ_p , if it succeeds continue to the next simple assertion;
 - b. If it fails, try consuming Q in σ instead, if it succeeds, continue to the next simple assertion;
 - c. If both fail, abort the consumption.

Step 1 produces the left-hand side of wand, which requires knowing all its parameters. Therefore, all parameters in \vec{E}_1 and \vec{E}_2 must be in-parameters of the wand assertion. Then, step 2 consumes the right-hand side of the wand, which requires knowing all its in-parameters, but learns its out-parameters in the process. Therefore, \vec{E}_3 are in-parameters of the wand assertion and \vec{E}_4 are out-parameters.

To exemplify, say $p_1(x; y) = x \mapsto y$ and $q_1(x; y, z) = x \mapsto y \star y \mapsto z$. Further, say we know $x = 1$ and $y = 2$ and are in a state with a heap $\{2 \mapsto 3\}$. The heap satisfies the wand assertion $\exists z. p_1(x; y) \rightarrow* q_1(x; y, z)$. Indeed, by the above algorithm, the assertion can be consumed starting from the given heap, learning that $z = 3$ in the process.

⁵ For simplicity of presentation, the algorithm presented here assumes the absence of disjunction in the definitions of p and q .

6 Scalability and Performance

We now discuss the scalability and performance of MPs. We base our discussion on the MP implementation in Gillian, specifically, our discussion builds on the largest case study carried out in Gillian, i.e., the verification of C and JavaScript implementations of the deserialisation module of the AWS Encryption SDK message header [13]. First, we report MP-related scale and performance data for the AWS case study. Second, we report on a new MP-based optimisation we have implemented in Gillian for this paper, which allows for the creation of *aggregate matching plans* (AMPs). We show that this optimisation improves the total verification time of the AWS case study.

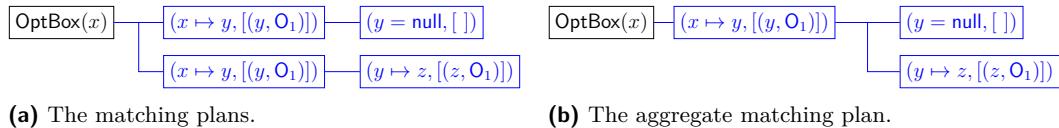

AWS case study. To measure the scale and performance of MPs, we have instrumented Gillian with data-and-performance counters and re-run the verification of the code from the AWS case study. From this experiment, we have found the cost of building MPs to be negligible compared to the total verification time. For the C/Javascript implementation of the AWS case study, building all MPs takes a total of 0.35s/0.096s, constituting 0.16%/0.25% of the total verification time. Over that time, MPs are built for 1073/378 assertions that consist of 41/28 simple assertions on average and 156/272 assertions at most. The creation of a single MP takes 0.33ms/0.26ms on average and 2.5ms/6.5ms at most. Note that MPs do not affect the verification time beyond the time it takes to create them; this is because MPs are separated from the consumption phase: the consumptions that take place during verification would be the same if the input assertions had instead been manually adopted (e.g., as illustrated in the discussion on VeriFast in §2).

Aggregate matching plans (AMPs). We discuss and evaluate *aggregate matching plans* (AMPs), a new performance optimisation we have implemented in Gillian for this paper. To illustrate AMPs, recall that an MP for a predicate is a list of MPs for the disjuncts of the body of the predicate (Def. 11), and that each disjunct is treated independently. AMPs identify and leverage simple assertions that are shared between disjuncts and represent this sharing within a tree structure.

To better understand how AMPs work, consider the following predicate:

$$\text{OptBox}(x) \triangleq (\exists y. x \mapsto y * y = \text{null}) \vee (\exists y, z. x \mapsto y * y \mapsto z)$$

and the MPs and AMP for this predicate in Fig. 3.

■ **Figure 3** Matching plans and aggregate matching plan for $\text{OptBox}(x)$.

Without AMPs, Gillian would create 2 MPs, one per disjunct of the predicate, which both have the same first step ($x \mapsto y, [(y, O_1)]$). However, when folding a predicate, Gillian tries to consume each disjunct of the predicate body in order until one succeeds to completion. Without AMPs, when the definition that could be folded was the second one, the first step would be consumed twice in the same symbolic state, duplicating the work. In contrast, using AMPs it is consumed only once, factoring out such duplicated work.

In our implementation of AMPs in Gillian, MPs are built for each disjunct of a predicate, and then aggregated into a single AMP. Before building the individual MPs, simple assertions within a single disjunct are sorted using a simple sort algorithm, maximising the chance of the existence of a shared root. A similar process is also performed for function specifications, as each function can have multiple specifications in Gillian.

Our evaluation of this new optimisation shows that utilising AMPs instead of lists of MPs in large verification projects leads to substantial performance improvements. For the C implementation of the AWS case study, AMPs made the total verification time drop from 240s to 211s, that is, a speedup of 12%. AMPs are especially effective when assertions are obtained from and/or augmented by a compilation process which often adds the same contextual information, such as type information, to all cases (which is the case for the Gillian assertion compiler for C).

7 Related Work

We place matching plans in the context of previous work on automated frame inference. Specifically, we compare matching plans with the approaches of three modern SL-adjacent and SMT-based semi-automated verification tools: VeriFast [7], Viper [16], and CN [20].

VeriFast. VeriFast [7], whose approach is closest to our work, is a verification tool for C and Java. It is based on consumers and producers, and its assertion language is the traditional SL assertion language. Given the similarities between VeriFast and our work, in particular the shared assertion language, we expect it would be straightforward to adapt our work on MPs for VeriFast. Currently, the approach of VeriFast offers less automation than MPs, as it leaves the responsibility of constructing MPs to the tool user, who has to provide the MP implicitly when providing assertions, e.g., as part of predicate definitions. To illustrate, consider again the singly-linked list predicate from our running example, now in VeriFast’s syntax for C:

```
struct node { int entry; struct node* next; };

predicate list(struct node* x, list<int> vs) =
  x == NULL
  ? vs == nil
  : malloc_block_node(x) && x->entry |-> ?v &&
    x->next |-> ?x' && list(x', ?vs') && vs == cons(v, vs');
```

Note that this list predicate is defined using the ternary conditional operator rather than disjunction, and that existentially quantified variables are annotated with a question mark at first use. In VeriFast, simple assertions are consumed in the order given by the tool user: e.g., in the non-`NULL` case of the list predicate, `malloc_block_node(x)` is consumed before `x->entry |-> ?v`, which in turn is consumed before `x->next |-> ?x'`, and so on. This means that if the user does not arrange the simple assertions appropriately, the verification will fail even though there might exist an MP. Further, VeriFast offers less automation than MPs w.r.t. learning variables: it can only learn a variable if that variable is the single occupant of an *out* or the left-hand side of an equality: for example, assuming `x` is known, VeriFast can learn `y` from `y == x` but not from `x == y` or `x == y + 1`.

Another difference between our approach and that of VeriFast is that in our approach *ins* and *outs* are checked at definition time whereas in VeriFast they are checked at use time, leading to less local/precise error reporting. For example, if we tried to fold a list in VeriFast

using `close list(_)`, where `_` denotes that VeriFast should infer the argument, we would get the error message “Unbound variable ‘`x`’”, referring to the `x` variable in the `list` predicate definition, instead of an error saying that it is not possible to infer an *in* of a predicate.⁶

Viper. Viper [16] is a platform for building verification tools. It has been instantiated, among other languages, to Java and Rust. It is based on consumers and producers, but also on an alternative assertion language known as implicit dynamic frame theory (IDF) [24], which combines SL with dynamic frame theory [10].⁷ Tool users familiar with SL but not IDF must therefore learn IDF before they can start using Viper. This difference also means that both consumption and learning *outs* from *ins* look different than in our setting, making a detailed comparison complex. We illustrate this using our linked-list running example, now in Viper’s IDF syntax:

```
field entry : Int
field next : Ref

predicate list(this : Ref) {
    acc(this.entry) && acc(this.next) &&
    (this.next != null ==> list(this.next))
}

function elems(this : Ref) : Seq[Int]
requires list(this) {
    unfolding list(this) in
    this.next == null ? Seq(this.entry)
                      : Seq(this.entry) ++ elems(this.next)
}
```

The above `list` predicate captures the shape, but not the contents, of lists. The predicate is expressed using `acc`, a construct called accessibility predicate, closely resembling the cell assertions in SL. The contents of lists are specified using a heap-dependent function `elems`. Such functions, as their name suggests, are functions over the heap of the current symbolic state. In the setting of accessibility predicates and heap-dependent functions, the *ins* look similar to *ins* in our setting, but the *outs* become the return values of heap-dependent functions. Assertions must be self-framing, in the sense that assertions must ensure accessibility to at least the locations they read. Self-framedness is checked in a left-to-right manner in Viper, meaning that the assertion `acc(x.f) && 0 < x.f` is considered self-framing, whereas `0 < x.f && acc(x.f)` is not. That is, like VeriFast, Viper is sensitive to the order of simple assertions. Quantifiers, e.g., over array indices, are more prominent in IDF than in SL, and variables, quantified or otherwise, that cannot be inferred are instantiated by giving the underlying SMT solver trigger hints [14], in the style of, e.g., Boogie [12].

CN. CN [20] is a verification tool for C, and is designed for, what its authors call, “predictable proof automation”. One means employed towards this goal is that CN is based on a new tool-specific assertion language, which uses variable scoping to ensure that *outs* can always be learnt. In other words, the limitations of CN’s learning algorithm are reflected directly in

⁶ VeriFast has support for checking “preciseness of predicates”, which allows for definition-time checking of their *ins* and *outs*. However, this feature does not affect the error reporting at use sites of predicates, i.e., errors remain nonlocal. The rules are the same as for the run-time check and are described by inference rules by Jacobs et al. [7] and by prose text by Jacobs et al. [8].

⁷ Parkinson and Summers [19] establish a formal connection between SL and IDF, and Jost and Summers [9] (partially) extend the result to include predicates as well.

syntax of assertions, ensuring that tool users do not accidentally fall out of the plannable subset of the assertion language. To exemplify, in CN syntax, the singly-linked list predicate for the same `node` data type as in the above discussion on VeriFast becomes:⁸

```
predicate { list<integer> l } List (pointer p) {
    if (p == NULL) {
        return { l = nil<integer> };
    } else {
        let Head = Owned<struct node>(p);
        let Tail = List(Head.value.next);
        return { l = cons(Head.value.entry, Tail.l) };
    }
}
```

Since new variables, including *outs*, must be the output of functions, they are necessarily learnable. The downside of this approach is that tool users have to learn a new specification language.

Another feature aimed at predictable proof automation is that CN targets a decidable SMT fragment, disallowing, e.g., nonlinear arithmetic in SMT queries. Instead, these must be handled manually by tool users, by proving lemmas in, e.g., Coq, and then manually applying them in CN. This trade-off is not CN-specific and could also be done in an MP-based approach. Similarly, manual fallbacks for complex quantifiers are required as well.

Other related work. Many other SL and SL-adjacent verification tools share similarities with the work presented here, all the way back from Smallfoot [2, 3], the very first such tool. Important differences between our work and Smallfoot include that Smallfoot is not SMT-based and that its frame inference procedure is more akin to proof search than the approach presented here, as is the case for its most well-known descendant Infer [4]. Another important approach to semi-automating SL is embedding one’s verification tool inside an interactive theorem prover (ITP). A recent example of this approach is RefinedC [22]. Such tools do not reduce the verification problem to a series of SMT queries but instead to a series of proof obligations that tool users must then discharge within the ITP by the usual means available, including various proof automation machinery.

There are also important connections to be highlighted between the work presented here and logic programming. The above-mentioned work on RefinedC [22] highlights this connection, as the tool is implemented in the “separation logic programming language” Lithium (which, in turn, is implemented in Coq), which is introduced in the same paper. Diaframe [15] is based on similar ideas. Nguyen et al. [17] highlight the connection between what we call *ins* and *outs* and argument modes in logic programming. Lastly, some logic programming languages contain features that address some of the problems of the traditional left-to-right evaluation order of logic programming, such as constraint logic programming and co-routining (e.g., `dif/2`) (cf. the recent survey by Körner et al. [11]).

Finally, an earlier version of MPs, dubbed unification plans (UPs), was briefly outlined by Fragoso Santos et al. [6] in the context of the JavaScript analysis tool JaVerT, the forefather of the Gillian platform. UPs featured a more limited form of learning than our MPs and were constructed purely syntactically: *ins* and *outs* were computed independently of a knowledge base, which meant that, for example, while it was possible to learn b from $b = a$ or $\text{list}(a; b)$ knowing a , it was not possible to learn c from $a = b + c$ or learn list lengths. No paper has covered UPs in the same depth we have covered MPs in this paper.

⁸ The definition is taken from the CN paper, where the authors add: “Note that CN does not currently support logical functions on lists; this example is for illustration only.”

Abstract

Large-scale software repositories are a source of insights for software engineering. They offer an unmatched window into the software development process at scale. Their sheer number and size holds the promise of broadly applicable results. At the same time, that very size presents practical challenges for scaling tools and algorithms to millions of projects. A reasonable approach is to limit studies to representative samples of the population of interest. Broadly applicable conclusions can then be obtained by generalizing to the entire population. The contribution of this paper is a standardized experimental design methodology for choosing the inputs of studies working with large-scale repositories. We advocate for a methodology that clearly lays out what the population of interest is, how to sample it, and that fosters reproducibility. Along the way, we discourage researchers from using extrinsic attributes of projects such as stars, that measure some unclear notion of popularity.

1 Introduction

And so it begins...

count the number of stars associated with each repository. The number of stars relate to how many people are interested in that project. Thus, we assume that stars indicate the popularity of a project. We select the top 50 projects in each language

Sentences like these appear in the methodology sections of software engineering papers, with sometimes, little more in terms of experimental design. This paper aims to convince readers that using extrinsic features of projects, such as popularity, may limit applicability of results of the studies relying on them. Instead one should select projects based on their intrinsic features and spell out expectations as well as threats to validity.

Empirical software engineering studies are experiments performed on a corpus of software to validate some hypotheses. For instance, one could take projects written in various languages and attempt to show that some language feature has an impact on the quality of the code written using it. The value of large-scale corpus study often does not lie in what we learn about the projects that were analyzed, but rather in what these can teach us about the larger population. There is limited value in, say, finding out that a new Java language feature is beneficial in a handful cases if we cannot generalize that result to a broader portion of the Java ecosystem.

Yet, many papers in the field do not articulate how broadly applicable their results are expected to be. Even the simple question of how the projects that were analyzed were selected is not clear. While large-scale code repositories, such as GitHub, are a boon to the software engineering community, their sheer size requires care. We argue that better experimental design will strengthen research done in the field.

Consider Table 1 which has a meta-study of three years of the *Mining Software Repositories* conference. Forty-one papers relied on subsets of GitHub. Out of those, five papers lacked sufficient information about their dataset to determine how they selected their inputs, twenty-one used GitHub stars to obtain a subset of projects, ten used simple combinations of attribute thresholds and only five relied on random sampling over the entire population.

■ **Table 1** Experimental design in MSR 2019, 2020 and 2021.

papers	class	description	# of projects
5	Unknown	Unknown or proprietary	1–35K
21	Stars	Filter projects using stars	5–2M
10	Other	Other filter for projects	7–290K
5	Random	Filter and sample randomly	6–51K

What is the right choice here? None of the papers analyzed the entire ecosystem as that would mean tens to hundreds of millions of projects. The question thus becomes how to sample the population of projects hosted on GitHub. In this paper, we criticize the use of GitHub stars as they are appealing and popular, yet also dangerous. But, really, our point generalizes to any extrinsic attributes of a project. So, again, what is the right choice? The answer is, of course, that it depends. The rest of this paper attempts to shed some light on how to make a reasoned choice of inputs.

First, let us return to stars and ponder why they play such an important role in our experimental methodology? We believe expectations and pragmatics are the explanation. Community standards are largely set by the papers we publish. The literature codifies expectations for authors of the next batch of papers. These expectations slowly evolve in response to reviewer attitudes. So, we use stars because our peers do. And just as importantly for the pragmatic reason that GitHub does not provide an index of projects, nor does it allow to query over intrinsic attributes of code. Finding inputs is thus hobbled by limitations of our tools. Stars play a double role. They are a queryable index of projects as GitHub does provide an interface to obtain them. They also come with an expectation that starred projects enjoy some notion of quality [8]. This paper will show that stars do not necessarily correlate with quality and that they introduce reproduction barriers.

We propose a methodology for designing reproducible software engineering experiments over large-scale repositories with the explicit goal of improving the generalizability of our results. The methodology is in line with evolving community standards [23] but specific to large-scale code analysis. We propose to follow the following protocol when designing a new experiment:

1. **Population Hypothesis:** Give a brief description of the population of interest the research should generalize to; it may be narrow such as “programs written by students learning JavaScript” or as broad as “commercial code”.
2. **Frame Oracle:** Give a procedure for deciding if a project belongs to the population of interest. The procedure should be efficiently computable over intrinsic attributes of a project. An oracle could, say, return projects with a single JavaScript file created by a user with no previous commits.
3. **Sampling Strategy:** Describe a strategy for selecting a subset of the entire population. Ideally, specified algorithmically. An example is random sampling without replacement from a known seed.
4. **Validity:** Give an argument as to how the oracle and the sampling strategy are valid means to obtain representative samples. This can be a discussion of how to check result quality, such as manual inspection of samples written by beginners, and threats to validity.
5. **Reproduction Artifacts:** Publish an artifact that reproduces exactly the reported results, and supports changes to either the input or the details of the experiment.

Reproducibility has nuances. Our emphasis is on providing support for the following three use cases: *Repetitions* which run the reproduction artifact to obtain bit-for-bit equal results. This is the most stringent use case and often requires a reproduction artifact that bundles code and inputs. *Reanalysis* alters either the method or its input, it requires an executable artifact and a method for acquiring new inputs. Finally, *reproductions* are independent implementations that require the paper to have an unambiguous description of all experimental details.¹ Supporting reproducibility can be greatly simplified with appropriate tooling. Our work builds on the CodeDJ infrastructure (codedj-prg.github.io). Our contributions are:

1. **A dataset** of 2Mio+ projects with intrinsic attributes precomputed.
2. **A characterization of stars** as a means to select inputs for code analysis experiments.
3. **A methodology** that can be readily adopted to improve reproducibility.
4. **A reproduction** that highlights challenges to generalization due to project selection.

Our community has been moving towards broader adoption of the practice of artifact evaluation [11]. While artifacts are clearly helpful as they make papers providing them easier to reproduce, the selection of inputs is often hardwired and not considered part of the reproduction. The impact of our proposal, if adopted, would be to encourage authors of large-scale code studies to consider the collection of the inputs to their work to be part of the experiment and thus make it easy to change the way inputs are selected.

Road map. The structure of the paper is as follows.

- Section 2 begins with a short overview of the state with respect to methodologies for project selection and tooling to support it.
- Section 3 takes four practical examples, papers published at the Mining Software Repositories conference, and attempts to couch their experimental design in the terms introduced above. These example suggest that authors are not always clear about their intent and strategy. While looking at these papers we found a number of practical impediments to reproducibility.

¹ The terminology comes from [24] and was used by SIGPLAN artifact evaluation committees.

- Section 4 describes characteristics of the projects hosted on Github and argues that stars cannot yield a representative sample of developed projects.
- Section 5 outlines our proposal for how to design large-scale program analysis experiments.
- Section 6 follows our guidelines and attempts to repeat the studies of Section 3 while perturbing the experimental inputs.
- Section 7 is responsive to reviewers of this paper and their request to reproduce an experiment from a paper with a verified artifact.
- Section 8 concludes and gives some parting thoughts. This paper improves on the state of the art in that it argues for a structured experimental design that relies on tooling for input selection.

2 Related work

We review relevant advice, warnings and the state of tooling.

2.1 Community standards

A push towards reproducibility is underway. The standards framework of Ralph et al. [23] includes a section on experimental design and specifically on sampling. This is further explored by Baltes and Ralph [1]. They argue that software engineering faces a generalizability crisis. In their meta-analysis of 120 papers, they find that convenience sampling² is widely used to select projects to analyze from a large population. Convenience sampling rarely leads to representative samples, and – without a careful study of potential sources of bias – can lead to conclusions that do not generalize. They explain this state of affairs by a fundamental challenge: the lack of appropriate sampling frames to access elements of the population of interest. Earlier work by Nagappan et al. [19] already attempted to address this problem by defining the notion of sample coverage as a way to assess the quality of the data used as input to an experiment. Even closer to our paper is the study by Cosentino et al. [4] which reported that out of 93 large corpus papers, 63 papers failed to provide replication datasets. Most papers did not use random samples and omitted mentions of any limitations.

2.2 Mining repositories

GitHub is a popular data source. Warnings about its perils go back to the work of Kalliamvakou et al. [10] which highlighted “noise” among hosted projects. In particular, they point out, tiny and inactive projects dominate the platform. Lopes et al. [13] poured oil on that fire, showing that up to 95% of the files containing code in some language ecosystems were copies of one another and filtering by stars reduces the proportion of duplicates without eliminating them. One way researchers have strived to find signal in GitHub’s sea of noise is to use stars. But what do stars mean? We would like them to be correlated with quality code, code worth analyzing. Borges and Valente [2] conducted a user survey that found the most common reasons for starring a project was to show appreciation (e.g. *starred this repository because it looks nice*) and bookmark it (e.g. *starred it because I wanted to try it later*). They also warn against promotional campaigns to drive up ratings. Popularity of projects was studied by Han et al. [8], they found that while users believe stars are a measure of a project’s popularity, intrinsic attributes such as branches, open issues and

² The Wikipedia definition of convenience sampling is a type of non-probability sampling that involves the sample being drawn from that part of the population that is close to hand.

contributors are better predictors. Expanding on that result, Munaiah et al. [18] propose classifier for *engineered projects*, which they define as projects that leverage sound software engineering principles. They show that the classifier outperforms stars. Pickerill et al. [22] further improved classification with an approach based on time-series clustering.

2.3 Tools for miners

A number of infrastructures have been developed to assist researchers in the field. The most ubiquitous was, the now defunct, GHTorrent [6]. The project offered a continuously updated database of metadata about public projects that was a valuable building block for other tools. Boa is complementary as it lets users write sophisticated queries over source code [5]. CodeDJ is a newer infrastructure that supports queries over both meta-data and file contents and is language agnostic [15]. Recent works address performance issues of querying at scale [14, 17]. Of these, only CodeDJ ensures reproducible queries.

3 State of practice

How do people design experiments for large-scale code studies? This section gives some examples that we believe to be representative which we will revisit later when we attempt to reproduce the results with different inputs. For each paper, we provide a brief summary of the scientific claims made by the authors. Then, we attempt, with our best understanding of the work, to reverse engineer a version of the protocol laid out in the introduction. We, thus, give an account of each paper’s population hypothesis, a description of the frame oracle, sampling strategy, validation and reproduction artifacts. We conclude the section with some observations general reproduction issues that show up in these papers.

3.1 MSR 2020: What is software

“Software” has an intuitive definition, namely code, but there is more. The paper by Pfeiffer [21] classifies the content of repositories in categories such as code, data and documentation. They, then, observe that software is more than just code. Documentation is an integral constituent of software, and software without data is often correlated with libraries, and finally that software without code is rare, but exists. The paper answers the question “*what are the constituents of software and how are they distributed?*” The paper argues that existing definitions of the term are non-descriptive, inconclusive and even contradictory.

Population Hypothesis: Implicitly, the population is all inclusive.

Frame Oracle: Given the lack of details, we assume all projects on GitHub belong.

Sampling Strategy: the authors carry out convenience sampling by choosing popular repositories. Stating “*by popularity we mean the starred criteria with which GitHub users express liking similar to likes in social networks.*” Most-starred projects in 25 languages were acquired by executing one query by language, saying that “*without language qualifier, the API returns only 1,020 repositories in total, which we decided is not enough for our study.*”

Validity: No discussion of relevant issues or threats.

Reproducibility Artifacts: A listing of files and repositories is provided along with the code of the classifier and a notebook. Repository contents were not preserved.

3.2 MSR 2020: Method chaining

In an object-oriented language, a *method chain* occurs when the result of a method invocation is the receiver of a subsequent invocation. In Java, chains manifest as sequences of calls connected by dots. Nakamura et al. [20] analyze trends in usage of method chains and conclude that they increase over a period of eight years.

Population Hypothesis: Java projects developed “*by real-world programmers*.” The authors state that they “*did not apply any filter to the collected repositories. This supports the generalizability of our results*.” The authors also consider generalization beyond Java, saying “*our results are more likely to be applied to a language that does not provide such a construct (e.g. PHP and JavaScript). The empirical study of this hypothesis is future work*.”

Frame Oracle: Implicitly, all Java projects hosted on GitHub.

Sampling Strategy: The authors use convenience sampling, taking 2,814 projects that appeared at least once in the list of the 1K most-starred projects in November 2019. Projects were deduplicated and filtered for syntactically invalid files.

Validity: No discussion of relevant issues.

Reproducibility Artifacts: Project metadata and computed chain lengths are available. Communication with the authors reveals that their reproduction package is not available.

3.3 MSR 2019: Style analyzer

Each software project seems to develop its own formatting conventions. Markotsev et al. [16] demonstrate that an unsupervised learning algorithm can automate project-specific code formatting. They reproduce styles with a high degree of precision for a set of repositories.

Population Hypothesis: The authors speak of “*real projects*” and their artifact support JavaScript, so we assume an expectation that the projects “developed” in a sense similar to [18].

Frame Oracle: All developed JavaScript projects hosted on GitHub.

Sampling Strategy: Convenience sampling yielded 19 JavaScript projects with high star counts.

Validity: Authors manually inspected projects in the selection.

Reproducibility Artifacts: A GitHub repository containing the tool and a file with project URLs along with their head and base commits is provided. Contents of repositories are not included. Run scripts did not run out of the box.

3.4 MSR 2020: Code smells

Code smells are programming idioms correlated with correctness or maintenance issues. Jebnoun et al. [9] contrast code smells in projects related to deep learning and general purpose software. Their claim is that for large and small projects there is a statistical difference in the occurrence of code smells, whereas medium sized projects are indistinguishable.

Population Hypothesis: The paper focuses on two populations: projects related to deep learning, and general purpose software. For pragmatic reasons, they focus on Python as it is popular for machine learning.

Frame Oracle: Python projects with keywords indicating machine learning, discarding tutorials. Furthermore, the authors “*also carefully select popular and mature DL projects from them by employing maturity and popularity metrics (e.g., issue count, commit count, contributor count, fork count, stars)*.”

Sampling Strategy: A staged strategy was employed. The authors relied on judgment sampling to manually select 59 deep learning projects. For general purpose projects, they used a top-starred list of 106 Python projects from [3] and randomly sampled 59 projects. Projects were further clustered into small ($\leq 4,000$), medium, and large ($\geq 15,000$) based on size.

Validity: No issues were discussed.

Reproducibility Artifacts: A listing of the 59 deep learning projects is provided.

3.5 Summary and discussion

The papers we have reviewed do not explicitly talk about any of the four points in our protocol, in all cases we had to reverse engineer (or guess) some of them. This suggests that our proposal would improve the generalizability of the research.

While the mentioned research projects were done with care, there were challenges reproducing them out of the box. Common sources of reproducibility failures that occur in the papers we have reviewed are:

- *Missing descriptions:* Failure to specify either one of: population hypothesis, frame oracle or sampling strategy. Reproduction is fraught with perils and an apple-to-apple comparison between papers is difficult. This affects [21, 20, 16, 9] as their descriptions are open to interpretation.
- *Missing projects:* Even with a list of URLs, the corresponding projects may vanish at any time (e.g., deleted or made private). Reproductions are partial at best, we have seen a project disappear while being downloaded. This affects [21, 20, 16, 9].
- *Fading stars:* Stars are volatile. [20] observed close to 3,000 projects in the top 1K during a period of two months. Without a history of star attribution and a timestamp, reconstructing the star listings is not possible. Stars volatility also caused problems for [9].
- *Shifting contents:* The contents of a project change with new commits. To reconstruct the data, ids of the last observed commit must be specified. Even that is not foolproof as Git histories can be updated destructively. This affects [21, 20, 9].
- *Language attribution:* Projects contain code in many languages. For reproduction attribution must be specified. While delegating to, e.g. GitHub, is reasonable, one should be aware that GitHub has changed their attribution algorithm several times. Double counting a project is sometimes valid. This affects [21, 20, 16].
- *Deterministic replay:* Non-determinism must be limited. Random sampling seeds should be specified. This affects [16].

4 Mapping the GitHub landscape

The meta-study of Table 1 highlights the dominant position of GitHub as a data source in large-scale code analysis studies. The size of GitHub is such that it is necessary to resort to sampling to yield manageable datasets. As shown in the previous section, authors often look for some notion of “developed” projects, that is, they want projects that contains code of some quality.

We claimed that convenience sampling using stars as a proxy for various other characteristics of “real-world” software is flawed. While this may sound plausible to some readers, it should be backed up with data. Given the size of GitHub, this section uses sampling to answer the following questions: *Are starred projects a representative sample of all projects?*

and *Are starred projects a representative sample of developed projects?* where what it means for a project to be developed is purposefully left open as there is no agreement on a precise definition of the term.

Since the later parts of this paper require Java, Python and JavaScript, we acquire samples of these three ecosystems. We use CodeDJ to do this. It is an open source project that allows users to create a dedicated input project database and ensure reproducibility of queries.

We used random sampling over the entire GHTorrent dataset to select which projects to acquire in each of the languages of interest. The number of downloaded projects is somewhat arbitrary as it is based on available hardware during the acquisition phase. The datastore has 1,111,950 Java projects, 216,602 Python projects and 1,259,856 JavaScript projects. To give an idea of the scale, our Java dataset accounts for 20% of all non-forked GitHub Java projects. To get a manageable size, we down-sample further, randomly selecting 1Mio Java and JavaScript projects, and 200K Python projects.

4.1 Attributes

With CodeDJ, it is easy to write queries that compute project attributes. For this paper, we calculate five attributes that highlight the differences between projects:

- **C-index:** A developer handle has a C-index of n if that developer was party to at least n commits to n projects (i.e. n^2 commits). The C-index of a project is the highest such number across developers. This measures developer expertise.
- **Age:** The age of a project is the number of days separating the first commit and the most recent commit. This correlates with the maturity of a project.
- **Devs:** The count of unique developer handles in the git logs; includes both the author of a code change and the committer of that change. Devs approximates the size of a team, as some individuals may have more than one handle this is an upper bound.
- **Locs:** The total number of lines in files that are recognized as code, in any language, and appear in the head of the default branch.
- **Versions:** A version is implicitly created for each commit touching a file, be that for creation, deletion or update. This counts versions in the entire project's history including branches. Versions measure the activity in a project.

While we make no claims that these attributes suffice to fully describe a software project, we have found them to be an effective summary in many interesting dimensions.

4.2 Stars v. All

What do these attributes tell us about the overall population and about starred projects? If starred projects were representative of the entire population, they would share the same statistical distribution.

Fig. 1 is a histogram of each attribute; the x-axis is log scaled values in the unit of each attribute, the y-axis is the proportion of projects normalized for the maximum height. Grey denotes the whole population, red and blue denote the 1K most starred projects written in Java and Python respectively. The black, red and blue bars denote the median of their respective populations.

Consider the grey bars for the whole population, when comparing Java and Python, we see the same general shapes. The C-index is low, with a median of 2 for Java and Python. This means that half of the projects hosted on GitHub, have developers who have made at most two commits. The median age of Java projects is 7 days, while Python projects trend

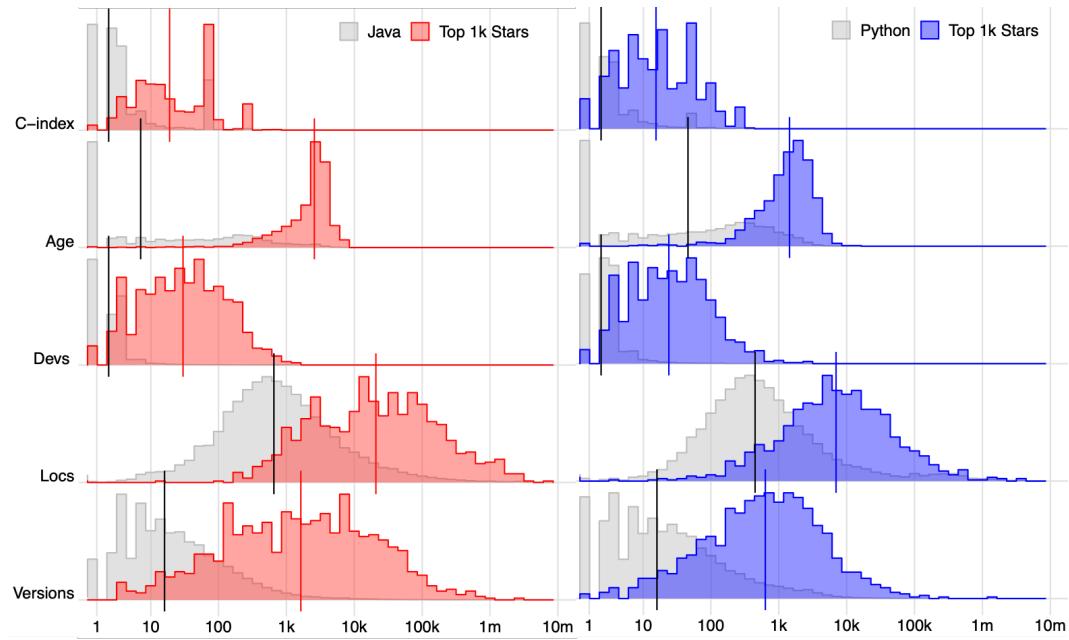

Figure 1 Comparing datasets.

slightly older, 46 days. The median number of developers for both languages is 2. As for median lines of code, Java project are slightly larger than Python, 655 compared to 448. The median number of commits (versions) is 16 for both languages. Overall, this confirms that most projects are small, short-lived and created by relative newcomers.

The top 1K starred projects have a very different make up. Visually it is clear from the fact that every distribution is shifted right. Starred projects are larger, older, with more experienced developers. While there are slight differences between languages, the overall picture is consistent.

Consider for instance, the C-index and age attributes. While many starred projects are team efforts, a significant number of projects have few contributors. Their C-index is high, with median of 19 for Java and 15.5 for Python, suggesting that experienced developers tend to contribute to popular repositories. The median age projects is more surprising with 2,581 and 1,440 days. Manual inspections suggest that many starred projects are indeed long lived but also have been inactive for years. Projects rarely “loose” stars, so if a project gets to the top there is a chance it will stay there long past its useful lifetime.

The answer to our first question is clearly negative. Starred projects are not representative of the overall population. This is not necessarily a bad thing, as folklore suggests that most of GitHub is uninteresting. Perhaps it is the case that starred projects are more “interesting.”

4.3 Stars v. Developed

Researchers often look for *engineered* [18, 22] or *developed* projects – informally, projects created with some care – alas there is little agreement on a precise definition.

Slightly easier, perhaps, is to settle on what we do not want, the projects that are uninteresting, one that are clearly of little value for any reasonable research question. Moreover, one could hope that the complement of uninteresting projects are the projects researchers look for. Let us define a project as *uninteresting* if it has less than 100 lines of

code, fewer than 7 days old, and fewer than 10 commits. When this definition is used to filter projects, this rather low bar manages to eliminate 71% of Java and 55% of Python projects. For the purpose of this discussion we term the remaining projects are developed or interesting. It would be nifty if stars were a proxy for filtering out uninteresting projects.

Fig. 2 shows the distribution of the whole population in Grey (in the same way as in Fig. 1), the interesting projects in Black and the top 1K starred projects in Red. Clearly, the shape of the Black and Red distributions do not align suggesting that stars do not represent interesting projects.

Manual inspection of the starred project highlights their main issue – stars are extrinsic properties without a direct connection to any attributes of a project. Unlike our computed attributes, stars grow monotonically. Their meaning is unclear as users award them for various reasons including humor and shock value. Some projects earned stars because of a joke not fit for this audience (e.g. github.com/dickrnn/dickrnn.github.io), or have dared users to star junk (github.com/gaopu/java). Stars do not measure quality or usefulness of repositories.

To further illustrate the limitation of stars as a filter, we take, for each attribute, the 20 projects with the lowest score for that attribute. Table 2 shows a manual classification of these projects. None of these projects is useful: externals lack histories, widgets are small and biased by their application domain, babies are too small to yield much insights, and the remaining ones only have code snippets.

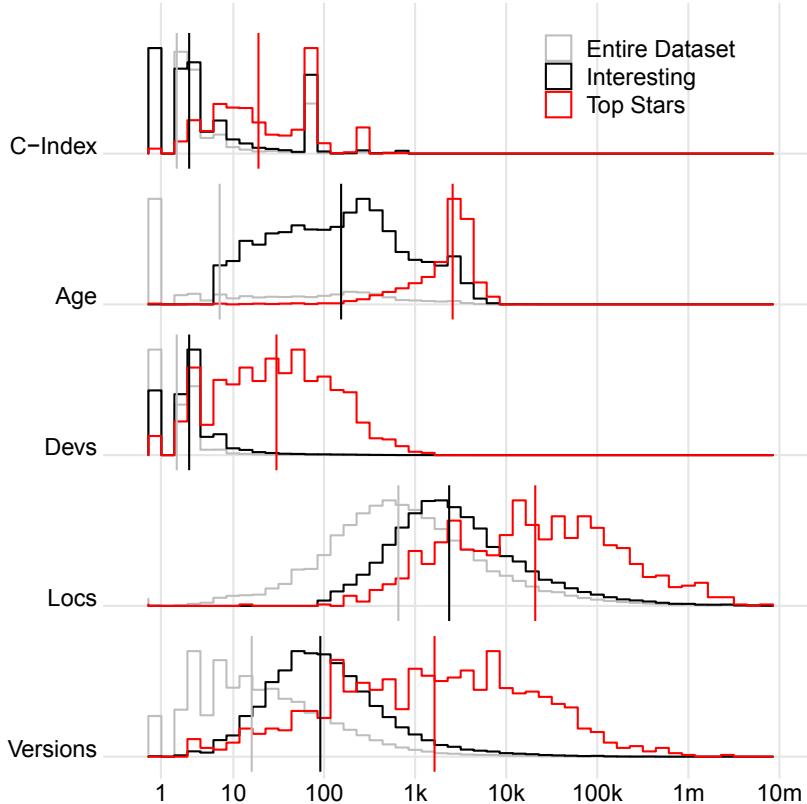

Figure 2 Comparing developed and starred projects.

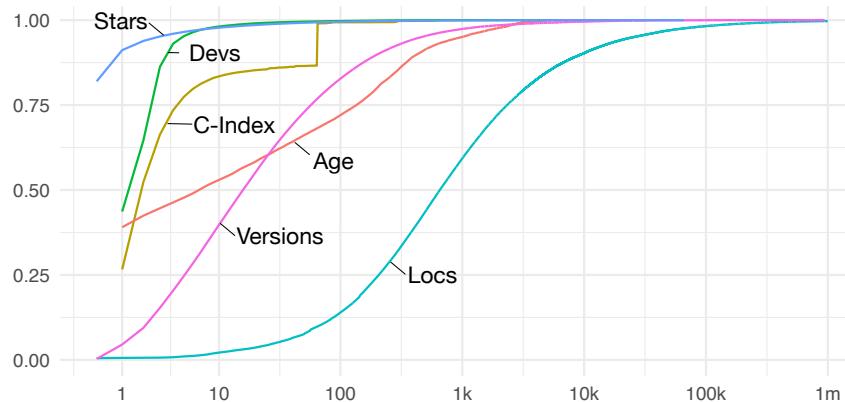

■ **Table 2** Categorizing 200 starred projects.

Category	Java	Python	Description
Externals	9%	5%	Infrequent synchronization with another repository.
Widgets	43%	0%	Tiny projects with little activity, popular UI widgets or plugins.
Docs	4%	15%	Interview questions, course materials, games, knitting patterns.
Tutorials	17%	9%	Educational materials, tutorials and example applications.
Babies	16%	32%	Valid but extremely small projects with little activity.
Artifacts	0%	21%	Research artifacts developed elsewhere and deposited for sharing.
Deprecates	1%	5%	Deprecated projects, no code on the main branch.

The answer to our second question is also negative. Starred projects are not representative of the interesting ones. To summarize what we learned about stars, they capture extrinsic characteristics of GitHub projects and are at best an indirect and noisy proxy for a robust frame oracle.

4.4 How to select projects?

What to use for project selection if not stars? We argue that selection must be based on intrinsic features – measurable attributes of a project’s contents. While one may use machine learning [18, 22] to build classifiers, in this paper we will use our five computed attributes (we leave machine learning as an interesting area of future work).

■ **Figure 3** Cumulative Density Functions.

Fig. 3 is the cumulative density function of the various attributes for Java (the shapes of the curves for Python are similar). The interpretation of each line is what percentage of the dataset is filtered for a particular attribute value. Project selection can be performed by a combination of attributes with cutoffs. We do not argue for a particular formula; researchers must make their own choices in this respect.

For instance, if one were to use 10 days of age as a cutoff, then 52% of the dataset would be filtered out. Whereas picking a 10 star cutoff, filters out 98% of projects.³

³ The discontinuity of C-Index at 65 is odd. After manual investigation, we found that there is a single developer with that C-index, it turns out that the “developer” is a bot doing automated updates.

4.5 Validity of our dataset

We noticed an oddity around project ages in our dataset. Experience with GitHub trained us to expect the unexpected. Our investigation started with a plot of creation dates.

Fig. 4 shows the log scaled counts of new projects over time. While there is a steady progression in the count of projects created each year, we see a significant drop in 2015 and a plateau until 2019.

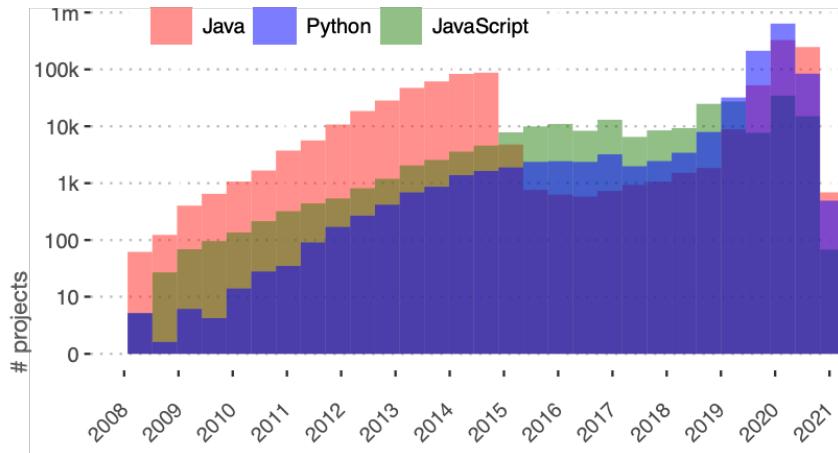

Figure 4 Creation date.

We reviewed our pipeline to no avail. We use GHTorrent to acquire all available URLs. Then, we randomly sample projects from that list. We validated both acquisition and sampling. This leaves us with two hypotheses. First is a consistent flaw in the CodeDJ downloader causing some projects to fail to download. 17% URLs obtained from GHTorrent point to dead projects, but there is no apparent bias. Second some projects could be missing in GHTorrent.

Another issue showed up on inspection, JavaScript project ages are significantly higher than those of other languages. We found that GitHub timestamps are frequently inconsistent. Why should JavaScript be more affected? Until an explanation can be found, we removed JavaScript from the overall comparison and use JavaScript projects in the reproduction with extreme care.

5 Reproducible large-scale analysis experiment design

This paper proposes that researchers conducting experiments over large-scale software repositories follow a specific experimental design methodology to ensure their work can be reproduced and increase chances that their results generalize as expected. While the mechanics of reproducibility of the actual experiment itself vary, the setup of the experiment is a common problem. The proposed methodology has five steps, we encourage researchers to document each of these steps explicitly.

5.1 Population hypothesis

Formulating a population hypothesis lets researchers stake a claim about the applicability of their work. This represents the population to which the result of an experiment should generalize to. The statement of that hypothesis can be brief and appeal to intuition, the other parts of the description flesh out the details.

Ideally, we would like our results to be as broadly applicable as possible, but pragmatically designing experiments that back up overly broad claims is difficult. Some populations of interest are difficult to sample, for instance “commercial software” is a relatively simple and unambiguous description but one that we typically cannot sample from as most of the commercial software is not in the public domain. Other populations can be difficult to identify. Imagine a study of the challenges linked to retraining imperative programmers to use functional idioms. Finding code written by such developers can be done manually but is difficult to automate. It is often easier to describe a population by intrinsic features of projects such as the language used to write the code or some estimate of the size of the project.

5.2 Frame oracle

A frame oracle is a, possibly noisy, deterministic algorithm for deciding if a project belongs to the population of interest. The oracle is our best approximation of the population of interest. An executable and reproducible oracle allows to compare different papers with the same selection. The description of the oracle should specify the data source along with any information required to acquire projects. The procedure for evaluating a project should be clear and based on intrinsic attributes. A paper should at least have a short description of the oracle, full details should be given in the reproduction artifact.

5.3 Sampling strategy

The literature has an abundant advice on sampling (see e.g. [12]). Briefly, a sampling strategy picks the type of sampling (probabilistic or non-probabilistic) and describes the steps used to obtain a sample. The sampling implementation is expected to be found in the reproduction artifact.

Many works use convenience sampling as it is simpler, cheaper and less time consuming. A better alternative is some form of probabilistic sampling as it is more likely to yield a representative sample. Probabilistic sampling can be staged if the structure of the population is more complex. The simplest approach is random sampling where each element has the same chance of being picked. We often have to resort to stratified sampling when the population is divided into subgroups of different sizes. Typically we sample without replacement as we do not want to pick the same project multiple times.

5.4 Validity

The validity section argues, when there are reasons for doubt, why using the frame oracle and the sample strategy results in representative samples of the population of interest. This section should address potential sources of bias and attempts by the authors to control for them. This section also should address any foreseen challenges to reproducibility and offer means to mitigate them.

5.5 Reproducibility artifacts

Finally, we advocate to link the paper to a reproduction artifact that contains code and data to support experimental repeatability and reanalysis.

Section 3 listed issues with reproducibility. In some cases, the authors did not give a precise description of the steps needed for reproduction. Following our proposed methodology along with a reproduction artifact will greatly help.

The second category of issues are more pragmatic, it is difficult to repeat the analysis of a paper because some aspect of the data used is not available. We suggest that research infrastructures should support this task.

An example of an infrastructure is CodeDJ which is both a continuously updated datastore and a database that can be queried by a DSL. We adopted it for our work and illustrate how it helps with reproducibility. The implementation of a frame oracle and sampling strategy can be combined into a single expression. Fig. 5 shows a query which starts by filtering out projects containing fewer than 80% JavaScript code, then it uses pre-computed attributes Locs, Age and Devs to filter further. The last stage of filtering involves computing an attribute on the fly, here we sum up the commits in the project, before performing random sampling.

```
database.projects().filter(|p| {
    p.language_composition().map_or(false, |langs| {
        langs.into_iter().any(|(lang, rate)| { lang == JavaScript && rate >= 80 })
    })
})
.filter_by(AtLeast(Locs, 5000))
.filter_by(AtLeast(Age, Duration::from_months(12)))
.filter_by(AtLeast(Devs, 2))
.filter_by(AtLeast(Count(Commits), 100))
.sample(Random(30, SEED))
```

Figure 5 Project selection with CodeDJ.

CodeDJ is split between a persistent datastore in which every data item is timestamped, and an ephemeral database used to service queries. A reproducible query is a Rust crate archived in a git repository associated to the datastore. Running the query produces a *receipt* which is the hash of a *commit* automatically added to the archive repository. The receipt can be used to share the query (exactly as executed) and its results (exactly as produced). It can be used to retrieve the Rust crate and re-execute the code. Code re-execution is helped by the fact that queries are deterministic and the crate contains a list of all dependencies, a timestamp, and all random seeds. When a query with an embedded date is executed, CodeDJ accesses the exact state of the datastore at the specified date. Since CodeDJ stores the contents of files, entire experiments can be fully reproduced.

6 Reproductions

We illustrate the use of the proposed methodology by revisiting the papers we discussed in section 3. For each paper, we attempt reproduction where we vary the input. The original papers used stars in their selection, we will explore different inputs based on intrinsic attributes.

If the results of the reproduction match the original results, then it suggests that stars were an appropriate filter. If the reproduction departs, this suggests that there may be need to conduct further experiments to be confident in the results.

For each paper, we picked a subset of the scientific claims to fit the reproduction in the available space. We use our proposed methodology to describe the details of the reproduction.

One may wonder how we selected the paper to reproduce. Our criteria were (1) papers that used automated techniques to analyze properties of the code contained in Github projects, (2) their population of interest was a large subset of Github, (3) a working artifact could be located, and (4) the input could be changed with ease. We did not cherry-pick as even positive results would be interesting. Our choice was limited by the fact that many

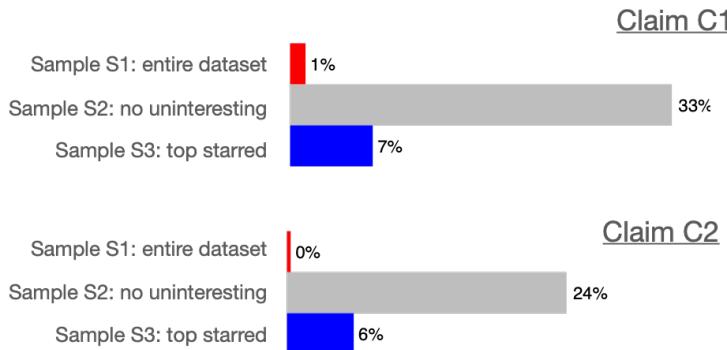

Figure 6 Proportion of projects without code, data or documentation.

papers either did not have artifacts or that they were not working anymore. Furthermore, some papers had hardwired their selection of projects by, for example, preprocessing the input data and omitting to include the tooling to repeat that processing. Given more time, more works could be reproduced.

6.1 Reproduction: What is software

This reproduction aims to validate two findings of [21]: (C1) 4% of repositories do not contain code, data and documentation; (C2) 2% of repositories do not contain documentation.

Population Hypothesis: The universe of software projects.

Frame Oracle: To understand the impact of project selection we consider two oracles. O1 accepts any project hosted on GitHub. O2 removes uninteresting projects (as defined above).

Sampling Strategy: We report on three samples. S0 is a convenience sample of starred following [21]. S1 and S2 are random samples without replacement from O1 and O2 respectively, stratified by language and deduplicated.

Validity: Our reproduction differs in the number of languages (3 v. 25) and by categorizing files based on the file path alone. We tested stability of our results with multiple samples of varying sizes and manually inspected the produced labels.

Reproduction Artifact: Our artifact contains a CodeDJ receipt for this query.

6.1.1 Results

Fig. 6 shows results for claims C1 and C2. Compare the percentages between S0 (original) and S1 (target population). Statistical analysis is not required to see that the difference is significant. The sample S2 (without uninteresting projects) is there to illustrate the impact of slightly more developed population, but even these are still quite different.

Would the results agree if we included more languages? The three languages we downloaded account for most of GitHub, it is conceivable that other languages could affect results, but that would just push the generalizability issue somewhere else as the claims would become language-specific.

6.2 Reproduction: Method chaining

Nakamura et al. [20] claim that 50% of projects in 2018 had method chains longer than 7 while in 2010 that number was 42%. They state that “chains of length 8 are unlikely to be composed by programmers who tend to avoid method chaining, this result is another supportive evidence for the widespread use of method chaining.”

Population Hypothesis: The universe of real-world Java programs.

Frame Oracle: We accept any Java project hosted on GitHub and delegate to Github for language attribution.

Sampling Strategy: Stratified sampling to randomly select projects with commits in 2010 and 2018.

Validity: To reproduce the original results, we performed stratified sampling to get top starred projects active in the target years. The authors used a different sample of top stars. The original paper had different sample sizes for each year, but those are not specified. We fix the sample size to 250. The authors could not locate the code of their chain detector, so we use our own implementation.

Reproduction Artifact: Our artifact contains a CodeDJ receipt for this query.

6.2.1 Results

Fig. 7 shows the difference in proportion of projects at various chain lengths. The solid line uses stars, colors represent different random samples. For instance, if we pick chains of length 8, the number used by [20], the difference is a 13% increase in the number of projects between 2011 and 2018. The differences for our random samples are -2%, 0.6% and 0.7%. In other words, the samples from this particular population do not seem to show the effect expected by the authors. We surmise that some notion of developed project may show more favorable results, but without more guidance in the population hypothesis it is hard to guess which to pick.

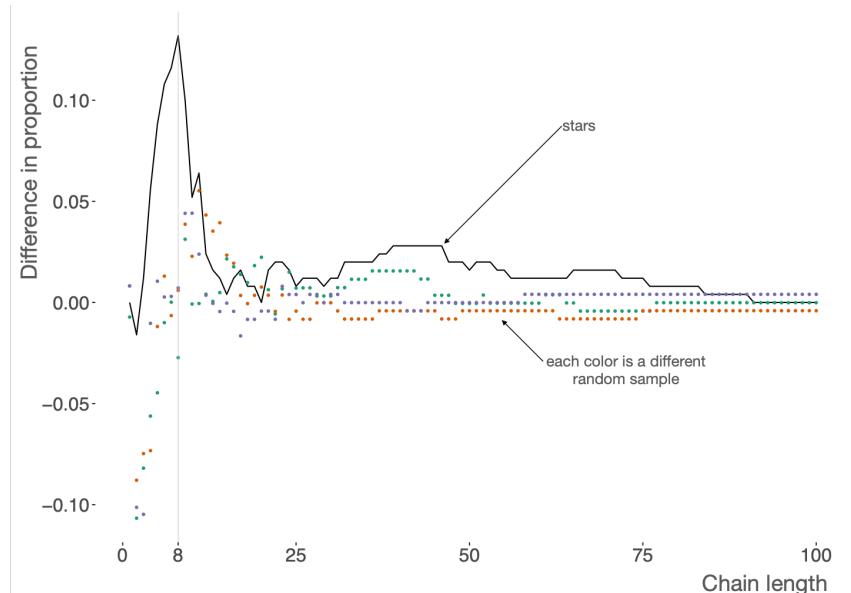

Figure 7 Difference in chain lengths.

6.3 Reproduction: Style analyzer

Markovtsev et al. [16] builds a model of the style of a repository and apply this model on a held-out part of that repository to produce corrections. Their experiment uses 19 top-starred JavaScript project to gauge the precision with which the tool flags formatting discrepancies and the relationship between this precision and the size of the project. They report a precision of 94% (average, weighed by project size) and better overall performance for large projects and projects with better style guidelines.

Population Hypothesis: Developed JavaScript projects.

Frame Oracle: JavaScript projects with at least 80% JavaScript code, $\text{Loc} \geq 5000$, $\text{Age} \geq 12 * 31$ and $\text{Devs} \geq 2$.

Sampling Strategy: We randomly select 10 sets of 30 projects. This is more projects than the original sample to account for errors in processing. After processing is finished, following the original paper, we randomly select 19 projects out of the pool of successfully processed projects.

Validity: Given that the author's artifact lacks a configuration, we used the default one. This increases project size, as compared to the published numbers, by 38% per project (up to a maximum of 154%) and causes precision to diverge by 2.2% on average, and up to 7.9%.

The tool failed to process 4 projects: `freecodecamp` and `atom` due to errors in unicode processing, `express` due to a programming bug, and `30-seconds-of-code` due to bad file identification. Three of the missing projects were located close to the median in terms of precision, prediction rate, and project size in the original paper, while `axios` was in the lower quartile for sample count.

Style analyzer analyzes each project at two points in its history specified by a base commit and a head commit. The base commit is a point in the past which the tool checks out to learn the project's formatting style. The head commit is a more recent point used to evaluate the model and calculate precision. The original paper provides head and base commits for each project in their experiment, but does not specify the method of selecting these commits. We pick the current head of the default branch as the head commit. For base commit we pick one that lies at an offset equal to 10% of the number of all commits in the default branch from the head commit. This retrieves different commits than the original paper, which causes a 3% median change in precision (up to 17%– `telescope`) and a median project size increase of 76%, and up to 311% (`reveal.js`).

Reproduction Artifact: Datasets, receipts from submitted queries, style analyzer's reports and scripts for the entire experimental pipeline are included in the artifact.

6.3.1 Results

We recreate a plot of the effect of the number of items in the training set on precision from the original paper in Fig. 8. The training set consists of snippets created around tokens/AST nodes relevant to formatting (whitespace, indentation, quotes, zero-length gaps). We plot the selection from the original paper along three selections from our interesting project frames. In addition, we plot the distributions of precision in each selection in

In Fig. 9, we compare the precision scores in each sample with the selection used in the original paper using a Mann-Whitney U test to show which samples performed statistically differently from the original. The scatter plots show a different grouping of results from the original paper. The groupings in the scatter plot visibly differ between selections. The distribution comparison shows that our selections generate significantly smaller training

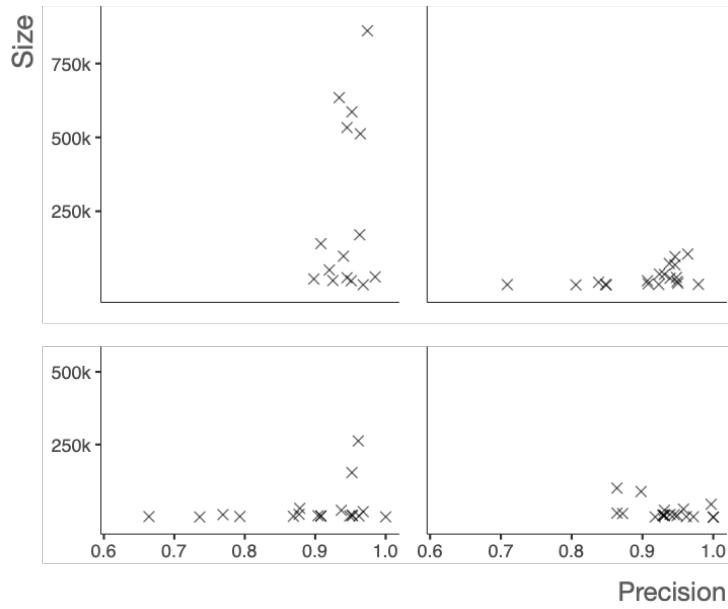

Figure 8 Relationship between label groups and precision.

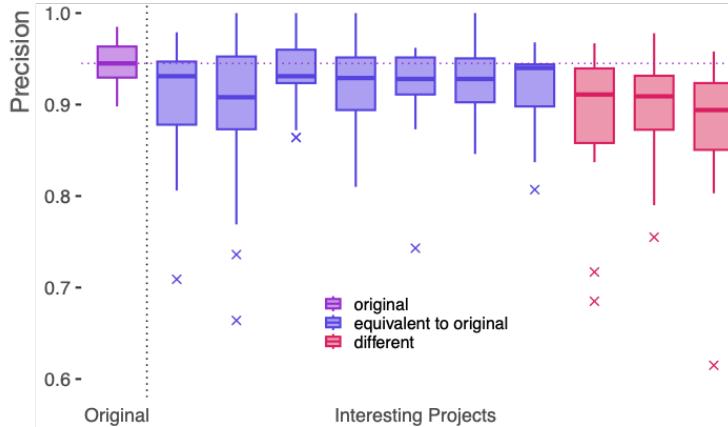

Figure 9 Comparing label group count and precision.

sets in all cases and yield lower precision. In addition, 3 out of the 10 interesting project selections produced significantly lower precision, with the remainder producing a statistically equivalent distribution.

Overall, we see our selections yielding precision between 0.9 and 0.95 (the paper sets a precision of 0.95 as a benchmark for success). We also do not see a clear relationship between the number of label groups and precision, such as the one the authors note in the original paper.

6.4 Reproduction: Code smells

We seek to validate the claim of [9] that for large and small projects there is a statistical difference in the occurrence of code smells between machine learning and most popular Python repositories, whereas medium sized projects are indistinguishable.

Population Hypothesis: Mature Python projects in all application domains including machine learning.

Frame Oracle: Projects with $C\text{-Index} \geq 5$, or $\text{Age} \geq 180$, or $\text{Locs} \geq 10,000$, or $\text{Versions} \geq 100$.

Sampling Strategy: The deep learning projects were provided by the authors. Out of 59 projects, 57 were still accessible on August 2nd 2021. At download time there were 6 small, 13 medium, and 38 large deep learning projects. For the reproduction of the original results, we used a staged strategy, first convenience sampling the top starred Python projects and amongst those used stratified sampling to select 57 projects with a similar distribution of sizes. To generalize the results we used quota sampling to match the size distribution.

Validity: Our reproduction uses the Locs reported by CodeDJ. The date the authors downloaded the repositories is unknown. We use the content of the main branch of each repository as of April 1st, 2020. The authors say “*each of repositories is pre-processed and prepared for code smell detection*”, however details are missing. We used the default thresholds of their tool.

Reproduction Artifact: A CodeDJ receipt is included in our reproduction package along with code to run the experiment.

6.4.1 Results

Fig. 10 contrasts the distribution of code smells for deep learning projects, top starred projects, and three random samples. Computing the p-values with the non-parametric Mann-Whitney Wilcoxon shows that while we were able to reproduce the statistically significant results for the small projects, we disagree on the large most popular projects with the original. The disagreement is even greater in the random samples where no large projects and only one small project is statistically different. Generalizability of the results is thus questionable.

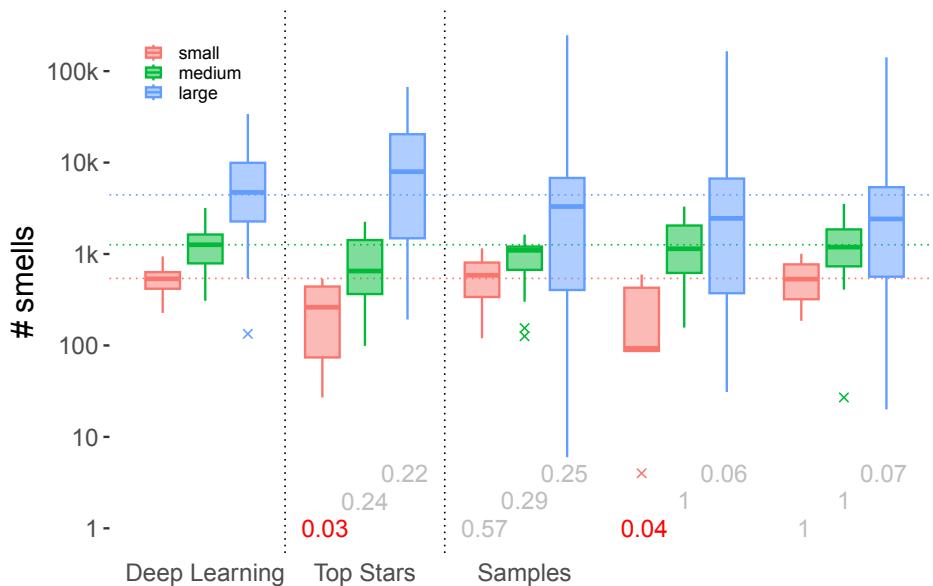

Figure 10 Comparing Smells. Numbers are p-Values indicating a significance of the difference from the deep learning projects. Statistically significant different p-Values (cutoff at 0.05) are shown in color, insignificant ones are in gray.

7 Collaborative Reproduction

We perform one last reproduction in which we obtain the assistance of the study’s authors to validate whether stars are a good input selection strategy. For this reproduction we selected a distinguished paper from the Foundations of Software Engineering conference (2020), “The Evolution of Type Annotations in Python” [7]. The paper has a reusable artifact for repetition of the original results. Our reproduction only required to change the list of GitHub URLs used as input in the analysis. The authors helpfully allowed us to run the rather computationally intensive workload on their machine.

The original study reported the following protocol for input selection. *“We group projects by creation date, considering projects created in the years 2010 to 2019, into ten groups. We sort each group by number of stars and select the top-1000 per group, which yields a total of 10,000 projects. The rationale for first grouping and then sampling is to avoid biasing our study toward projects created in a particular time frame, e.g., mostly old projects. Removing projects that we could not clone, e.g., because they became unavailable since the beginning of our study, the total number of analyzed repositories is 9,655.”*

The first research questions was related to the evolution in the number of type annotations in projects. The main insight from the work was that *“better developer training and automated techniques for adding type annotations are needed, as most code still remains unannotated, and they call for a better integration of gradual type checking into the development process.”*

For this reproduction, we discussed input selection criteria with the authors and arrived at the following formulation.

Population Hypothesis: Python projects in all application domains with earliest commit date in 2015⁴ as this was the year when early adoption of type annotations began.

Frame Oracle: Python projects whose life span is longer or equal to 7 days and that have over 100 lines of Python code. The study authors intended their work to be representative of most of the Python ecosystem, but closer inspection of some of the small projects suggested that they would introduce noise. The particular cutoffs were chosen heuristically.

Sampling Strategy: Projects were grouped by year active and, for each year, a random sample of 1200 projects was selected. The goal was to get close to a thousand usable projects for each year. As some of the projects in our database are no longer available, the sample size is increased heuristically.

Fig. 11 illustrates the reproduction results (and mirrors Fig. 2 in [7]). The plot on the left shows the number of type annotations found per thousand lines of code in the projects being looked at. The red line has the new data, the blue one is for the original study. The y-axis is logarithmic. The two lines start at zero in 2015. Both data sets tell a similar story: type annotations are gradually added to projects. The plot on the right shows the total number of annotations found each year in all projects. The y-axis is in thousands. In 2021, the original data had close to 800,000 annotation while the new data is under 250,000.

Both data sets are large. The original one contains 1,123,393 commits and the new data set 1,535,824 – suggesting that projects are slightly larger in the randomly selected data than in the most starred projects. In both cases, only a fraction of the repositories have types. In the old data 668 repositories are type-annotated, whereas in the new data 1,040 projects have at least one type. The fraction of commits that change a type annotation is small in both cases 5.5% in the original data and 2.1% in the new data.

⁴ 2015 is when type annotations were added to Python.

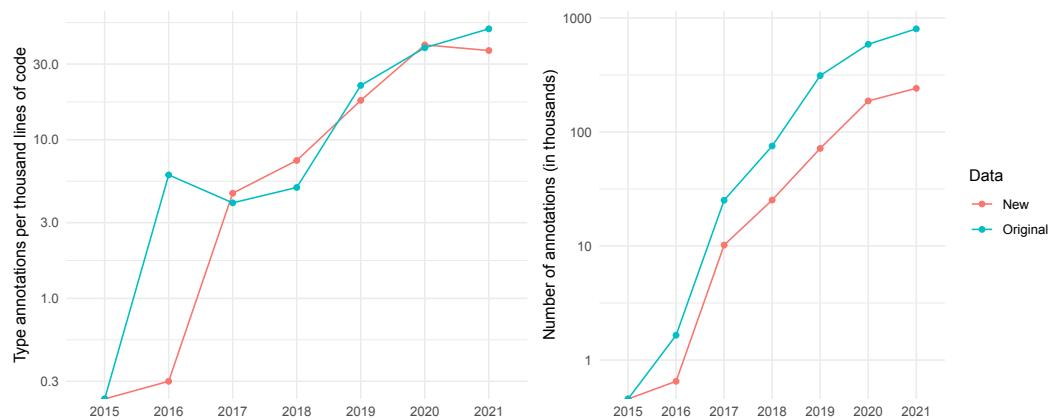

Figure 11 Types in Python.

Overall, the reproduction verifies and, even, strengthens the conclusion of the original paper. Five years after introduction of type annotations, their use remains rather limited. Having said this, it is true that actual values reported are different enough to be noticeable.

8 Conclusions

Sometimes, doing it wrong is so much easier than the alternative, that we convince ourselves that a little wrong can be right enough. Our paper is unusual. While it purports to contain a call to arms for better experimental practices, it is just as much a record of our own journey to that goal. What reads as criticism is really written in self-reflection. So, what can a researcher take away from this paper? There are three ideas we would like to leave the reader with.

Generalizability. The value of an experiment often lies as much in what it generalizes to, as in the experiment's outcome. We found that many researchers rely on GitHub stars to pick representative samples of software projects, yet starred projects tend to be larger in most dimensions than typical ones, also that they are more likely to be inactive, and that their ranking is not a measure of intrinsic qualities of the code. Hopefully, this paper is the last nail in that coffin. More generally, we advocate for the use of probabilistic sampling over populations defined by intrinsic attributes of software, and also for clear and standardized documentation of experimental design.

Reproducibility. The value of a scientific experiment also lies in our ability to reproduce it. Carrying out reproducible experiments over large-scale software repositories is hard. Especially when aiming to support the three reproduction modalities: repetition, as practiced in artifact evaluation, where an artifact is re-executed to obtain identical results; reanalysis, where the artifact or its input are modified; and independent reproduction, where the entire experiment is re-implemented from scratch. The first modality requires faithful replay and is best served if all data used is included with the artifact. The second, requires support for automatically acquiring new representative samples. The third needs an unambiguous description of all experimental steps. We advocate for reproductions artifacts that supports the first two modes, and a detailed description of the experiment for the last.

Tooling. Generalizability and reproducibility, while worthy goals, represent much work, and they are work that is orthogonal to the scientific goals of researchers. The only reasonable answer is to provide tooling that automates acquisition of representative samples and generation of reproduction artifacts. In this paper, we used CodeDJ and found it helpful as it let us specify queries over attributes of the code for many projects, while also supporting experimental repetition and reanalysis through historical queries. It has its limitations, we found execution times to be somewhat long and doubt it will scale to the whole of GitHub.

Our vision for a brighter future is one where the community agrees on standard tools and techniques for this kind of experiment, tools which automate the acquisition and packaging of input datasets and the re-execution of entire experiments.

Static Basic Block Versioning

Abstract

Basic Block Versioning (BBV) is a compilation technique for optimizing program execution. It consists in duplicating and specializing basic blocks of code according to the execution contexts of the blocks, up to a version limit. BBV has been used in Just-In-Time (JIT) compilers for reducing the dynamic type checks of dynamic languages. Our work revisits the BBV technique to adapt it to Ahead-of-Time (AOT) compilation. This Static BBV (SBBV) raises new challenges, most importantly *how to ensure the convergence of the algorithm* when the specializations of the basic blocks are not based on profiled variable values and *how to select the good specialization contexts*. SBBV opens new opportunities for more precise optimizations as the compiler can explore multiple versions and only keep those within the version limit that yield better generated code.

In this paper, we present the main SBBV algorithm and its use to optimize the dynamic type checks, array bound checks, and mixed-type arithmetic operators often found in dynamic languages. We have implemented SBBV in two AOT compilers for the Scheme programming language that we have used to evaluate the technique's effectiveness. On a suite of benchmarks, we have observed that even with a low limit of 2 versions, SBBV greatly reduces the number of dynamic type tests (by 54% and 62% on average) and accelerates the execution time (by about 10% on average). Previous work has needed a higher version limit to achieve a similar level of optimization. We also observe a small impact on compilation time and code size (a decrease in some cases).

1 Introduction

Optimizing compilers perform various analyses to discover properties of the program that are preconditions for performing optimizations. In a Just-In-Time (JIT) compiler, the cost of these analyses and optimizations is a critical issue as the time they take becomes part of the program's execution time. The use of expensive analyses and optimizations incur a long *warm-up* where the first part of a program's execution is sluggish and the program may even terminate before it has reached an optimization steady state.

Basic Block Versioning (BBV) is an optimization approach that strikes a balance between the optimization cost and the speed of the generated code to achieve a fast warm-up time and reasonably good execution speed. BBV has been used in JIT compilers for dynamically typed programming languages; in research compilers for JavaScript [5, 6] and Scheme [27, 28], and it is now used successfully in production in the official Ruby implementation [7, 8].

BBV uses the program's Control Flow Graph (CFG) created by the compiler as a template for creating a specialized CFG. For this, BBV traverses the CFG starting at its entry point while keeping track of the *context* that contains program properties of relevance

for specialization, such as the type of the values contained in the live variables. Each basic block has a set of contexts. The information contained in this set is *conservative*: for each possible program state when that basic block is reached during a program execution, there must be at least one context consistent with that state. Due to its conservative nature, it is allowed to have unreachable contexts in the set. In principle, each basic block of the original CFG could be specialized to all contexts in its context set, including unreachable contexts. The specialized versions of a basic block may contain optimizations that are valid in the corresponding context, such as the elimination of type checks when the type of a value has been determined at an earlier point in the execution.

An important concern is that multiple specialized copies of each basic block may be created, leading to a larger amount of code (*bloat*) and a longer compile time, load time, and execution time (due to the reduced performance of the instruction cache, among other reasons). In theory the bloat can be exponential in the size of the program.

Previous works use the same approach to this issue: a cap is placed on the number of versions for each basic block (*i.e.*, the number of versions is no greater than N , typically a small number like 5 or 10). In a JIT compiler the versions of a basic block are generated as the program's execution advances and reaches a basic block with a new context. This variant of BBV is called *lazy* BBV. When a new context is encountered and this would cause the version limit to be reached, a version specialized to that context must not be created because it would prevent another specialization if one was needed later in the execution. Instead, a *fully generic* version that covers all possible contexts is created as the last version and is used whenever a new version would be needed. Lazy BBV is relatively simple to implement but it has some important limitations:

- **Lazy BBV is a greedy algorithm.** The versions that are generated before the generic version, which are the first ones encountered at execution time, may not be the versions that are part of hot code. For example, if some function is used both during the initialization phase and in the main part of the program, then the specializations will be focused on what happens in the initialization phase. This function may be hot code when called from the main part of the program in a new context and, because the version limit is reached, it will be using the generic version (likely the slowest of them all).
- **High specialization is hard to achieve reliably.** The precision of the versioning context, *i.e.*, the number and information content of the program properties it tracks, has a direct impact on how quickly the slow generic version is used. For example, a precise versioning context that tracks not only the type but the range of values of an integer loop iteration variable starting at 1 and incremented at each iteration, will be able to create specialized versions of the first few iterations of the loop body (one version for each specific value of the iteration variable below N). This will not work well for loops that have a large number of iterations, because the iterations N and above will be handled by a slow generic version of the loop body. On the other hand, a context of this precision will work very well for programs where the loops have fewer than N iterations because BBV will completely unroll these loops. The BBV implementer will have to choose a moderate precision of the versioning context to avoid using the generic version too quickly, and consequently this will miss optimizations in some cases, such as total loop unrolling.
- **It requires JIT compilation.** The nature of a JIT compiler makes it easy to ensure that versions for unreachable contexts are never created. Unfortunately, this entails a warm-up time at execution, and in some use cases JIT compilation is not an option. In [5], an *eager* variant of BBV suitable for an Ahead-of-Time (AOT) compiler was described and compared to lazy BBV. That implementation of eager BBV yielded comparatively

poor speed and bloat because specialization is not guided by the actual need of a program execution and parts of the CFG that are explored are not typically executed, such as error cases and out-of-line handlers. Consequently, the specialized versions created before the limit is reached are more likely to be irrelevant at improving execution speed.

In this paper we describe a new design for a BBV algorithm suitable for an AOT compiler that mitigates these limitations. Our algorithm also traverses the CFG to determine which contexts reach each basic block. The first main difference with previous work is the handling of the version limit. When a new context is encountered and this would cause the version limit to be exceeded, the algorithm heuristically chooses a pair of contexts reached for that basic block and replaces them by a *merged* context that is more conservative than the contexts in the pair (in other words, a more general context). The algorithm continues traversing the CFG until a fixed-point is reached, *i.e.*, no new versions need to be created. The use of context merging allows contexts to be very precise at first, and it is the algorithm that reduces the precision as needed to keep the number of versions within the limit. The second main difference with previous work is the refinement of the notion of types to integer intervals to allow the BBV optimization to remove integer arithmetic overflow checks and array indexing bound checks.

In the next section, we present our algorithm and discuss its termination. In Section 3 we extend the algorithm with more precise contexts. The implementation in two mature compilers is explained and evaluated in Section 4. Related work is given in Section 5.

2 The Static BBV Algorithm

In this section we present the *Static* BBV (SBBV) algorithm. We will start with an overview by illustrating the algorithm's behavior using the traditional `find` function that many dynamic and functional languages provide.

2.1 SBBV by Example

The `find` function takes a predicate and a list of values and it returns the first element of the list that satisfies the predicate or false if no such element is found. In the Scheme programming language [17], which we use throughout this paper, it can be defined as:

```

1 (define (find p x)          ;; p is the predicate and x is the list to search
2   (if (pair? x)            ;; is the list non-empty?
3     (if (p (car x))       ;; call predicate on the first element
4       (car x)              ;; return it if it satisfies the predicate
5       (find p (cdr x)))    ;; otherwise, continue searching the rest of the list
6     #f))                  ;; return false when no element in the list satisfies the predicate

```

The safety of this code is guaranteed by verifying the validity of the arguments of the primitive operations at run time. In this example, the primitive operations for which a type verification is needed are the `car` and `cdr` accessors (lines 3-5) and the function invocation of the predicate (line 3). In safe mode, a Scheme compiler adds the required dynamic checks to the code, making the possible points of failed safety checks explicit:

```

1 (define (find p x)
2   (if (pair? x)
3     (if ((if (procedure? p) p (fail)) (if (pair? x) (car x) (fail)))
4         (if (pair? x) (car x) (fail))
5         (find p (if (pair? x) (cdr x) (fail))))
6     #f))

```

Here we use calls to the `fail` function to indicate cases where execution cannot continue due to a failed verification. The `fail` function is special in that it never returns.

One might expect a smart compiler, such as one implementing *occurrence typing* [32], to discover that the type tests on x are redundant, but let us assume that no such optimization is applied. This is done for illustrative purpose and because one of our objectives is to show that SBBV subsumes other optimization techniques, such as occurrence typing.

The unoptimized CFG of `find` is displayed in Figure 1a. SBBV will produce an optimized version of that CFG with fewer dynamic checks. For that, it propagates the information about variables in order to produce *specialized* versions of the basic blocks. For instance, block #12 (Figure 1a) checks that the end of the list is not yet reached by testing if x is a pair. In the positive branch, that is the path starting at block #4, it is known to be a pair and no further type tests are needed to ensure the correct execution until an assignment to x occurs (*i.e.*, the other tests that x is a pair are redundant).

The CFG produced by SBBV is shown in Figure 1b. We observe that SBBV has isolated the first iteration of the loop of the `find` function and the other iterations are handled by the loop formed by the subgraph $\{ \#23, \#25, \#27, \#29, \#31, \#32 \}$. In that loop the type of p is never tested because it has been tested in the first iteration before entering the loop handling the other iterations, and the argument x is only tested once per iteration, which is a necessary part of the loop termination logic. We also observe that for this simple example, SBBV has produced an optimal CFG in the sense that in a dynamic context with no global knowledge about the variable types and the data structure types, it executes the minimum number of dynamic checks required to ensure a safe execution. In Section 4.2 we evaluate the number of type tests SBBV is able to remove on more realistic programs.

In the rest of this section, we present and explain the algorithm that transforms the graph of Figure 1a into that of Figure 1b.

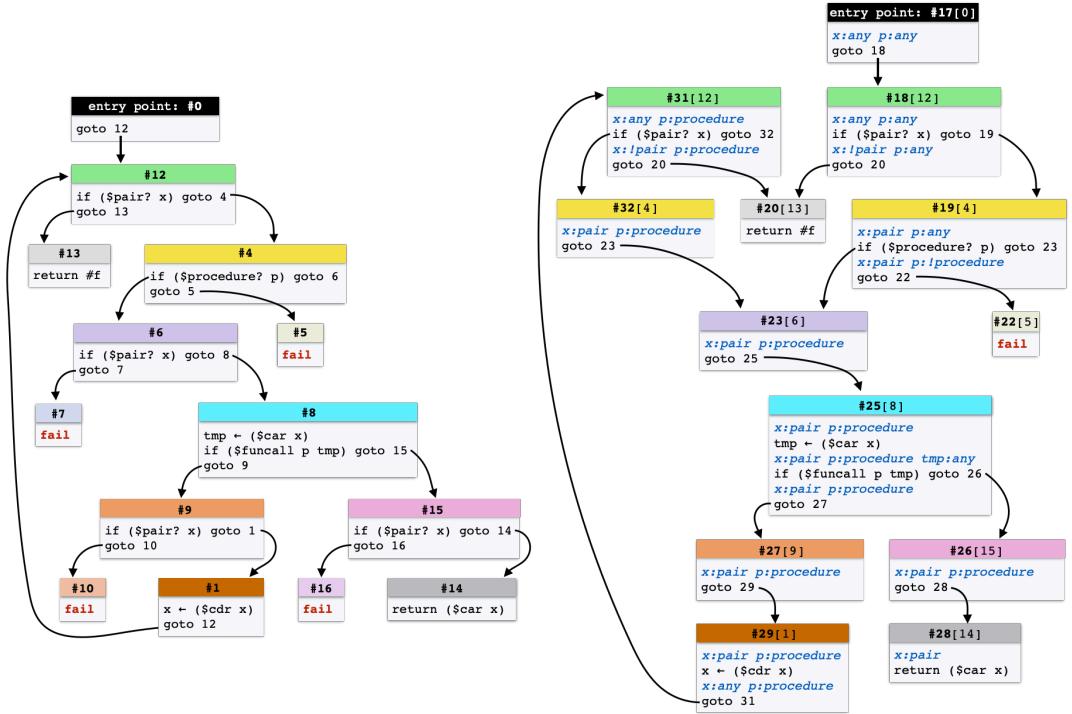

2.2 The Algorithm

SBBV specializes a CFG, which might either denote the whole program to be compiled or only a fragment of it. For instance, it can be decided to use SBBV for specializing each function in isolation or to specialize the whole program at a time. The main function of the algorithm (Algorithm 1) takes a basic block to specialize and the initial context used for that specialization as parameters. The data structures it uses are presented in Figure 2. A context is a mapping of variable names to value information. In this section these mappings associate variables to types. We will see in Section 3.2 that contexts can contain more precise type information. The algorithm specializes each instruction of the basic block and it recursively specializes the blocks that follow the basic block currently under specialization.

The algorithm performs a breadth-first traversal of the CFG. For that, it uses a work queue where it pushes the basic blocks and contexts that need further specializations. Specializing a block may cause the algorithm to specialize new blocks. For instance, when the algorithm scans the block #12 of Figure 1a, it discovers that in the positive branch the variable x is known to be a pair and then, it pushes onto the work queue the demand of a new specialization of the block #4 for the context $\{ x \mapsto \text{pair} \}$.

If the block extracted from the queue has not been merged (we explain in a moment what it means for a block to be merged), then it is specialized (line 10). This, in turn, can add new pending specializations to the queue. The algorithm proceeds until the queue is empty.

To ensure the convergence of the algorithm, it is enough to ensure that the function `BLOCKNEWVERSION` (Algorithm 2) pushes a new block onto the queue if and only if no such block has already been specialized for the requested context as the contexts contain a finite number of variable to value mappings. However, this convergence criteria is not enough in practice, the code size expansion of the specialization should also be controlled. This is the

(a) Original unspecialized CFG.

(b) Specialized CFG.

Figure 1 The original and specialized CFGs of the `find` function. Basic blocks have a numeric label for easy reference. In the specialized CFG, basic blocks have the same color as the original block they were specialized from (whose label is in square brackets). For instance, block #19 is a specialized version of block #4 of the original CFG. In the specialized CFG, the contexts of the specializations are displayed in blue. It can be observed that a given block can be specialized multiple times. For instance, block #12 has been specialized twice (blocks #18 and #31) and block #4 has been specialized twice (blocks #19 and #32). Blocks #7, #10, and #16 have no version in the specialized CFG because they do not have a reachable specialized context. Blocks #9 and #15 have been specialized to an unconditional jump because the `($pair? x)` test is known to be true.

context: ctx, ctx_0, \dots
■ types: a list of mappings of variable to type information
basic block: bb, bb_0, \dots
■ instrs: a list of instructions
■ versions: a list of specialized basic blocks
specialized basic block: bs, bs_0, \dots
■ bb: the corresponding basic block
■ merge: a specialized basic block into which it has been merged or false
■ ctx: a context

Figure 2 The data structures used in the SBBV algorithm.

28:6 Static Basic Block Versioning

Algorithm 1 Main algorithm.

```

1: function SBBV( $bb_0, ctx_0$ )           > specialize a CFG starting with the block  $bb_0$ 
2:    $wq \leftarrow empty\_queue$           > create a fresh queue used for this specialization
3:    $bs_0 \leftarrow \text{BLOCKNEWVERSION}(bb_0, ctx_0, wq)$  > push the request for specialization of  $bb_0$ 
4:   while  $\neg wq.\text{isempty}()$  do
5:      $bs \leftarrow wq.\text{pop}()$            > fetch the first bb of the queue
6:      $bb \leftarrow bs.\text{bb}$               > get the original unspecialized bb
7:     if  $|\{\forall b \in bb.\text{versions}, \neg b.\text{merge}\}| > \text{VERSION\_LIMIT}(bb)$  then
8:        $\text{BLOCKMERGESOME}(bb, wq)$       > too many specializations, merge
9:     if  $\neg bs.\text{merge}$  then
10:       $\text{BLOCKSPECIALIZE}(bs, wq)$     > specialize the block only if not already merged
11:   return  $bs_0$                   > return the specialization of the initial block

```

purpose of the test at line 7 of Algorithm 1. If the number of specialized versions of a single block exceeds a threshold, which is a parameter of the algorithm, some specializations of that block must be merged (see line 8).

The ancillary function BLOCKNEWVERSION is responsible for creating new blocks to be specialized. First, it checks if the requested block already exists, in which case it returns it. Otherwise, it creates a fresh version and pushes it onto the queue (line 9). Note that at this stage the instructions of the block are not scanned nor specialized. Pushing the block onto the queue is a mere request for specialization. It might be the case that at the moment where the block will be popped from the queue that this block has been merged into a less specialized version. This happens to prevent code size explosion.

Algorithm 2 Create or fetch a specialized version.

```

1: function BLOCKNEWVERSION( $bb, ctx, wq$ )
2:   if  $ctx \in bb.\text{versions}$  then
3:     return  $\text{BLOCKLIVE}(bb.\text{versions}[ctx])$       > return the already specialized block
4:   else
5:      $bs \leftarrow \text{new basic block}$            > create a fresh empty basic block
6:      $bb.\text{versions}[ctx] = bs$              > connect the new block and the parent block
7:      $bs.\text{bb} = bb$                       > initialize the new block
8:      $bs.\text{ctx} = ctx$ 
9:      $wq.\text{push}(bs)$                   > push it onto the queue for future specialization
10:    return  $bs$ 

```

The utility function BLOCKLIVE returns the first specialized version of a block that has not been merged into a more general version.

Algorithm 3 Follow a chain of merged blocks.

```

1: function BLOCKLIVE( $bs$ )
2:   if  $bs.\text{merge}$  then
3:     return  $\text{BLOCKLIVE}(bs.\text{merge})$ 
4:   else
5:     return  $bs$ 

```

When the number of specializations of a basic block bb exceeds $\text{VERSION_LIMIT}(bb)$, some contexts need to be merged. Note that we express the version limit as a function of the basic block to allow the algorithm to adapt the limit to different types of basic blocks, such as

those marked by the compiler front-end as probably benefiting from more specialization. This function could simply return a constant value, as we have done in our experiments. Context merging is done by the function BLOCKMERGE SOME (Algorithm 4). It selects two versions not already merged (line 2), computes the union of the two corresponding contexts (line 3), and then replaces the merged blocks in the CFG (line 14). Merging is only triggered when a version is removed from the work queue (Algorithm 1, line 5). This allows the number of versions to temporarily exceed the version limit. This *delayed merging* increases the choices available to the selection heuristic and possibly leads to better merges.

Merging a block in the CFG entails deleting all incoming edges of the merged blocks to redirect them to the block resulting from the merge. Any deletion of an edge may render some specialized block unreachable from the CFG’s entry point. Similarly, an added edge can make some previously unreachable block reachable anew. Keeping track of unreachable blocks is required since those no longer have to be traversed and must not be considered when selecting versions to merge in BLOCKMERGE SOME (line 2). This can be done efficiently by maintaining an Even-Shiloach tree [14] of the CFG to help the SBBV algorithm detect whenever the reachability of a specialized block changes. Any block made unreachable by a merge is marked so that it is no longer considered in the merge selection and CFG traversal.

Algorithm 4 Merge blocks.

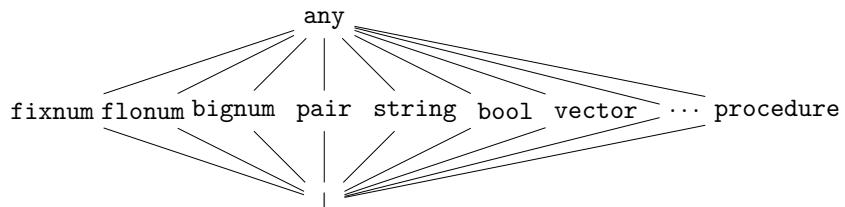

```

1: function BLOCKMERGE SOME(bb, wq)
2:   bs1, bs2  $\leftarrow \Theta^2\{\forall b \in bb.\text{versions}, \neg b.\text{merge}\}$            ▷ select two versions to merge
3:   ctx  $\leftarrow bs_1.\text{ctx} \sqcup bs_2.\text{ctx}$            ▷ merge the two corresponding contexts
4:   bs  $\leftarrow \text{BLOCKNEWVERSION}(bb, ctx, wq)$            ▷ create a new block for the merge
5:   if bs1  $\equiv$  bs then           ▷ replace the merged blocks
6:     | BLOCKMERGEANDREPLACE(bs2, bs)
7:   else if bs2  $\equiv$  bs then
8:     | BLOCKMERGEANDREPLACE(bs1, bs)
9:   else
10:    | BLOCKMERGEANDREPLACE(bs1, bs)
11:    | BLOCKMERGEANDREPLACE(bs2, bs)
12: function BLOCKMERGEANDREPLACE(obs, mbs)
13:   | obs.merge  $\leftarrow mbs$            ▷ mark that obs is merged into mbs
14:   | replace obs with mbs in the CFG           ▷ patch the CFG

```

The operator Θ^2 selects two unmerged specializations for the block *bb*. For the sake of the correctness of the algorithm, this operator might select any two versions. For instance, it could select two random versions. Of course, a better operator would positively impact the result of the compilation. In Section 4.3 we present the operator we have used so far.

The behavior of the merge operator \sqcup is independent of the SBBV algorithm but it must produce a new context that at least encompasses the contexts of the merged blocks. The natural solution is to use a lattice for organizing the information associated with variables and to go up some level for each merge. We will use the following lattice:

28:8 Static Basic Block Versioning

Note that a number can be a `flonum` (floating point numbers), a `fixnum` (small integers that fit in a machine word), or a `bignum` (integers that don't fit in a machine word). While this would be a good match for JavaScript numerical types, for a full Scheme, or Python, implementation there would also be a representation for rational and complex numbers, but we will ignore them to simplify the discussion.

Consider the merge of two contexts mapping a variable v respectively to the types `fixnum` and `flonum`. The merge operation should produce a context mapping v to `any`. In Section 3.2 we show the use of a more precise lattice for representing properties.

The last part of the SBBV algorithm is in charge of specializing blocks. It merely creates a new block where the instructions have been specialized one by one.

Algorithm 5 Specialize a block and its instructions.

```

1: procedure BLOCKSPECIALIZE( $bs, wq$ )
2:    $bb \leftarrow bs.bb$ 
3:    $ctx \leftarrow bs.ctx$ 
4:   for all  $i \in bb.instrs$  do
5:      $(ni, nctx) \leftarrow \text{INSSPECIALIZE}(i, ctx, wq)$ 
6:      $bs.instrs \leftarrow bs.instrs + ni$ 
7:    $ctx \leftarrow nctx$ 
```

Specializing an instruction that implements a type test produces a new context. For instance, when specializing the block #12 of Figure 1a, in the positive branch, the argument `x` is known to be a pair. The block #4 is then specialized with a context that reflects that information, which is then propagated to following blocks. Conversely, on the negative branch, the argument `x` is known not to be a pair. This information too, is propagated to following blocks. To handle these evolutions of the contexts, the procedure `BLOCKSPcialize` updates the context it uses for specializing the instructions after each iteration (Algorithm 5, line 7).

The function `INSSPECIALIZE` selects a specializer appropriate for the instruction.

Algorithm 6 Specialization of an instruction.

```

1: function INSSPECIALIZE( $i, ctx, wq$ )
2:   if  $i.kind$  is "goto" then return INSSPECIALIZEGOTO( $i, ctx, wq$ )
3:   else if  $i.kind$  is "if" then return INSSPECIALIZEIF( $i, ctx, wq$ )
4:   else if  $i.kind$  is ... then ...
5:   else return ( $i, ctx$ )
```

The specialization of a `goto` instruction mostly consists in forwarding the specialization context `ctx` to the target of the instruction. For instance, when specializing the `goto` in block #1 of Figure 1a with the context $\{x \mapsto \text{pair}, p \mapsto \text{procedure}\}$ the `goto` instruction triggers the specialization of the block #12 with the same context. The instruction brings no new knowledge about the variables types so it returns an unmodified context.

Algorithm 7 Specialization of `goto` instructions.

```

1: function INSSPECIALIZEGOTO( $i, ctx, wq$ )
2:    $ni \leftarrow i.dup()$ 
3:    $ni.target \leftarrow \text{BLOCKNEWVERSION}(i.target, ctx, wq)$ 
4:   return ( $ni, ctx$ )
```

The specialization of an `if` is more involved because this is where new knowledge is acquired and where requests for new specializations are emitted. If the test of the expression is not a type test, the specialization behaves as the specialization of a `goto` instruction (Algorithm 8, line 2). If the instruction implements a type check and if the context is such that the test always succeeds, then the instruction is replaced with a `goto` instruction which directly branches to the positive block (line 6). This is illustrated by the specialization of the block #6 of Figure 1a into the block #23 of Figure 1b. Conversely, if the test is known to evaluate to false, the instruction is replaced with a `nop` instruction.

Algorithm 8 Specialization of `if` instructions.

```

1: function INSSPECIALIZEIF( $i, ctx, wq$ )
2:   if  $\neg i.\text{test}$  is a typecheck then
3:      $ni \leftarrow i.\text{dup}()$ 
4:      $ni.\text{target} \leftarrow \text{BLOCKNEWVERSION}(i.\text{target}, ctx, wq)$ 
5:     return ( $ni, ctx$ )
6:   else if  $ctx.\text{types.isTrue}(i.\text{test})$  then
7:      $ni \leftarrow \text{new insGoto}(i.\text{target})$ 
8:     return INSSPECIALIZE( $ni, ctx, wq$ )
9:   else if  $ctx.\text{types.isFalse}(i.\text{test})$  then
10:     $ni \leftarrow \text{new insNop}()$ 
11:    return ( $ni, ctx$ )
12:   else
13:      $ni \leftarrow i.\text{dup}()$ 
14:      $ctx^+ \leftarrow ctx \cup \{ i.\text{test.var} \mapsto i.\text{test.type} \}$ 
15:      $ctx^- \leftarrow ctx \cup \{ i.\text{test.var} \mapsto \neg i.\text{test.type} \}$ 
16:      $ni.\text{target} \leftarrow \text{BLOCKNEWVERSION}(i.\text{target}, ctx^+, wq)$ 
17:     return ( $ni, ctx^-$ )

```

The most interesting situation is when the result of the type test cannot be inferred from the current context (line 12). In that case, two new contexts are created, in accordance to the narrowing rules for that test. The positive branch of the test will be specialized with a context reflecting the success of the type test and the context reflecting a negative result is returned to the procedure `BLOCKSPARLIZE` (for instance, see the block #12 of Figure 1a that creates the context of the block #19 of Figure 1b).

3 Improved Specializations

In Section 2 we have presented the general SBBV algorithm. We have exposed its principles that we have illustrated with a simple type analysis that maps variable usages to types. In this section, we show how the algorithm can be extended to specialize the blocks according to more fine-grained information.

3.1 Variable Aliasing

The contexts used in the example in Figure 2 enables SBBV to specialize blocks according to the type of the variables. However, it does not keep track of variable aliases, which jeopardizes the benefit of the optimization. Compilers tend to introduce many temporaries for evaluating expressions and if these aliases are not handled efficiently by the SBBV specialization, what is learned about a variable's value will not be propagated to the other

context: ctx, ctx_0, \dots

- types: a list of mappings of variable to type information
- equiv: a list of equivalence classes

Figure 3 Extended specialization contexts with variable class equivalence.

variables containing the same value. Thankfully, handling aliases merely requires extending the definition of the contexts and to handle the specialization of the `mov` instruction, which assigns a value to a variable. The new definition of the contexts is extended into that of Figure 3. The specialization of the `mov` instruction, that copies a variable into another and that is represented by the \leftarrow operator in the CFGs, is given in Algorithm 9. For the sake of simplicity, this extension keeps track of aliasing of read-only variables only. Assigned variables are never treated as aliases of other variables. Also, not presented here, the specialization of the `if` instruction (Algorithm 8) is modified so that it also propagates the gathered type information to the variable's aliases.

Algorithm 9 Specialization of `mov` instructions.

```

1: function INSSPECIALIZEMOV( $i, ctx, wq$ )
2:    $nctx \leftarrow ctx$ 
3:    $nctx.equiv[i.target] \leftarrow \emptyset$ 
4:   if  $i.source$  is a read-only variable then
5:      $nctx.equiv[i.target] \leftarrow \{i.source\}$ 
6:   return ( $i, nctx$ )

```

3.2 Specialization of Arithmetic Operations

The SBBV algorithm is general-purpose and it can be applied to other properties of the variables and values to go beyond type check removal. In this section we show how to leverage this flexibility to also specialize the basic blocks according to fixnum integer intervals `LO..HI`, where `LO` and `HI` are values in the fixnum range. This will allow the compiler to generate code using fixnum arithmetic operators that are fast (because they directly map to machine instructions) and removing overflow checks and bound checks.

The benefits of this extension can be illustrated on the expression `(+ x 1)`, which adds 1 to `x`, a very common operation in most programs. The specific operation executed depends on the type of `x`. The result could be a fixnum, a flonum, a bignum, or the operation could raise an exception if `x` is not a numerical type. Moreover, the result of `(+ x 1)` will be a bignum if `x` is maxfix, the largest fixnum value. A similar dispatch is part of the semantics of most arithmetic operators `(-, *, ...)` and comparison operators `(=, <, ...)`, and in the general case, such as `(+ x y)`, the dispatch is on the combination of types of `x` and `y`.

Optimizing compilers usually inline the handling of the most common cases, such as all operands being fixnums, and all operands being flonums, and defer the handling of the remaining cases to an out-of-line function. For example, the expression `(+ x 1)` could be expanded by the compiler to this code:

```

(if ($fixnum? x)
  (or ($fix+? x 1)    ;; fixnum add 1 with overflow check (#f returned on overflow)
      ($+ x 1))       ;; call $+ function to handle bignum result case
  (if ($flonum? x)
      ($fl+ x 1.0)    ;; flonum add 1
      ($+ x 1)))      ;; call $+ function to handle other cases including errors

```

Here we use names prefixed with ‘\$’ to indicate internal operations of the system:

- $(\$fixnum? \ x)$ and $(\$flonum? \ x)$ test to see if x is a fixnum, or a flonum respectively.
- $(\$+ \ x \ y)$ is an addition function in the runtime system that handles all possible type combinations for x and y , including those that raise an exception.
- $(\$fl+ \ x \ y)$ adds two flonums to give a flonum result.
- $(\$fx+? \ x \ y)$ adds two fixnums to give a fixnum result or false in the case of an overflow. This operation includes an overflow check that makes it somewhat more expensive than $(\$fx+ \ x \ y)$ that does not check for overflow (note the absence of the trailing ‘?’).

When the CFG of the above expansion of $(+ \ x \ 1)$ is processed by the SBBV algorithm various optimizations can happen. If the context indicates that x is a fixnum then the $(\$fixnum? \ x)$ test in the specialized basic block is an unconditional jump to the CFG of $(\text{or} \ (\$fx+? \ x \ 1) \ (\$+ \ x \ 1))$, effectively removing the code that handles flonums, bignums, and other types. Moreover, if it is known that x is in the interval LO..HI where $\text{HI} < \text{maxfix}$, then the result of $(\$fx+? \ x \ 1)$ is in the fixnum interval $\text{LO} + 1..\text{HI} + 1$, so an overflow is impossible, i.e., $(\$fx+? \ x \ 1)$ is necessarily a fixnum. Consequently the CFG can be specialized to $(\$fx+ \ x \ 1)$, which is a machine integer addition with no overflow check.

Other languages, such as Ruby, support similar generic arithmetic, but more importantly, languages such as JavaScript [16] and Python that do not expose small integers require that the compiler be able to detect when operations can be implemented as fixnum operations. Hence, these fast implementations must be able to detect when an operation overflows and, exactly as Scheme does, promote the number in such a case (JavaScript promotes them to IEEE floating point numbers, Python to bignums).

To extend the analysis, we refine the definition of specialization contexts (Figure 4) and we refine the lattice of values (Figure 5). Fixnum values are now represented with intervals.

Handling numerical values requires us to modify the specialization of the *if* and the *fixnum arithmetic with overflow* instructions, such as $\$fx+?$. The first one must compute new interval approximations to be propagated in the positive and negative branches by using interval narrowing techniques [11]. The second one must implement arithmetic operations over intervals [23], such as $x_{\text{lo}}..x_{\text{hi}} + y_{\text{lo}}..y_{\text{hi}} = (x_{\text{lo}} + y_{\text{lo}})..(x_{\text{hi}} + y_{\text{hi}})$.

Algorithm 10 Specialization of *if* instructions with numerical values.

```

1: function INSSPECIALIZEIF( $i, ctx, wq$ )
2:   if  $i$  is an integer comparison then
3:      $(ctx^+, ctx^-) \leftarrow \text{intervalNarrowing}(i, ctx)$ 
4:      $ni \leftarrow i.\text{dup}()$ 
5:      $ni.\text{target} \leftarrow \text{BLOCKNEWVERSION}(i.\text{target}, ctx^+, wq)$ 
6:     return  $(ni, ctx^-)$ 
7:   else
8:     as in algorithm 8

```

For instance, let us assume the specialization of the instruction “*if* $(\$fx> \ i \ 3)$ ” in a context $\{i \mapsto \text{minfix}..\text{10}\}$. The new INSSPECIALIZEIF will generate the two new contexts $\{i \mapsto 4..\text{10}\}$ and $\{i \mapsto \text{minfix}..3\}$ for the positive and negative outcomes respectively.

The numerical operation specialization replaces a numerical operator, such as $\$fx+?$, whose result is known not to overflow with a faster operator that does not check for overflow, such as $\$fx+$. It must also implement some widening operation [10] in order to hasten the convergence of the algorithm. Without widening the algorithm would require a number of iterations proportional to the size of the interval representing numbers, which would be prohibitive. The widening is handled by the \sqcup operator of the Algorithm 4 (see Section 2.2).

Figure 4 Specialization contexts extended with integer intervals.

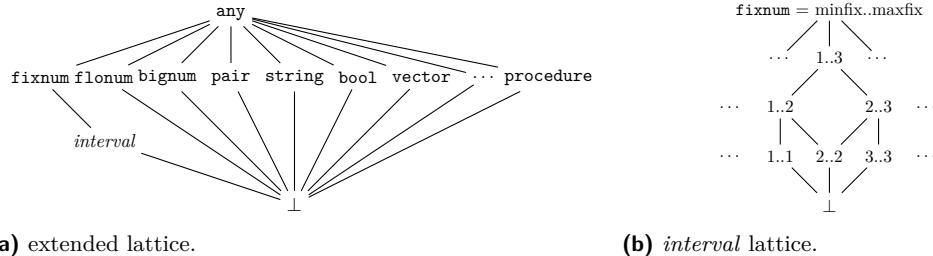

Figure 5 Extending the lattice used for variable values to handle integer intervals.

3.3 Vector Support

The previous section showed how to extend SBBV to approximate integer values as intervals described with two integer bounds. While this enables the compiler to remove overflow checks, it is insufficient to remove bound checks of vector accesses as the length of a vector is generally unknown statically and cannot be represented with an exact integer value.

To handle vectors we introduce a refined representation of intervals. With this extension interval bounds can be represented with integers as before, but also with the symbolic value $\llbracket v \rrbracket - i$ that is equal to the length of vector v minus the integer offset $i \geq 0$. Here we assume that the length of a vector is always a nonnegative fixnum. For instance, the interval $0..\llbracket v \rrbracket - 1$ denotes all the nonnegative fixnums that are lower than the length of the vector v , in other words, the valid indexes of vector v . The upper bound of that interval, *i.e.*, $\llbracket v \rrbracket - 1$, itself denotes a fixnum in the interval $-1..maxfix - 1$.

We illustrate the benefit of this extension to SBBV with a variant of the `find` function presented in Section 2 that operates on vectors and lists:

```

1  (define (findv p x)
2    (if (vector? x)
3        (let ((len (vector-length x)))
4            (let loop ((i 0))
5                (if (< i len)
6                    (let ((e (vector-ref x i)))
7                        (if (p e)
8                            e
9                            (loop (+ i 1)))))
10                   #f)))
11    (find p x)))

```

```

1 (define (findv p x)
2   (if ($vector? x)
3     (let ((len (if ($vector? x) ($vector-length x) ($fail))))
4       (let loop ((i 0))
5         (if (and ($fixnum? i) ($fixnum? len))
6             ($fx< i len)
7             (if (and ($flonum? i) ($flonum? len))
8                 ($fl< i len)
9                 ($< i len)))
10            (let ((e (if (and ($vector? x) ($fixnum? i))
11                  ($fx>= i 0) ($fx< i ($vector-length x)))
12                  ($vector-ref x i)
13                  ($fail)))
14              (if ((if ($procedure? p) p ($fail)) e)
15                  e
16                  (loop (if (and ($fixnum? i) ($fixnum? 1))
17                          (or ($fx+? i 1) ($+ i 1))
18                          (if (and ($flonum? i) ($flonum? 1))
19                              ($fl+ i 1)
20                              ($+ i 1)))))))
21            #f)))

Figure 6 The code of the `findv` function where all dynamic checks are explicit.

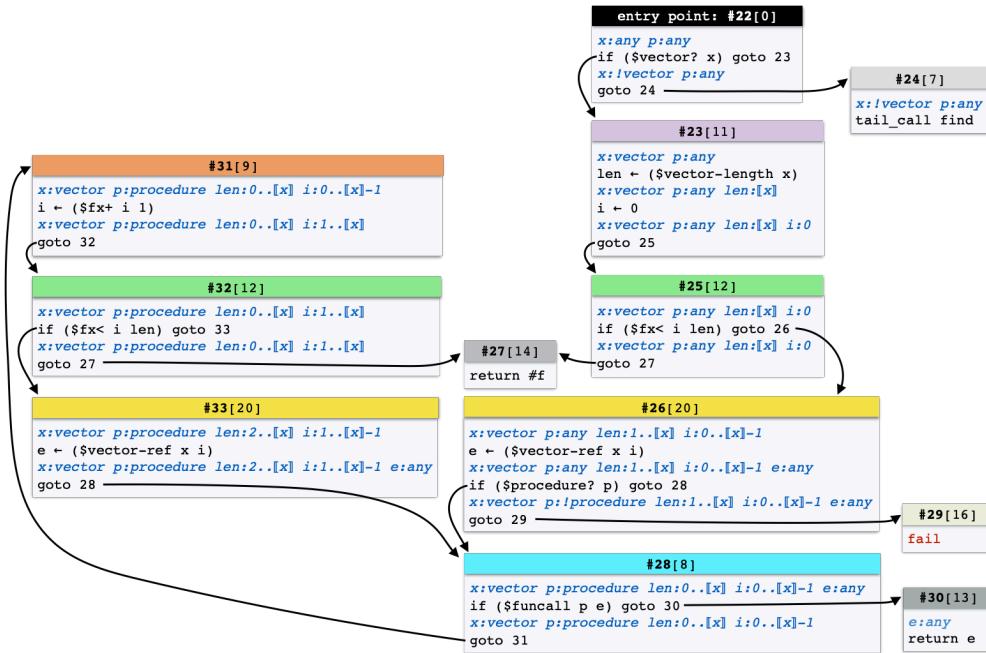

Figure 7 The specialized CFG of the `findv` function showing that the index calculations are done entirely with fixnums with no overflow checks and no vector bound checks. For brevity, we write $\llbracket x \rrbracket$ instead of $\llbracket x \rrbracket - 0$, and the interval $\llbracket x \rrbracket .. \llbracket x \rrbracket$ is abbreviated to $\llbracket x \rrbracket$.

Figure 6 shows the code after the compiler has blindly expanded each operation to include all required dynamic checks. The refinements of SBBV presented in this section enables the compiler to create the specialized CFG shown in Figure 7, which is optimal (all bound checks and overflow checks have been removed). There is only a procedure check for parameter p in the first iteration of the loop, and only if parameter x is a non-empty vector.

This refinement does not impact the SBBV algorithm nor does it demand to change the specialization of the arithmetic instructions but it requires us to extend the interval operators to treat cases where at least one bound is a symbolic value. For example, in the case of the interval addition $x_{\text{lo}}..x_{\text{hi}} + y_{\text{lo}}..y_{\text{hi}} = (x_{\text{lo}} + y_{\text{lo}})..(x_{\text{hi}} + y_{\text{hi}})$, the addition of the lower bounds ($x_{\text{lo}} + y_{\text{lo}}$) is computed from the following rules, where i and j denote integer values, and v and w denote vector identifiers:

$$\begin{aligned} i +_{\text{lo}} j &\mapsto i + j \\ ([v] - i) +_{\text{lo}} j &\mapsto j - i \\ j +_{\text{lo}} ([v] - i) &\mapsto ([v] - i) +_{\text{lo}} j \\ ([v] - i) +_{\text{lo}} ([w] - j) &\mapsto -i - j \end{aligned}$$

and the addition of the upper bounds ($x_{\text{hi}} + y_{\text{hi}}$) is computed from the following rules, where *overflow* denotes an upper bound that is not a fixnum:

$$\begin{aligned} i +_{\text{hi}} j &\mapsto i + j \\ ([v] - i) +_{\text{hi}} j &\mapsto [v] - (i - j) \quad \text{if } i \geq j \\ ([v] - i) +_{\text{hi}} j &\mapsto \text{overflow} \quad \text{if } i < j \\ j +_{\text{hi}} ([v] - i) &\mapsto ([v] - i) +_{\text{hi}} j \\ ([v] - i) +_{\text{hi}} ([w] - j) &\mapsto \text{overflow} \end{aligned}$$

The narrowing operations for comparisons are similar to that of regular intervals, considering that vector lengths are themselves modelled as intervals from 0..maxfix. Below are the rules for the narrowing of $x < y$ from which the rules for the other comparisons can be derived:

Narrowing rule for: $x < y$ with $\{x \mapsto x_{\text{lo}}..x_{\text{hi}}, y \mapsto y_{\text{lo}}..y_{\text{hi}}\}$

Positive outcome: $\{x \mapsto x_{\text{lo}}.. \min_{\text{hi}}(x_{\text{hi}}, y_{\text{hi}} - 1), y \mapsto \max_{\text{lo}}(x_{\text{lo}} + 1, y_{\text{lo}})..y_{\text{hi}}\}$

Negative outcome: $\{x \mapsto \max_{\text{lo}}(x_{\text{lo}}, y_{\text{lo}})..x_{\text{hi}}, y \mapsto y_{\text{lo}}.. \min_{\text{hi}}(x_{\text{hi}}, y_{\text{hi}})\}$

$$\begin{aligned} \max_{\text{lo}}(x, y) &\mapsto x \text{ if } \text{val}_{\text{lo}}(x) > \text{val}_{\text{lo}}(y) \text{ else } y \\ \min_{\text{hi}}(x, y) &\mapsto x \text{ if } \text{val}_{\text{hi}}(x) < \text{val}_{\text{hi}}(y) \text{ else } y \end{aligned}$$

$$\begin{aligned} \text{val}_{\text{lo}}(i) &\mapsto i \\ \text{val}_{\text{lo}}([v] - i) &\mapsto i \end{aligned}$$

$$\begin{aligned} \text{val}_{\text{hi}}(i) &\mapsto i \\ \text{val}_{\text{hi}}([v] - i) &\mapsto \text{maxfix} - i \end{aligned}$$

It is noteworthy that, as a result of the interval widening, some of the inferred intervals are somewhat conservative (for example at block #28 the interval for `len` could have been $1..[v]$). The widening loses some information but makes computing a fix-point faster.

4 Experiments

In this section we demonstrate the practicality of SBBV through experiments. To ensure that our results are not overly system specific, we have integrated an SBBV pass in the compilation pipeline of two existing Scheme compilers, Bigloo [19] and Gambit [20]. Both

of these are independently developed mature optimizing AOT Scheme to C compilers that use a CFG representation of the compiled program. Moreover these compilers are used as back-ends of optimizing compilers for JavaScript [31, 30] and Python [22]. Bigloo and Gambit implement a slew of features and classical optimizations such as constant-folding, function inlining, flat closures, and lambda-lifting. Any performance improvements would constitute a notable achievement given the many years of fine-tuning that went into their development. We put this in perspective in Section 4.5.

Adding SBBV to these compilers allows them to use the type, range and value of variables to perform flow sensitive code specialization that is tailored to the program logic, with low code bloat. The experiments have been designed to demonstrate further performance improvements by SBBV than by other optimization techniques implemented by these compilers.

We evaluate the impact of SBBV by applying it to a suite of benchmarks. Each benchmark is compiled with and without SBBV to measure its impact on the number of dynamic checks, program size, execution time, and compilation time. Section 4.1 provides a brief description of the benchmark suite. Benchmarks were executed on a machine with an Intel Core i7-7700K, 48 GB of RAM, and under Debian 10.13 with kernel version SMP Debian 4.19.269-1.

In order to measure SBBV’s impact on the number of dynamic checks, both compilers have been instrumented to count the number of dynamic checks during a program execution. Executions for measuring time and dynamic checks are done separately to ensure that counting checks does not affect the measured execution time. Execution time is measured by profiling each executable with “`perf stat`” to measure its execution real-time. Each benchmark is parameterized such that its execution lasts at least five seconds on our machine, and is repeated 50 times, removing the top and bottom 5 outliers. The parameters of each benchmark are provided as command-line arguments to ensure that the compiler does not optimize for specific values or types. All timing results in this section are the average execution time of each benchmark. The relative standard deviation of the execution time never exceeds 0.24% on macrobenchmarks, and 2.20% on microbenchmarks; consequently we omit standard deviations in figures to improve readability.

4.1 Benchmark Programs

Our benchmark suite combines programs from two sources: the R7RS benchmark suite [1] that is commonly used for evaluating the performance of Scheme systems, and benchmark programs used in [30] that have Scheme and JavaScript versions.

We use both macrobenchmarks and microbenchmarks, which we classify according to their size (fewer than 150 lines of code is a microbenchmark). These two classes are distinguished because microbenchmarks stress a narrow set of features and consequently are poor predictors of the overall performance of a system. We only use microbenchmarks as instruments for shedding light on specific behaviors of the SBBV algorithm.

Here is a brief description of the benchmark programs:

Macrobenchmarks:

- `almabench` (430 LOC): Compute the celestial coordinates of the sun at noon. Uses floating point numbers, vectors, and assignments.
- `boyer` (610 LOC): Prolog-like rule-directed rewriting engine. Uses pairs and symbols.
- `compiler` (11,740 LOC): Old version of the Gambit Scheme compiler generating M68000 code. Uses pairs, symbols, vectors, and strings.
- `conform` (490 LOC): Graph type checker using equivalence classes. Uses lists and strings.

28:16 Static Basic Block Versioning

- **dynamic** (2,350 LOC): Dynamic type inference for Scheme. Uses lists, symbols, and higher-order functions.
- **earley** (660 LOC): Earley parser parsing an ambiguous grammar. Uses vectors, lists, small integers and symbols.
- **l eval** (560 LOC): Scheme interpreter based on closures. Uses lists, symbols, and higher-order functions.
- **maze** (740 LOC): Hexagonal grid maze generator. Uses vectors and small integers.
- **nucleic** (3,510 LOC): 3D structure determination of a nucleic acid. Uses vectors and floating point numbers.
- **peval** (630 LOC): Partial evaluator for Scheme. Uses lists, symbols, and higher-order functions.
- **scheme** (1,090 LOC): Other Scheme interpreter based on closures. Uses lists, symbols, and higher-order functions.
- **slatex** (2,470 LOC): Scheme to Latex processor. Uses characters, strings, lists, vectors, and small integers.

Microbenchmarks:

- **ack** (10 LOC): Ackermann function. Uses small integers and recursion.
- **bague** (110 LOC): Solver of the *baguenaudier* puzzle. Uses small integers and vectors.
- **fib** (20 LOC): Fibonacci function. Uses small integers and recursion.
- **fibfp** (20 LOC): Fibonacci function. Uses floating point numbers and recursion.
- **nqueens** (40 LOC): Solver of the N-queens puzzle. Uses lists, small integers, and recursion.
- **primes** (40 LOC): Sieve algorithm for finding primes. Uses lists and small integers.
- **tak** (20 LOC): Takeuchi function. Uses small integers and recursion.

4.2 Counting Dynamic Checks

In the Bigloo and Gambit implementations, many built-in procedures implicitly check the type of their arguments and signal an error if they are invalid, such as arithmetic on non-number types or index out of bound when indexing a vector. Polymorphic operators also use implicit dynamic type checks to dispatch computation to specialized primitives.

To measure dynamic checks, all built-in procedures used in our benchmarks are redefined with macros that use inline checks. This is semantically equivalent to operations that apply checks and dispatch to specialized primitives implicitly. For instance, the `BBVvector-ref` and `BBV+` macros implement the `vector-ref` and `+` operations respectively:

```
1 (define-macro (BBVvector-ref v i)
2   '(let ((v ,v) (i ,i))
3     (if (and ($vector? v) ($fixnum? i)
4              ($fx>= i 0) ($fx< i ($vector-length v)))
5         ($vector-ref v i)
6         (error "vector-ref error")))))
7
8 (define-macro (BBV+ x y)
9   '(let ((x ,x) (y ,y))
10    (if (and ($fixnum? x) ($fixnum? y))
11        (or ($fx+? x y) ($+ x y))
12        (if (and ($flonum? x) ($flonum? y))
13            ($f1+ x y)
14            ($+ x y)))))
```

The macros use specialized operators (prefixed with \$ in the example), making all checks explicit (type checks, array bound checks, and integer overflow checks) and ensuring that both compilers perform the same set of checks and in the same order (see Section 3.2 for the definitions of `$fx+?`, `$+`, and the other primitive operations).

When SBBV has determined the type of a value, the type tests that are in the expansion of these macros (`$fixnum?`, `$flonum?`, etc) are effectively removed. Similarly, SBBV’s interval analysis may determine the range of possible integer values, allowing comparisons such as `($fx>= i 0)` to be removed, and calls to overflow checking operators such as `($fx+? x y)` to be replaced by the non-overflow checking `($fx+ x y)` when the result cannot overflow.

However, not all dynamic checks originate from safe operators since programmers can add type tests and bound checks as part of their program’s logic. For this reason, we distinguish between checks introduced by safe operators, which we call *safety* checks in the context of this experiment, and those introduced by the programmer. The number of safety checks is computed by replacing all operators, such as `BBVvector-ref` and `BBV+`, by unsafe ones that execute no type tests, overflow checks or array bound checks. By subtracting the number of checks executed by the unsafe version of a program from the number of checks of its safe version, we obtain the number of safety checks.

4.3 Merge Selection

Applying SBBV requires a heuristic for selecting which versions of a block to merge when that block’s version limit is exceeded. This corresponds to choosing a concrete implementation for the Θ^2 operator from Algorithm 4. The quality of the selection function impacts the general performance of the SBBV algorithm. The current Bigloo and Gambit implementations use a merge heuristic that is rudimentary but still sufficient to establish the benefit of the approach.

In our implementations, when the version limit of a basic block is exceeded, versions that are the most similar are merged first. The similarity of two versions is computed by counting how many variables have the same type when entering the block. While both Bigloo and Gambit implement a *selection by similarity*, the exact implementations of their selection functions differ slightly due to how they represent types internally.

Given that the versions selected depend solely on the contexts when entering a block, this is a *local* merge heuristic. It requires no usage analysis of each variable in the block and its successors. A nonlocal merge heuristic could lead to better results if it prioritizes some versions over others with the objective of maximizing the benefits for the whole program. The space of possible merge heuristics is large and we intend to explore it in future work.

4.4 Results

We first present broad results before diving into a deeper analysis in the subsequent sections.

SBBV permits a trade-off between code size and dynamic checks removal. As the version limit increases, more blocks are duplicated and more dynamic checks are removed. This comes at the cost of increased executable size and compilation time. We found a limit of 2 versions to offer a good trade-off between checks removal, size, and compilation time.

Figure 8 shows the proportion of safety checks removed by SBBV, such as type, overflow, and array bound checks. In all benchmarks, the number of checks decreases when compared to the executable without SBBV. This indicates that SBBV can remove dynamic checks that the existing optimizations of Bigloo and Gambit could not remove.

The proportion of checks removed varies between Bigloo and Gambit, despite both compilers applying the same SBBV algorithm. Bigloo removes more checks without applying SBBV, thus leaving fewer checks to be removed by SBBV. However, the absolute number of remaining checks is similar between both implementations. To a lesser extent, differences in the implementations of the heuristic for selecting versions to merge also influence the number of removed checks by each compiler.

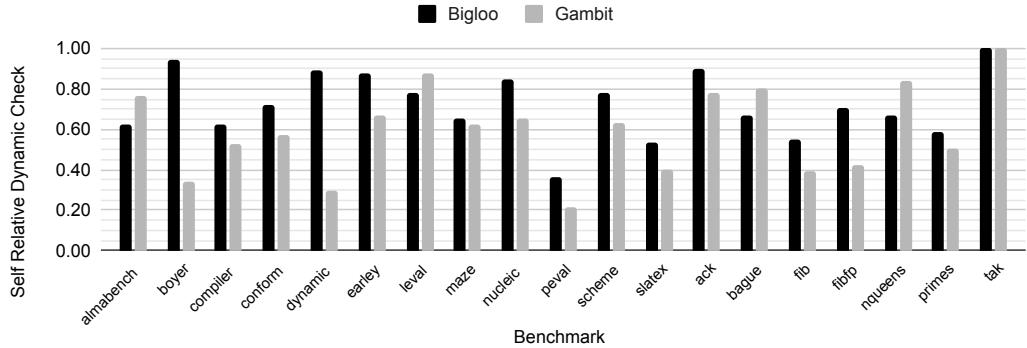

Figure 8 Relative number of safety checks executed for benchmarks compiled with and without SBBV (limit of 2 versions), separately for Bigloo and Gambit. 1.0 corresponds to compilation without SBBV. Lower values indicate fewer dynamic checks with SBBV.

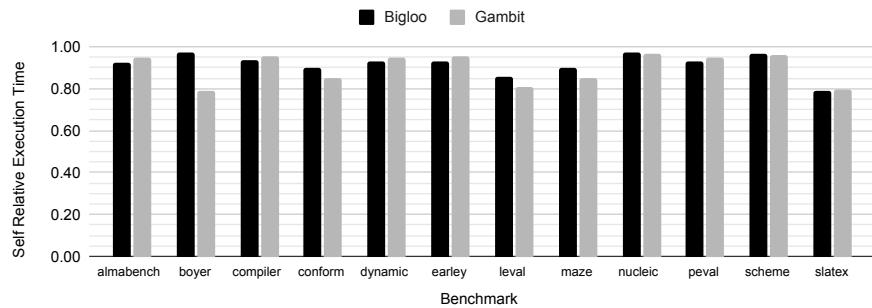

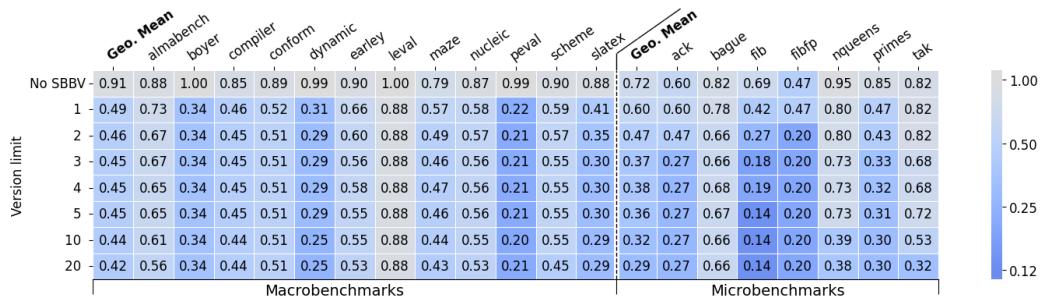

Figure 9 Relative execution time of macrobenchmarks compiled with and without SBBV (limit of 2 versions), separately for Bigloo and Gambit. 1.0 corresponds to compilation without SBBV. Lower values indicate better performance with SBBV.

Although the number of dynamic checks decreases with higher version limits, it does not always lead to a similar reduction of the execution time. Figure 9 shows that all macrobenchmarks execute faster with SBBV and a limit of 2 version (by 10% on average). However, no significant speedup is observed by further increasing the version limit. The relation between the version limit and execution time is discussed further in Section 4.4.3.

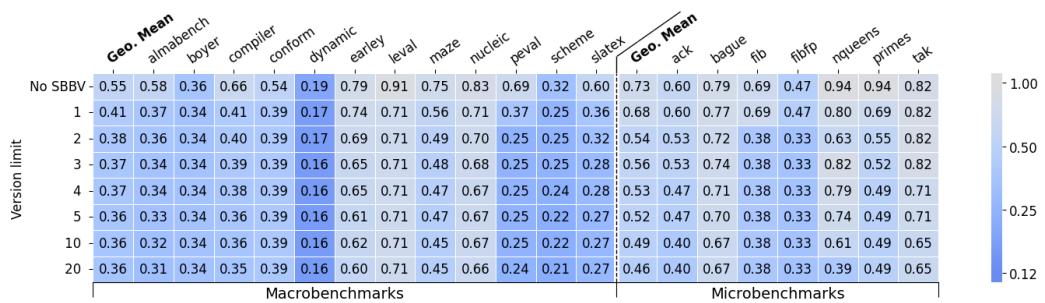

Increasing the version limit allows for more specialized versions. In the following sections, we take into account the impact of the version limit on the removal of dynamic checks, program size, execution speed, and compilation time. Each benchmark is compiled with version limits ranging from 1 to 5, as well as with limits of 10 and 20 versions, and it is compared to a compilation without SBBV. Limits higher than 5 are probably not very practical due to diminishing returns for the added compilation time. We tested with limits of 10 and 20 versions mostly to check the performance in extreme cases.

4.4.1 Dynamic Checks

Figure 10 shows the proportion of safety checks remaining after SBBV with increasing version limits. We estimate the number of remaining safety checks by subtracting checks in the unsafe version of a benchmark from those in the benchmark compiled with SBBV. To compute the total number of safety checks without SBBV, we apply the same formula to each benchmark compiled with no optimization, which effectively preserves all checks.

(a) Gambit.

(b) Bigloo.

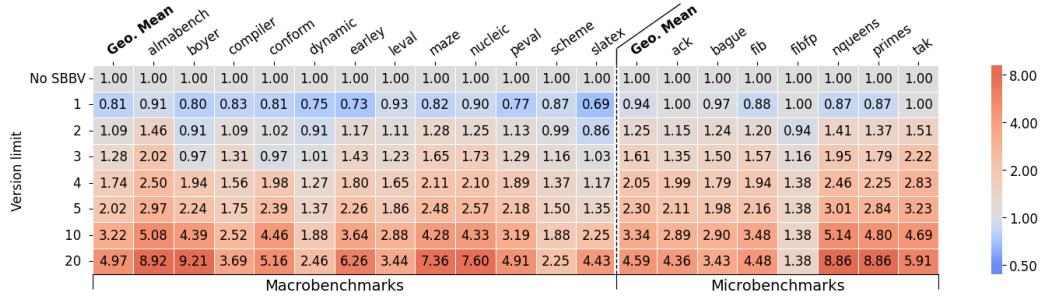

Figure 10 Effect of SBBV on the removal of dynamic checks (type, overflow, and array bound checks) with increasing version limits. Each cell shows the proportion of safety checks remaining for a given version limit and benchmark when compared to an unoptimized execution. The first row shows checks when SBBV is not applied and only existing optimization techniques are used. A ratio of 1 means that no dynamic checks were removed. Lower values indicate that more checks were removed.

Figures 10a and 10b show, on the first row, the proportion of remaining checks after applying the standard Gambit and Bigloo optimization techniques (*No SBBV*). The following rows display results with SBBV and specific version limits. For all benchmarks, SBBV removes more checks than the standard optimizations. As the version limit increases, more specialized versions are generated, allowing removal of additional checks.

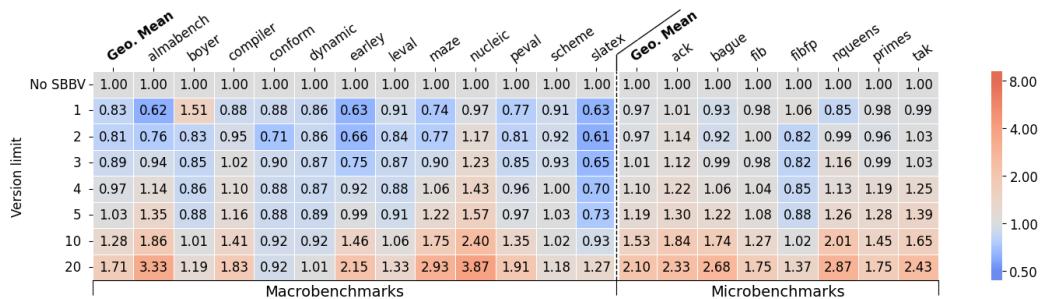

For low version limits, the number of dynamic checks steeply decreases as the limit increases. However, beyond a version limit of about 4, there is a diminishing return for almost all benchmarks. In some benchmarks, an upper bound is rapidly reached beyond which almost no more checks are removed (such as `boyer` at 1 version). In these cases, further increasing the limit contributes to the generation of relatively unimportant versions. Conversely, new useful versions are still discovered when increasing the version limit beyond 10 for some benchmarks (such as `tak` with Gambit).

Increasing the version limit sometimes increases the number of dynamic checks. For instance, in Figure 10a, the number of dynamic checks increases when incrementing the version limit from 2 to 3 in the `nqueens` benchmark with Bigloo. Increasing the version limit delays the merge of excess versions until more candidates are discovered. Given additional choices, the selection function may choose differently, merging a useful version that would have been kept otherwise. This highlights the room for improvement of our selection function.

28:20 Static Basic Block Versioning

(a) Gambit.

(b) Bigloo.

Figure 11 Program size with increasing version limits, relative to using the standard optimizations (No SBBV). Each cell shows the ratio between the program size with and without SBBV for a given version limit and benchmark. Lower values are better.

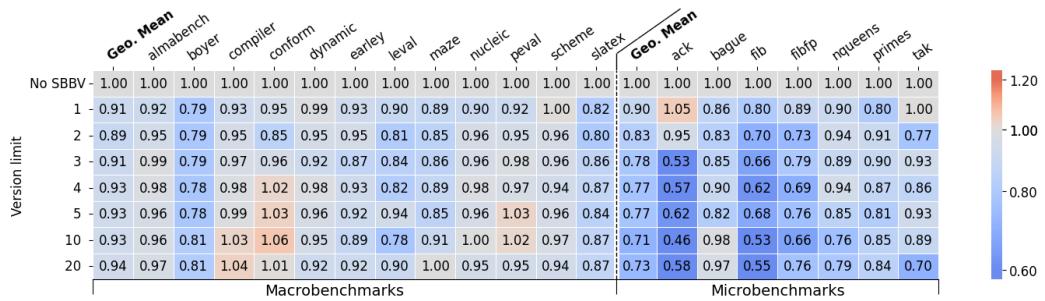

4.4.2 Program Size

We measured the program size of benchmarks compiled with SBBV. The size in bytes of each benchmark is obtained by disassembling its executable and subtracting the position of compiler specific labels. Hence, only the size of the code corresponding to each benchmark, excluding any runtime procedures, is considered.

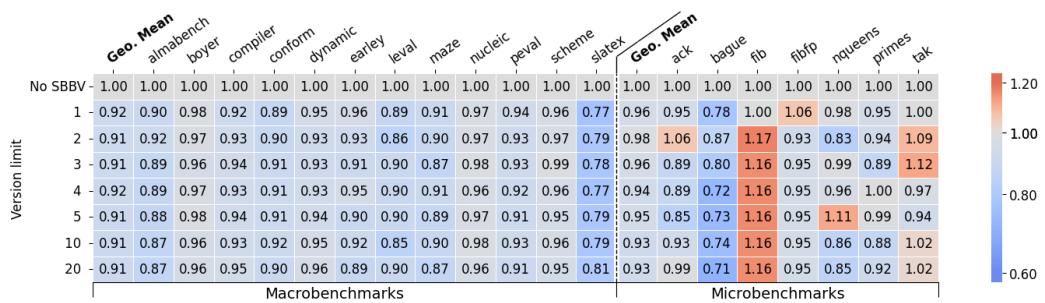

Since SBBV applies code duplication, higher version limits generally generate larger programs. Yet, low version limits may result in smaller executables. In the case of a limit of a single version, this is to be expected because SBBV becomes akin to a static type inference analysis without code duplication, which removes some unnecessary checks. However, for low enough version limits higher than one, SBBV can still reduce program size. In these cases, the removal of dynamic checks outweighs the duplication of basic blocks.

Figure 11b shows the relation between the size of a benchmark and the allotted version limit in Bigloo. On average, macrobenchmarks are smaller up to a limit of 5 versions. In general, the size increases with the version limit, but remains reasonably low with an average growth of about 1.7× on macrobenchmarks with a limit as high as 20 versions.

Figure 11a shows a similar pattern in Gambit, but with a higher growth rate. In the worst case, a growth of about 10× is observed (boyer, limit of 20 versions), highlighting the need to select a low enough version limit to curb code bloat. We found a version limit ranging from 2 to 4 to be a good compromise between removed dynamic checks and size.

(a) Gambit.

(b) Bigloo.

Figure 12 Execution time with SBBV and increasing version limits, relative to the standard optimizations (*No SBBV*). Each cell shows the ratio between the execution time with and without SBBV for a given version limit and benchmark. Lower values are better.

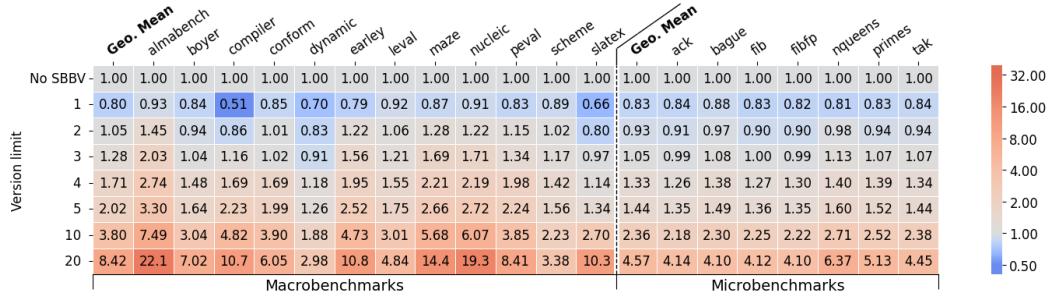

4.4.3 Execution Time

Figure 12 shows how the execution time of each benchmark varies with the version limit. Comparing performance to the number of dynamic checks from Figure 10 shows that a lower number of checks is not correlated to a faster execution in general. With Bigloo (Figure 12b), macrobenchmarks compiled with SBBV execute, on average, about 10% faster than without SBBV regardless of the version limit. With Gambit (Figure 12a), a similar speedup is observed for version limits below 4. Beyond this limit, execution speed still benefits, albeit to a lesser extent. We suspect that this discrepancy is caused by the increased code bloat observed with Gambit for high version limits, which reduces the performance of the instruction cache.

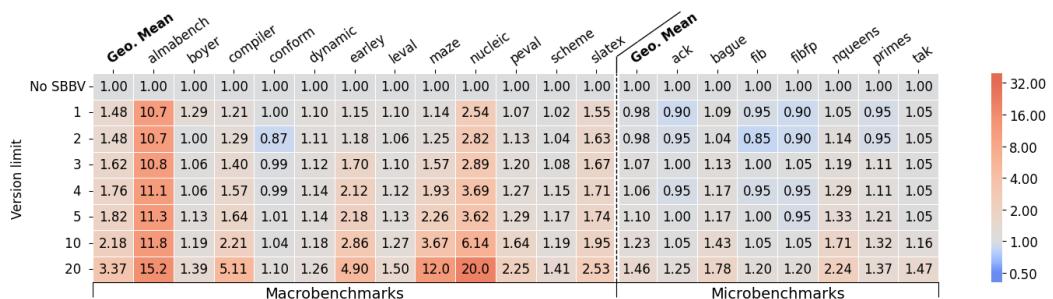

While some benchmarks benefit from a high version limit, the code speed and version limit is only vaguely correlated and contains noise. When optimizing for code speed, using a default version limit for all programs is suboptimal and it is good to give the programmer a manual control over the limit to explore the tradeoffs.

We explain this in part by hard-to-predict hardware optimizations by modern processor architectures. In particular, branch prediction makes dynamic type checking extremely cheap in typical code where a type check frequently returns the same result. Moreover, Bigloo and Gambit implement inexpensive type checks using pointer tagging. We hypothesize that SBBV would have a higher performance impact in implementations with more costly dynamic checks, such as NaN tagging, or object representations that need a memory access to check the type, such as BiBOP and object-oriented languages such as Java, Python, and Ruby.

28:22 Static Basic Block Versioning

(a) Gambit.

(b) Bigloo.

Figure 13 Compilation time with increasing version limits, relative to using the standard optimizations (No SBBV). Each cell shows the ratio between the compilation time with and without SBBV for a given version limit and benchmark. Lower values are better.

This highlights the need to refine the merge selection function. In the future, we intend to explore the space of possible merge heuristics, including nonlocal heuristics. We also wish to explore dynamic version limits, for instance by increasing the version limit of basic blocks that are likely to be in megamorphic code, as is done by YJIT [7, 8].

4.4.4 Compilation Time

We measured the compilation time for each benchmark and version limit and compared it to the compilation time without SBBV. Figure 13 shows the effect of the version limit on compilation time. In general, compilation time increases with the version limit. The reasons for this increase are twofold: firstly a higher version limit leads to more specialized versions of basic blocks within a control flow graph, secondly the increased size of the C code generated by Bigloo and Gambit leads to increased compilation time by the C compiler. Consequently, a lower program size is correlated to a shorter compilation time.

In the extreme case of a limit of 20 versions, compilation time increased by about 22× in the worst case (almbench with Gambit). However, in Section 4.4.1 we showed that there is a diminishing return from increasing the limit beyond about 4 versions. Choosing a limit of 2 caps the worst observed compilation time increase to about 1.5× with Gambit (almbench) while reaping most of the benefit of SBBV. On the same benchmark, Bigloo has a large compilation time increase starting at a limit of 1. This is due to the combined effect of a large function with multiple dispatch points and a live variable recalculation by the compiler that is not done by Gambit (register allocation is done before SBBV in the case of Gambit, and after SBBV in the case of Bigloo).

Program	Node.js 21.7.1	Bigloo 4.6a		Gambit 4.9.4-377		Chez 9.5.1	Racket 7.2
		No SBBV	SBBV	No SBBV	SBBV		
almabench	6.31	15.68	14.46	14.64	13.86	17.69	19.30
boyer	40.31	7.40	7.22	8.21	6.49	8.09	12.38
earley	56.75	14.90	13.83	10.87	10.34	9.53	24.73
leval	18.42	7.53	6.47	12.03	9.74	7.16	16.96

Figure 14 Average execution times of the benchmarks from [30] in seconds. Bold numbers indicate the fastest execution time for each benchmark. Lower is better.

4.5 Putting the Results in Context

The significance of the above results can be best appreciated through a comparison with other systems whose performance is more widely known. Our goal is to show that both Gambit and Bigloo are competitive with some of the leading implementations of dynamically typed languages, and thus that using SBBV is attractive in the context of high-performance implementations to increase performance further.

The Node.js system is a good comparable given that the JavaScript V8 JIT compiler on which it is based has been extensively engineered and it executes a dynamically typed programming language with similar core constructs as Scheme, to which prototype object-oriented features are added. The Chez Scheme [26] and Racket [25] systems are also interesting as high-performance representatives of the Lisp/Scheme family.

In order to do a fair comparison of systems for different languages, we use benchmark programs that have been translated to both Scheme and JavaScript in previous work [30]. Those programs are a subset of those used in the previous sections. Because of the similarity of JavaScript and Scheme, a systematic translation of the constructs is possible while avoiding important stylistic changes that would compromise the validity of the comparison. We have used the latest versions of those systems available at the time of writing through the Debian package manager (Node.js 21.7.1, Chez Scheme 9.5.1, and Racket 7.2). We measure the program execution time and, for Gambit and Bigloo, we compile the program without SBBV and with SBBV and a limit of 2 versions. Figure 14 gives the execution times in seconds.

The execution time for Gambit and Bigloo without SBBV is faster than Node.js on all the benchmarks except `almabench`, up to 24× faster for `bague`. Node.js does better on `almabench` than any other system because V8 has special optimizations for floating point numbers and arrays that are used by `almabench`. Gambit and Bigloo without SBBV are in the same ballpark as Chez Scheme, faster on roughly half the benchmarks. Racket is typically slower than Chez Scheme, on which it is built internally. When SBBV is used, both Bigloo and Gambit are consistently faster than without SBBV, including on benchmarks on which they already outperformed other compilers. This reinforces our belief that SBBV allows some optimizing compilers for dynamically typed programming language to generate even better code.

5 Related Work

Basic Block Versioning (BBV) was introduced by Chevalier-Boisvert and Feeley [5] as a technique for type check removal in JavaScript. The *lazy* BBV variant, suitable for JIT compilers, only generates versions that are executed, so it limits code bloat. On the other

hand, when the version limit is reached a fully generic version must be used, which negatively impacts type check reduction. SBBV avoids falling back on a generic version by selecting a set of versions that cover all cases but that are at least somewhat specialized. As shown in their Figure 7, a version limit of 2, which is their setting $\text{maxvers}=1$, shows a modest reduction of type checks for many benchmarks when compared to $\text{maxvers}=5$ because the fallback on the fully generic version is reached too quickly. SBBV achieves good performance with lower version limits. A variant of lazy BBV is used in production in the YJIT compiler inside CRuby [7, 8], also falling back on a fully generic version upon reaching the version limit (which can be 4, 10, or 20 depending on the situation).

The *eager* BBV variant described in [5] is suitable for AOT compilers, like SBBV, but suffers from large code bloat so it was deemed impractical and not explored further [5]. In comparison, SBBV with a version limit of 2, which achieves a comparable level of dynamic check removal, causes an average code size increase of 9% for Gambit and a decrease of 19% for Bigloo.

SBBV can be explained by the theory of abstract interpretation introduced by Cousot and Cousot [10]. The authors presented a theoretical framework for building lattice-based fixed point algorithms. Their work ensures that the SBBV algorithm converges. Furthermore, their seminal paper introduced *union with widening*. Widening not only ensures that the algorithm converges, but also that it converges fast enough to be practical.

SBBV generalizes well-known optimization techniques such as loop-unrolling [2], constant-folding [2], and tail duplication [24]. Tail duplication replicates the code after conditional branches instead of merging the control flow to a single basic block. This permits propagating the information acquired from a condition beyond the body of each branch, allowing further optimizations.

Determining when to apply tail duplication remains a challenge. Leopoldseder *et al.* proposed a simulation-based approach to determine which duplications are the most promising in term of optimization opportunities while minimizing code size [18]. This is analogous to how the choice of a selection function impacts the efficiency of SBBV.

More recently, D’Souza *et al.* applied tail duplication in TASTyTruffle, a Scala JIT compiler using Truffle. TASTyTruffle performs tail duplication at the AST level to generate guarded versions of polymorphic functions that are then specialized by the Graal compiler [13].

Our work is related to occurrence typing that is in particular used in Racket [33]. Occurrence typing is a type system that allows a context-sensitive refinement of variable types during static analysis, for instance by typing a variable differently in each branch of a conditional statement. In the context of our work, occurrence typing synergizes well with tail duplication to further propagate context-sensitive type information.

Partial function inlining can also be done if SBBV is applied interprocedurally. We have not done this in the current work because it is tricky to extend the versioning contexts to track code pointers for function entry and return points. This will require future work.

Code optimization by duplication and specialization has been extensively studied and used for various programming languages [12, 3, 29, 4, 9]. Recently Flückiger *et al.* [15] optimized the compilation of R programs by function specialization. They show that this technique makes programs run $1.7\times$ faster on average. Subsequently a study by Mehta *et al.* [21] has used a mechanism that keeps multiple versions of a given function specialized for contexts encountered at runtime by JIT compilers. Specialized versions of a function are stored in an external repository, allowing switching between versions when de-optimization occurs and to reuse versions of functions across executions and programs. SBBV is related to these techniques but the granularity of cloning is finer as it clones basic blocks while all

those previous works clone whole function bodies. This enables SBBV to better control the code expansion and to spend the cloning budget on relevant specializations without falling back on a fully generic version or using de-optimization, which is not an option in an AOT context. This sort of fine optimization tuning is out of reach for techniques that specialize at the level of whole function bodies.

6 Conclusion

Previous work has shown that the lazy variant of Basic Block Versioning (BBV) is effective in practice for optimizing dynamic checks in JIT compilers for dynamic languages [5, 27, 7, 8]. The *static* BBV (SBBV) approach that we have described in this paper is a variant of BBV that determines, through a fix-point program analysis, a set of basic block versions that are appropriate for the program and that covers all possible contexts without exceeding some versioning limit. This gives control over the code bloat induced by the multiple specializations of individual basic blocks in a way that avoids falling back on an unoptimized generic version of the basic block when the versioning limit is reached. SBBV is thus particularly interesting for use in AOT compilers and consequently it does not suffer from a warmup time.

At the core of the SBBV algorithm is a heuristic to drive the merging of previously generated versions to keep the number of versions within the allowed limit. We have shown through experiments that even a simple merge heuristic removes dynamic checks effectively in practice.

As a second contribution, we have shown in this paper how to extend the BBV approach to implement optimizations that go beyond the elimination of dynamic type checks. We have shown how to use it to remove integer overflow checks and bound checks effectively. By doing so, we have shown that the BBV approach can be viewed as a general programming analysis methodology that can be used to implement various optimizations that otherwise are implemented in isolation using dedicated techniques.

Abstract

Tensors are multi-dimensional data structures that can represent the data processed by machine learning tasks. Tensor programs tend to be short and readable, and they can leverage libraries and frameworks such as TensorFlow and PyTorch, as well as modern hardware such as GPUs and TPUs. However, tensor programs also tend to obscure shape information, which can cause shape errors that are difficult to find. Such shape errors can be avoided by a combination of shape annotations and shape analysis, but such annotations are burdensome to come up with manually.

In this paper, we use gradual typing to reduce the barrier of entry. Gradual typing offers a way to incrementally introduce type annotations into programs. From there, we focus on tool support for *type migration*, which is a concept that closely models code-annotation tasks and allows us to do shape reasoning and utilize it for different purposes. We develop a comprehensive gradual typing theory to reason about tensor shapes. We then ask three fundamental questions about a gradually typed tensor program. (1) Does the program have a static migration? (2) Given a program and some arithmetic constraints on shapes, can we migrate the program according to the constraints? (3) Can we eliminate branches that depend on shapes? We develop novel tools to address the three problems. For the third problem, there are currently two PyTorch tools that aim to eliminate branches. They do so by eliminating them for just a single input. Our tool is the first to eliminate branches for an infinite class of inputs, using static shape information. Our tools help prevent bugs, alleviate the burden on the programmer of annotating the program, and improves the process of program transformation.

1 Introduction

Multidimensional data structures are a common abstraction in modern machine learning frameworks such as PyTorch [13], TensorFlow [1], and JAX [5]. A significant portion of programs written using these frameworks involve transformations on tensors. Tensors in this setting are *n*-dimensional arrays. A tensor is characterized by its *rank* and *shape*. The *rank* is the number of dimensions. For example, a matrix is two-dimensional; hence it is a rank-2

29:2 Generalizing Shape Analysis with Gradual Types

tensor. The *shape* captures the lengths of all axes of the tensor. For example, in a 2×3 matrix, the length of the first axis is 2 and the length of the second axis is 3; hence its shape is $(2, 3)$.

Programming with tensors provides the programmer with high level and easy to understand constructs. Furthermore, tensors can utilize modern hardware such as GPUs and TPUs for parallelization. For those reasons, programming with tensors is preferred over programming with scalars and nested loops.

Tensors in programming languages present the challenge that their shapes are hard to track. Modern machine learning frameworks support a plethora of operations on tensors, with complex shape rules. Addition for example, typically supports *broadcasting*, which is a mechanism that allows us to add tensors of different shapes, which is not intuitive. Complex shape rules make shapes hard to determine in programs, because shape information rarely explicitly appears in them. As a result, shape errors occur frequently [31].

When not caught statically, shape errors will appear at runtime, which is undesirable because we would only know about the error when the wrong operation is finally invoked on concrete runtime values. Tensor computations are costly and a program may take a long time to run before finally crashing with an error. Additionally, some shape errors occur only for specific input shapes.

The ability to reason about shapes is useful in various contexts in the machine learning area. It can prevent programmers from making mistakes and since programmers routinely transform machine learning programs [17], shape reasoning can also help program transformation tools to make valid program transformations because program transformations may depend on shape information.

Users often add asserts or comments to help them reason about shapes. These tasks have a high cognitive load on users, especially when they are dealing with complex tensor operations. Shape asserts present even further challenges; they can manifest in the form of branches on program shapes. We observed this pattern on various transformer benchmarks [30]. Thus, in that pattern, the result of a branch depends on the shape of the program input, so the branch result can vary over different inputs. In machine learning programs, branches can be undesirable because they limit the back-ends a program can be run on, such backends include TensorRT and XLA. The reason control-flow is undesirable is it complicates fix-point analysis, particularly in shape propagation [17]. In practice, various tools handle this challenge in different ways. Some tools reject such programs entirely while other tools run the program on a single input to eliminate branches. Running a program on a single input means that branch elimination is correct for just one input, which is an unsatisfactory solution.

Aiming to prevent the need for ad-hoc shape asserts, entire systems have been build to detect shape errors such as [15] and [24]. However, these systems are too specific. They lack a general theoretical foundation that enables their solution to be adapted to a variety of contexts, including incorporating their logic into compilers and program transformation tools.

A fundamental approach towards shape analysis is designing a type system that supports reasoning about shapes. In that approach, shapes are type annotations. Traditionally, types have been used to solve similar problems in the area of programming languages. A fully static type system with tensor shapes [20] has limitations. First, a static type system may need to be elaborate in order to capture the complexities of machine learning programs, which are typically written in permissive languages such as Python. As a result, refinement or polymorphic types may be needed. Second, a static type system has a high barrier of entry

because it requires the user to come up with non-trivial type annotations in advance. Third, many machine learning programs are in Python, so they are usually only partially typed. Therefore, fully typed programs are not readily available, which prevents this approach from being backwards-compatible.

A common way to circumvent the requirement of having fully typed programs is to use gradual types. In a gradually typed system, type annotations are not needed for the program to compile, when a compiler does type erasure. However, for a gradually typed system to be widely usable, it should enable principled yet practical tool support. Previous work such as [9] designed a gradually typed system for shapes but it is so powerful that practical, elaborate tool support may be hard to obtain. *We believe that the key to shape analysis with gradual types is to balance between (1) the expressiveness of a gradually typed system and (2) the ease of tool support in that system.*

We show that gradual types can help us tackle shape-related problems in a principled and unified way. We introduce a gradual typing system that reasons about shapes and enables tool support.

We distill the challenge of shape analysis into three key problems that we can ask of every gradually typed tensor program, and we introduce a general theory to solve all of them:

- Q(1): *Static migration*: Does the program have a static migration?
- Q(2): *Migration under arithmetic constraints*: Given a program and some arithmetic constraints on shapes, can we migrate the program according to the constraints?
- Q(3): *Branch elimination*: Can we eliminate branches that depend on shapes?

We use PyTorch as the setting for our tool design and evaluation, though our approach is more generally applicable. For Q(1) and Q(2), PyTorch does not currently have any comparable tools, so our tools for those challenges do something new in the PyTorch setting.

For Q(3), we incorporate our shape reasoning into two existing PyTorch tools that aim to eliminate branches from PyTorch programs. After augmenting both tools with our logic, we are able to improve the performance and accuracy of both tools as we will describe below. Our contributions can be summarized as follows:

1. A gradually typed tensor calculus that satisfies static gradual criteria [23].
2. A formal characterization of Q(1), Q(2) and Q(3) and their solutions.
3. A demonstration of how our approach works for Q(1) and Q(2) on four benchmarks.
4. For Q(3), a comparison on six benchmarks, against HuggingFace Tracer (**HFTtracer**) [30], a PyTorch tool. **HFTtracer** eliminates all branches based on a single input, while we eliminate all branches based on infinite classes of inputs. We use constraints to represent infinite classes of inputs.
5. For Q(3), a comparison on five benchmarks against **TorchDynamo** [2], a PyTorch tool. **TorchDynamo** eliminates 0% of the branches in these benchmarks, while we eliminate branches by 40% to 100% on infinite classes of inputs.

The full version has Appendices A–F with definitions and proofs.

2 Three Migration Problems

In this section, we introduce our type system informally, and we postpone the formal details to Section 3. A tensor type in our system is of the form `TensorType(d_1, \dots, d_n)` where d_1, \dots, d_n are dimensions.

Every gradually typed system has a type `Dyn`, which represents the absence of static type information. In our system, `Dyn` can appear as a dimension, in which case the dimension is unknown. `Dyn` can also appear as a tensor annotation, in which case even the rank of the tensor is unknown.

In a gradual type system, a precision relation refers to the replacement of some of the occurrences of `Dyn` with static types. `Dyn` is the least precise type because it contains no type information. `TensorType(1, 2, 3)` and `TensorType(1, 2)` are unrelated by the precision relation because we cannot go from one type to another by replacing `Dyn` occurrences with more informative types, while `TensorType(Dyn, 2)` is less precise than `TensorType(1, 2)` because we can replace the `Dyn` in

`TensorType(Dyn, 2)` with 1 to get `TensorType(1, 2)`. This relation extends to programs. Program *A* is less precise than program *B* if we can replace some occurrences of `Dyn` in program *A* to get to program *B*. Intuitively, program *B* is more static than program *A*. Precision gives rise to the *migration space* [12]. Given a well-typed program *P*, its migration space is the set of well-typed programs that are at least as precise as *P*.

Intuitively, the migration space captures all ways of annotating a gradually typed program more precisely. Those possibilities form a partially ordered set, and our goal is to help the programmer find the migration paths they are looking for. With that in mind, let us look at examples of how reasoning about the migration space is beneficial for solving key problems about the shapes in a gradually typed program. Specifically, in Section 2, we will see two examples about Q(1) and Q(2) respectively, and in Section 2, we will see an example about Q(3).

For an example of static migration, consider Listing 1 which has a type error.

```

1 class ConvExample(torch.nn.Module):
2     def __init__(self):
3         super(BasicBlock, self).__init__()
4         self.conv1 = torch.nn.Conv2d(in_channels=2, ...)
5         self.conv2 = torch.nn.Conv2d(in_channels=4, ...)
6
7     def forward(self, x: TensorType([Dyn, Dyn])):
8         self.conv1(x)
9         return self.conv2(x)

```

■ Listing 1 Ill-typed convolution.

In line 7, `x` is annotated with `TensorType([Dyn, Dyn])`. This is a typical gradual typing annotation which indicates that `x` is a rank-2 tensor. The annotation does not specify what the dimensions are. In line 8, we are applying a convolution to `x`. Intuitively, convolution is a variant of matrix multiplication; neural networks use it to extract features from images. According to PyTorch’s documentation, for the convolution to succeed, `x` cannot be rank-2. Thus, the type error stems from a wrong type annotation. The migration space of this program can easily inform us that the program is ill-typed, because the space will be empty. The reason for that is that the migration space of a well-typed program should contain at least one element, which is the program itself. A tool that can reason about the migration space can easily catch this bug in a single step.

Let us fix this bug by replacing the wrong type annotation with a correct one. In Listing 2, we change `x`’s annotation from a rank-2 annotation to a rank-4 annotation: `TensorType([Dyn, Dyn, Dyn, Dyn])`, which is correct. This program compiles, but it contains a more subtle bug. Let us look closely at the code to understand why.

In line 4, we initialize a field, `self.conv1`, representing a convolution, `torch.nn.Conv2d`, which takes various parameters. The parameter that’s relevant to our point is called `in_channels` and it is set to 2. In line 5, we are initializing another field, `self.conv2`, but this time, we set the `in_channels` to 4. In line 7, we have a function that takes a variable `x` and calls both convolutions on it in lines 8 and 9. To understand why this program contains a bug, we must ask: *how does the value of `in_channels` relate to `x`’s shape?* PyTorch’s

documentation [14] states that in the simplest case, the input to a convolution has the shape $(N, \text{in_channels}, H, W)$. Indeed, in line 7, `x` is annotated with `TensorType([Dyn, Dyn, Dyn, Dyn])`, a typical gradual typing annotation indicating that `x` is a rank-4 tensor. The annotation does not state what the dimensions are, but it is still consistent with the shape stated in the documentation. Notice however that `x`'s second dimension should match the value of `in_channels`, while we have two values for `in_channels` that do not match. This mismatch will cause the program to crash if it ever receives any input, but not before. Our key questions can help us discover the bug statically across all inputs.

```

1 class ConvExample(torch.nn.Module):
2     def __init__(self):
3         super(BasicBlock, self).__init__()
4         self.conv1 = torch.nn.Conv2d(in_channels=2, ...)
5         self.conv2 = torch.nn.Conv2d(in_channels=4, ...)
6
7     def forward(self, x: TensorType([Dyn, Dyn, Dyn, Dyn])):
8         self.conv1(x)
9         return self.conv2(x)

```

■ Listing 2 Gradually typed convolution.

By determining whether we can replace all the `Dyn` dimensions with numbers (which is the answer to Q(1) from our key questions), we can discover that it is impossible to assign a number to the second dimension of `x` and thus detect the error before running the program. More generally, the absence of a static typing may reveal that a program cannot run successfully on any input.

How can we benefit from the migration space to answer Q(1) and thus detect that this program cannot be statically typed? The migration space for this program contains programs where `x` is annotated to be a rank-4 tensor. A tool that can reason about the migration space can then take an extra constraint on the second dimension of `x`. The constraint should say that the second dimension must be a number. This constraint will narrow down the migration space to an empty set. The reason is that there is no such well-typed program. Therefore, we can conclude that the program cannot be statically typed because the second dimension cannot be assigned a number.

Let us fix the bug. One way to fix the bug is by removing `self.conv1` from the program. We get the program in Listing 3.

```

1 class ConvExample(torch.nn.Module):
2     def __init__(self):
3         super(BasicBlock, self).__init__()
4         self.conv2 = torch.nn.Conv2d(in_channels=4, ...)
5
6     def forward(self, x: TensorType([Dyn, Dyn, Dyn, Dyn])):
7         return self.conv2(x)

```

■ Listing 3 Gradually typed convolution.

The program can run to completion and there can be various correct ways to annotate it. The current annotation for the variable `x` is that it is a tensor with four dimensions, but each dimension is denoted by `Dyn`, so the values of the dimensions are unknown. Suppose we want to specify constraints on those dimensions and determine if there are valid migrations that satisfy those constraints. This would be useful, not just for the user, but for compilers, since they can use those constraints to optimize for resources.

We can require some of the dimensions of `x` to be static and then provide arithmetic constraints on each of them. In this example, let us require all dimensions to be static. A tool can accept four constraints indicating this requirement. Then it can accept constraints

29:6 Generalizing Shape Analysis with Gradual Types

that specify ranges on those dimensions. For example, the first dimension could be between 5 and 20. The second dimension can only have one possible value, which is 4. So it is enough to have a constraint requiring that dimension to be a number. The third dimension could also be between 5 and 20, while the fourth dimension could be between 2 and 10.

By giving these constraints as input to a tool, we are constraining the space to only the subspace that satisfies the constraints. A tool may find that this subspace indeed contains programs and outputs one of them. As a result, we may get the program in Listing 4. As shown, `x` has now been statically annotated with `TensorType([19, 4, 19, 9])`.

```
1 class ConvExample(torch.nn.Module):
2     def __init__(self):
3         super().__init__()
4         self.conv2 = torch.nn.Conv2d(in_channels=4, ...)
5     def forward(self, x: TensorType([19, 4, 19, 9])):
6         return self.conv2(x)
```

10        else:
11            return torch.nn.Dropout(x)
```

■ Listing 5 Branch elimination.

The program in Listing 5 can run to completion, and interestingly it contains control-flow in the form of a branch. We want to eliminate this branch. We refer to eliminating branches from a program by the term *branch elimination*. Eliminating branches enables programs to run on back-ends where branches are undesirable. For example, `HFTtracer` runs a program on a single input and computes the result of the branch and eliminates it accordingly. While the result of a branch could be fixed for all program inputs, the result may also vary. Thus, running a program on just a single input to eliminate a branch yields unsatisfactory branch elimination. We enable better branch elimination by finding all inputs for which a branch evaluates to a given result by reasoning about the program statically. We provide a mechanism to denote the set of inputs for which a branch evaluates to the given result. Notice that we reason about the static information given. Thus, if a variable has type `Dyn`, we optimistically assume that the program is well-typed and that the value for that variable will have the appropriate type at runtime.

The program in Listing 5 contains a condition that depends on shape information. This is a common situation, where ad-hoc shape-checks are inserted in a program to reason about its shapes. Line 8 has function that takes a variable `x` and applies a convolution to it, with `self.conv(x)`, and a condition that checks if the rank of `self.conv(x)` is 4. Since `x` is annotated as a rank-4 tensor on line 7, and convolution preserves the rank, `self.conv(x)` must also be rank-4. So the condition must always be true under the information given by `x`'s type annotation. We should be able to prove that the condition in line 8 always returns true without receiving any input for the program, by inspecting all the valid types that the program could possibly have. The migration space is useful for this analysis because it captures all possible, valid type annotations for a program.

Thus, under the convolution type rules, if `self.conv(x).dim() == 4` evaluates to true, then `x` is also rank-4, which is consistent with `x`'s current annotation.

In contrast, if `self.conv(x).dim() == 4` evaluates to false, i.e `self.conv(x).dim() != 4` is true, then this means that `x` is not rank-4. However, the migration space of a program can never include inconsistent ranks for a variable. Therefore, it is impossible to have `self.conv(x).dim() != 4`, while also having that `x` is rank-4. A tool that reasons about the migration space as well as arbitrary predicates can make this conclusion. In this example, we can make a definitive conclusion about the result of this condition and we can re-write our program accordingly, as shown in Listing 6. We will expand on and formalize this idea in Section 5. In particular, we will detail how we reason about the migration space in the presence of branches, and explain why our approach works.

```

1 class ConvControlFlow(torch.nn.Module):
2     def __init__(self):
3         super().__init__()
4         self.conv = torch.nn.Conv2d(
5             in_channels=512, out_channels=512, kernel_size=3)
6
7     def forward(self, x: TensorType([Dyn, Dyn, Dyn, Dyn])):
8         return torch.relu(x)

```

 **Listing 6** Branch elimination.

3 The Gradual Tensor Calculus

In this section, we describe our design choices, core calculus, and type system, and we prove that our type system satisfy gradual typing criteria.

Our design choices are guided by enabling four key requirements: (1) modularity and backwards compatibility, (2) tool support, (3) expressiveness, and (4) minimality of our language. We have made these four choices in the context of tool support for PyTorch, but they can be extended to other frameworks. Here, we outline those design choices.

First, we require our system to support *modularity and backwards compatibility* for programs. A gradually typed system suits our needs because it supports partial type annotations. One of the implications of this support is that gradually typed programs can compile with any amount of type annotations. In a gradually typed system, a missing type is represented by the `Dyn` type.

The `Dyn` type can sometimes be assigned to a variable that has been used in different parts of the program with different, possibly inconsistent types. This type is useful when the underlying static type system is not flexible enough to fully type that program. For example, we may have a program that takes a batch of images with a dynamic batch size, as well as dynamic sizes, but with a fixed number of channels. In this case, a possible type would be `TensorType(Dyn, 3, Dyn, Dyn)`, which indicates a batch of images, where the batch size is dynamic and the sizes are dynamic but the number of channels, which is 3, is fixed. Another example is that a variable could be assigned a rank-2 tensor at one point in the program, then a rank-3 tensor at a different point. A suitable type for that variable could simply be `Dyn`. In both examples, if we did not have the `Dyn` type, we would need more complex annotations. The `Dyn` type allows the gradual type checker to admit programs statically, and determine how to handle variables with `Dyn` types at runtime. The flexibility of gradual types stems from the consistency relation, which is symmetric and reflexive but not transitive. This relation allows a gradual type checker to statically admit programs in the absence of type information.

$$\frac{\Sigma, e \rightarrow^* \sigma, R, 0}{\Sigma, \text{reshape}(e, \text{TensorType}(d_1, \dots, d_n)) \rightarrow^* \Sigma, \text{RESHAPE}(R, (d_1, \dots, d_n))} (\text{Reshape})$$

$$\frac{\Sigma, e \rightarrow^* \Sigma, R, 0}{\Sigma, \text{Conv2D}(c_{in}, c_{out}, \kappa, e) \rightarrow^* \Sigma, \text{CONV2D}(c_{in}, c_{out}, \kappa, R)} (\text{Conv})$$

$$\frac{\Sigma, e_1 \rightarrow^* \Sigma, R_1, 0 \quad \Sigma, e_2 \rightarrow^* \Sigma, R_2, 0}{\Sigma, \text{add}(e_1, e_2) \rightarrow^* \Sigma, \text{ADD}(R_1, R_2)} (\text{Add})$$

 **Figure 1** Gradual tensor calculus, syntax and semantics.

Second, we require *tool support*. We design a simple type system for a core language to enable us to define and solve problems for tool support in a tractable way. Tool support is tractable because we define type migration syntactically. We base our approach on capturing the migration space by extending the constraint-based approach of [12] to solve our three key questions.

Third, we require our system to be *expressive* enough to capture non-trivial programs. Our type system is more expressive than PyTorch’s existing type-system, which does not reason about dimensions. Our language consists of a set of declarations followed by an expression. This structure is a convenient representation for the PyTorch neural network models we encountered, which mainly consisted of a function which takes a set of parameters. In the function body are tensor operations applied on those parameters. This calculus structure is inspired by the calculus from [18]. Rink highlighted that many DSLs can be mapped to their language. Besides adapting the structure of that calculus, we choose three core operations that present different challenges for tool support, and then extend our support to 50 PyTorch operations.

Fourth, we require our language to be *minimal* so we can focus on our core problems. First, we do not introduce branches to our core grammar since, in practice, all tools on which we ran our experiments either do not accept programs with branches or aim to eliminate branches. As [17] noted, many non-trivial tensor programs do not contain branches or statements. In Section 5 we extend the core language with branches and we show how to eliminate them.

Second, we do not consider runtime checks to support gradual types. Those checks are often a bottleneck for the performance of gradually typed programs [25, 8]. There has been extensive research to alleviate performance issues by weakening these checks. As shown by [7], the notion of soundness in gradual types is not an all-or-nothing concept. [7] discuss three notions of soundness at different levels of strength and how they relate to performance: higher-order embedding of [26], first-order embedding, as seen in Reticulated Python [28] and erasure embedding, as seen in TypeScript [4]. Similar to [18] and [17], we observe that a language free from higher-order constructs represents a large subset of programs that are written in the machine learning area. As such, runtime errors are not as interesting when compared to those that arise in languages with constructs such as branches and lambda-abstraction. Furthermore, runtime checks impose a computation cost on already costly tensor computations. A key goal of tensor programming is high performance so adding run-time checks seems undesirable. Thus, we leave out runtime aspects in this paper.

Figure 1 shows our core calculus. A program consists of a list of declarations followed by a return statement that evaluates an expression. We use ϵ to denote the empty list of declarations. The program takes its input via those declarations. The dynamic type is denoted by `Dyn`. A dimension can be `Dyn`, and a tensor can also be `Dyn`. A tensor is denoted by the constructor `TensorType($\sigma_1, \dots, \sigma_n$)` where $\sigma_1, \dots, \sigma_n$ are dimensions. However, if we denote a dimension by `U` or `D`, it means the dimension is a number and cannot be `Dyn`. Our language has four kinds of expressions. A variable x refers to one of the declared variables. The expression `add(e_1, e_2)` adds two tensors e_1 and e_2 . The expression `reshape(e, τ)` takes an expression e and a shape τ and reshapes e to a new tensor of shape τ if possible. Reshaping can be thought of as a re-arrangement of a tensor’s elements. That requires the initial tensor to have the same number of elements as the reshaped tensor. We require that τ can have a maximum of one `Dyn` dimension. Finally the expression `Conv2D($c_{in}, c_{out}, \kappa, e$)` applies a convolution to e , given a number representing the input channel c_{in} , a number representing the output channel c_{out} , and a pair of numbers representing the kernel κ . For example, in Listing 2, we had `self.conv1(x)`, which in our calculus can be expressed as `Conv2D(2, 2, (2, 2), x)`. The full version of convolution in PyTorch has more parameters. We have accounted for those parameters in our implementation, but because they create no new problems for us, our quest for minimality led us to leaving them out.

The operational semantics in Figure 1 evaluates an expression in an environment Σ that maps each declared variable to a tensor constant. Specifically, if e is an expression, R is a tensor constant, and E an error state (0 for success, 1 for failure), then the judgment $\Sigma, e \rightarrow^* R, E$ means that e evaluates to R in error state E .

The semantics uses the helper functions `ADD`, `RESHAPE`, and `CONV2D` that each produces both a tensor constant and an error state. In Appendix C, we give full details of those functions and we state their key properties. Here we summarize what they do. The function `ADD` extracts shapes from T_1 and T_2 and pads them such that they match, and then checks if the tensors are broadcastable based on the updated shapes. If they are not broadcastable, it returns the empty tensor with $E = 1$. Otherwise, it expands the tensors T_1 and T_2 according to the broadcasting rules of PyTorch that we omit here. It initializes a resulting tensor with

29:10 Generalizing Shape Analysis with Gradual Types

Consistency

$$\begin{array}{lll} \tau \sim \tau \text{ (c-refl-t)} & d \sim d \text{ (c-refl-d)} & d \sim \text{Dyn } (d\text{-refl-dyn}) \\ \frac{t \sim \tau}{\tau \sim t} \text{ (c-sym-t)} & \frac{d \sim \sigma}{\sigma \sim d} \text{ (c-sym-d)} & \tau \sim \text{Dyn } (t\text{-refl-dyn}) \end{array}$$

$$\frac{\forall i \in \{1, \dots, n\} : d_i \sim d'_i}{\text{TensorType}(d_1, \dots, d_n) \sim \text{TensorType}(d'_1, \dots, d'_n)} \text{ (c-tensor)}$$

Type Precision

$$\frac{\tau \sqsubseteq \tau \text{ (refl-t)} \quad d \sqsubseteq d \text{ (c-refl-d)} \quad \text{Dyn} \sqsubseteq d \text{ (refl-dyn-1)} \quad \text{Dyn} \sqsubseteq \tau \text{ (refl-dyn-2)}}{\text{TensorType}(d_1, \dots, d_n) \sqsubseteq \text{TensorType}(d'_1, \dots, d'_n)} \text{ (p-tensor)}$$

Program and Expression Precision

$$\frac{\forall i \in \{1, \dots, n\} : \text{decl}'_i \sqsubseteq \text{decl}_i \quad e' \sqsubseteq e}{\text{decl}'_1, \dots, \text{decl}'_n \text{ return } e' \sqsubseteq \text{decl}_1, \dots, \text{decl}_n \text{ return } e} \text{ (p-prog)} \quad \frac{\tau' \sqsubseteq \tau}{x : \tau' \sqsubseteq x : \tau} \text{ (p-decl)}$$

$$e \sqsubseteq e \text{ (p-refl)}$$

Matching

$$\frac{\text{TensorType}(\tau_1, \dots, \tau_n) \triangleright^n \text{TensorType}(\tau_1, \dots, \tau_n)}{\text{Dyn} \triangleright^n \text{TensorType}(l) \text{ where } l = [\text{Dyn}, \dots, \text{Dyn}] \text{ and } |l| = n}$$

Static context formation

$$\frac{}{\epsilon \vdash \emptyset} \text{ (s-empty)} \quad \frac{\text{decl}^* \vdash \Gamma \quad x \notin \text{dom}(\Gamma)}{\text{decl}^* x : \tau \vdash \Gamma, x : \tau} \text{ (s-var)}$$

 **Figure 2** Auxiliary functions.

the broadcasted dimensions and perform element-wise addition between the broadcasted tensors and return that tensor with $E = 0$. The function RESHAPE performs dimension checks to ensure that reshaping is possible, returning the empty tensor and $E = 1$ if the checks fails. Otherwise, it performs reshaping and returns the reshaped tensor with $E = 0$. The function CONV2D extracts the dimensions of the input tensor I , as well the dimensions for the kernel κ and uses them to determine the size of the output tensor. It then performs convolution and populates the output tensor one element at a time and return the updated tensor along with $E = 0$.

The semantics satisfies the following theorem, which says that in an environment, an expression evaluates to a tensor but may end with failure.

► **Theorem 1.** $\forall \Sigma, e : \exists a \text{ tensor constant } R : \exists E \in \{0, 1\} : \Sigma, e \rightarrow^* R, E$.

Figure 2 contains gradual typing relations that are used in our gradual typechecking, as well as the static context formation rules. Those relations allow the typechecker to reason about the `Dyn` type. Matching, denoted by \triangleright , and consistency, denoted by \sim , are standard in gradual typing and are lifted from equality in the static counter part of the system. Matching and consistency are both weaker than equality because they account for absent type information. Thus, if some type information is missing, matching and consistency apply. Matching is a relation that pattern-matches two types. It is useful for arrow types

$$\begin{array}{c}
\frac{\text{decl}^* \vdash \Gamma \quad \Gamma \vdash e : \tau}{\vdash \text{decl}^* \text{return } e \text{ ok}} \text{ (ok-prog)} \quad \frac{x : \tau \in \Gamma}{\Gamma \vdash x : \tau} \text{ (t-var)} \\
\\
\frac{\Gamma \vdash e : \text{TensorType}(D_1, \dots, D_n) \quad \prod_1^n D_i = \prod_1^m U_i}{\Gamma \vdash \text{reshape}(e, \text{TensorType}(U_1, \dots, U_m)) : \text{TensorType}(U_1, \dots, U_m)} \text{ (t-reshape-s)} \\
\\
\frac{\Gamma \vdash e : \text{TensorType}(\sigma_1, \dots, \sigma_m)}{\prod_1^m \sigma_i \text{ mod } \prod_1^n d_i = 0 \vee \prod_1^n d_i \text{ mod } \prod_1^m \sigma_i = 0 \quad \forall d_i, \sigma_i \neq \text{Dyn} \text{ and}} \\

\end{array}$$

■ **Figure 3** Type rules.

in traditional type systems. Specifically, an arrow type $t_1 \rightarrow t_2$ matches itself. Type Dyn matches $\text{Dyn} \rightarrow \text{Dyn}$. The ability to expand Dyn to become a function type $\text{Dyn} \rightarrow \text{Dyn}$ is valid in gradual types because it allows the system to optimistically consider the type Dyn to be $\text{Dyn} \rightarrow \text{Dyn}$. We have adapted this definition to our system. First, we annotated matching with a number n to denote the number of dimensions involved. So we have that $\text{TensorType}(\tau_1, \dots, \tau_n) \triangleright^n \text{TensorType}(\tau_1, \dots, \tau_n)$ because any type matches itself. Similar to how traditionally, $\text{Dyn} \triangleright \text{Dyn} \rightarrow \text{Dyn}$, we have that $\text{Dyn} \triangleright^n \text{TensorType}(\text{Dyn}, \dots, \text{Dyn})$, where $\text{Dyn}, \dots, \text{Dyn}$ are exactly n dimensions. Throughout this paper, we will only use matching with $i = 4$ so we may use matching as \triangleright instead of \triangleright^4 . Consistency is a symmetric, reflexive, and non-transitive relation that checks that two types are equal, up to the known parts of the types. For example, the type Dyn contains no information, so it is consistent with any type, while the dimensions 3 and 4 are inconsistent because they are unequal. Figure 2 contains the formal definitions for matching and consistency. The judgment $\text{decl}^* \vdash \Gamma$ says that from the declarations decl^* we get the environment Γ . We do static context formation with the rules (*s-empty*) and (*s-var*).

Figure 3 shows our type rules. We use shorthands that are defined in Appendix B. Let us go over each type rule in detail. *ok-prog* and *t-var* are standard.

t-reshape-s is the static type rule for reshape. It models that for reshape to succeed, the product of the dimensions of the input tensor shape must equal the product of dimensions of the desired shape. *t-reshape-g* assumes we have one missing dimension. Here we are modeling that PyTorch allows a programmer to leave one dimension as unknown (denoted by -1) because the system can deduce the dimension at runtime, see <https://pytorch.org/docs/>

29:12 Generalizing Shape Analysis with Gradual Types

[stable/generated/torch.reshape.html](#). We can still determine if reshaping is possible using the modulo operation instead of multiplication. In this approach, we admit a program if we cannot prove it is ill-typed statically. *t-reshape* admits the expression if too many dimensions are missing.

To maintain minimality, *t-conv* deals with only the rank-4 case of convolution. *t-conv* expects a rank-4 tensor, so it uses matching (\triangleright^4) to check the rank. Next, c_{in} should be equal to the second dimension of the input, so the rule uses a consistency (\sim) check. Since the output of a convolution should also be rank-4, then apply *calc-conv* which, given a rank-4 input and the convolution parameters, computes the dimensions of the output shape. If a dimension is *Dyn*, then the corresponding output dimension will also be *Dyn*.

Finally, *t-add* adds two dimensions. Unlike scalar addition, the types of the operands do not have to be consistent. The reason is that broadcasting may take place. Broadcasting is a mechanism that considers two tensors and matches their dimensions. Two tensors are broadcastable if the following rules hold:

1. Each tensor has at least one dimension
2. When iterating over the dimension sizes, starting at the trailing dimension, the dimension sizes must either be equal, one of them is 1, or one of them does not exist

That tensors involved in broadcasting do not actually get modified to represent the modified shapes. This implies that the input shapes are not always consistent. Instead, the broadcasted result is only reflected in the output of the operation. Therefore, we have defined *apply-broadcasting* to simulate broadcasting on the inputs and consider what the types for these inputs would be, if broadcasting was to actually modify the inputs. In a static type system, the types of the modified inputs should be equal for addition to succeed. In gradual types, the types of the modified inputs should be consistent because equality lifts to consistency. We accomplish these requirements in our type rule. In particular, *apply-broadcasting* takes care of broadcasting the dimensions. Suppose that we are adding a tensor of shape `TensorType(Dyn, 2, Dyn)` to a tensor of size `TensorType(1, 2, 2)`. Then the output must be `TensorType(Dyn, 2, 2)`. The reason is that the first *Dyn* could be any number as per the broadcasting rules. So we cannot assume its value. The last dimension; however, must be 2 according to the rules. We have that:

$$\begin{aligned} \text{apply-broadcasting}(\text{TensorType}(\text{Dyn}, 2, \text{Dyn}), \text{TensorType}(1, 2, 2)) = \\ (\text{TensorType}(\text{Dyn}, 2, \text{Dyn}), \text{TensorType}(\text{Dyn}, 2, 2)) \end{aligned}$$

After simulating broadcasting, we may proceed as if we are dealing with regular addition. In other words, we check that the modified dimensions are consistent and get the least upper bound: `TensorType(Dyn, 2, Dyn) \sqcup TensorType(Dyn, 2, 2) = TensorType(Dyn, 2, 2)`.

We will cover one last special case for addition. Simply applying the least upper bound to the modified input types of addition is not general enough to cover the following case. Suppose we are adding a tensor of shape *Dyn* to a tensor of shape `TensorType(1, 2)`, then we must output *Dyn* because the output type could be a range of possibilities. In this case, *apply-broadcasting* does not modify the types because the tensor of shape *Dyn* could range over many possibilities. We then apply our modified version of the least upper bound denoted by \sqcup^* , which behaves exactly like \sqcup except when one of the inputs is *Dyn*, where it returns *Dyn* to get that: `TensorType(1, 2) \sqcup^* Dyn = Dyn`.

We prove that our type system satisfies the static criteria from [23]. First, we prove the static gradual guarantee, which describes the structure of the migration space. Second, we prove the conservative extension theorem, which shows that our gradual calculus subsumes its static counter-part in Appendix A. This result is no coincidence: we first designed the

statically typed calculus in Appendix A and then we gradualized it according to [6]. We denote a well-typed program in the statically typed tensor calculus by $\vdash_{st} p : \text{ok}$. The full definitions and proofs can be found in Appendix D.

► **Theorem 2** (Monotonicity w.r.t precision). $\forall p, p' : \text{if } \vdash p : \text{ok} \wedge p' \sqsubseteq p \text{ then } \vdash p' : \text{ok}$.

► **Theorem 3** (Conservative Extension). *For all static p , we have: $\vdash_{st} p : \text{ok}$ iff $\vdash p : \text{ok}$*

4 The Migration Problem as a constraint satisfiability problem

A migration is a more static, well-typed version of a program. We can define that P' is a migration of P (which we write $P \leq P'$) iff $(P \sqsubseteq P' \wedge \vdash P' : \text{ok})$. Given P , we define the set of migrations of P : $Mig(P) = \{P' \mid P \leq P'\}$. Our goal is to use constraints to capture the migration space. Every solution to our constraints for a program must map to a corresponding migration for the same program. In other words, one satisfying assignment to the constraints results in one migration.

Our approach involves defining constraints whose solutions are order-isomorphic with the migration space. However, due to the arithmetic nature of our constraints, our solution procedure uses an SMT solver to find a satisfying assignment, which would equate to finding a migration. Later in this paper, we will show how to use this framework to answer our three key questions.

We have two grammars of constraints, see Figure 4: one for source constraints and one for target constraints. We will generate source constraints and then map them to target constraints (as explained in Appendix E), and finally process the target constraints by an SMT solver. Having two grammars is not strictly necessary, but it makes the constraint generation process more tractable and simplifies the presentation. We can view the source grammar as syntactic sugar for the target grammar.

Our source constraint grammar has fourteen forms of constraints, the most interesting of which we will introduce here. A precision constraint is of the form $\tau \sqsubseteq x$. Here, x indicates a type variable for the variable x from the program. Thus, x in the constraint $\tau \sqsubseteq x$ captures all types that are more precise than τ . Because we prioritize tractability of the migration space, we set the upper bound of tensor ranks to 4, via a constraint of the form $|[\![e]\!]| \leq 4$. We make this decision because all benchmarks we considered had only tensors with ranks that are upper-bounded by this number. We also have consistency constraints of the form $D \sim \delta, \langle e \rangle \sim \langle e \rangle$, matching constraints of the form $[\![e]\!] \triangleright \text{TensorType}(\delta_1, \delta_2, \delta_3, \delta_4)$, and least upper bound constraints of the form $\langle e \rangle \sqcup^* \langle e \rangle$. Those are gradual typing constraints that we use to faithfully model our gradual typing rules. Our constraint grammar also contains short-hands such as `can-reshape([\![e]\!], δ)` and `apply-broadcasting([\![e]\!], [\![e]\!])`. Those short-hands are good for representing the type rules as well. `can-reshape` expands to further constraints which evaluate to true if $[\![e]\!]$ can be reshaped to δ . Similarly, when expanded, `apply-broadcasting([\![e]\!], [\![e]\!])` captures all possible ways to broadcast two types.

In our target constraint grammar, we use n to range over integer constants. We use v as a meta variable that ranges over variables that, in turn, range over $\text{TensorType}(\text{list}(\zeta)) \cup \{\text{Dyn}\}$ and we use ζ as a meta variable that ranges over variables that range over $\text{IntConst} \cup \{\text{Dyn}\}$. This grammar is useful for our constraint resolution process. In particular, the first step of solving our constraints is to translate them to low-level constraints, drawn from our target grammar, before feeding them to an SMT solver.

Since our constraints involve gradual types, let us describe how we encoded types so that they can be understood by an SMT solver. Because we fixed the upper bound for tensor ranks to be 4, we chose to encode tensor types as uninterpreted functions, which means

$$\begin{aligned}
(\text{Source Constraints}) \quad \psi ::= & \quad \psi \wedge \psi \mid \psi \vee \psi \mid \text{True} \mid \llbracket x \rrbracket = x \mid \llbracket e \rrbracket = \tau \mid \tau \sqsubseteq x \mid \\
& \llbracket e \rrbracket \leq 4 \mid D \sim \delta \mid \langle e \rangle \sim \langle e \rangle \mid \\
& \llbracket e \rrbracket \triangleright \text{TensorType}(\zeta_1, \zeta_2, \zeta_3, \zeta_4) \mid \\
& \llbracket e \rrbracket = \langle e \rangle \sqcup^* \langle e \rangle \mid \text{can-reshape}(\llbracket e \rrbracket, \delta) \mid \\
& \llbracket e \rrbracket = \text{calc-conv}(\llbracket e \rrbracket, c_{out}, \kappa) \mid \\
& \langle e \rangle, \langle e \rangle = \text{apply-broadcasting}(\llbracket e \rrbracket, \llbracket e \rrbracket)
\end{aligned}$$

$$\begin{aligned}
(\text{Target Constraints}) \quad \psi ::= & \quad \psi \wedge \psi \mid \psi \vee \psi \mid \neg \psi \mid \text{True} \mid \\
& v = \text{TensorType}(\zeta, \dots, \zeta) \mid \\
& v = \text{Dyn} \mid v = v \mid \zeta = n \mid \zeta = \text{Dyn} \mid \zeta = \zeta \mid \\
& \zeta = \zeta \cdot n + n \mid (\zeta_1 \cdot \dots \cdot \zeta_m) \text{ mod } (\zeta'_1 \cdot \dots \cdot \zeta'_n) = 0
\end{aligned}$$

 **Figure 4** Source constraints and target constraints.

that we have a constructor for each of our ranks, of the form `TensorType1`, `TensorType2`, `TensorType3`, and `TensorType4`. Each of the functions take a list of dimensions. Moving on to the dimensions, we have that dimensions are either `Dyn` or natural numbers. We can easily represent natural numbers in an SMT solver but we must also represent `Dyn`. One way to encode a `Dyn` dimension d is as a pair (d_1, d_2) . If $d_1 = 0$, then $d = \text{Dyn}$. Otherwise, d is a number, and its value is in d_2 . Let us formalize the constraint generation process next.

From p , we generate constraints $\text{Gen}(p)$ as follows. Let p have the form `decl* return e`. Let X be the set of declaration-variables x occurring in e , and let Y be a set of variables disjoint from X consisting of a variable $\llbracket e' \rrbracket$ for every occurrence of the subterm e' in e . Let Z be a set of variables disjoint from X and Y consisting of a variable $\langle e_1 \rangle, \langle e_2 \rangle$ for every occurrence of the subterm `add`(e_1, e_2) in e . Finally, let V be a set of variables disjoint from X , Y , and Z consisting of dimension variables ζ . The notations $\llbracket e \rrbracket$ and $\langle e \rangle$ are ambiguous because there may be more than one occurrence of some subterm e' in e or some subterm e'' in e . However, it will always be clear from context which occurrence is meant. For every occurrence of ζ , it is implicit that we have a constraint $0 \leq \zeta$ to ensure that the solver assigns a dimension in \mathbb{N} . We omit writing this explicitly for simplicity. With that in mind, we generate the constraints in Figure 5. Let us go over the rules in Figure 5. The rules use judgments of the form $\vdash x : \tau : \psi$ for declarations, and it uses judgments of the form $\vdash e : \psi$ for expressions. In both cases, ψ is the generated constraint.

$t\text{-}decl$ uses the precision relation \sqsubseteq to insure that a migration will have a more precise type, while $t\text{-}var$ propagates the type information from declarations to the program.

$t\text{-}reshape$ considers all possibilities of reshaping any tensor e with rank, at most 4, via the constraint $\llbracket e \rrbracket \leq 4$. This restriction constraint captures all rank possibilities for $\llbracket e \rrbracket$ in addition to $\llbracket e \rrbracket$ being `Dyn`. For each possibility, the number of occurrences of `Dyn` in δ and $\llbracket e \rrbracket$ varies. This impacts the arithmetic constraints that make reshaping possible, as we can see from the typing rules. As such, `can-reshape` simulates all such possibilities and generates the appropriate constraints.

$t\text{-}conv$ contains matching and consistency constraints, to model matching and consistency in convolution's typing rule. We have a constraint `calc-conv`, which generates the appropriate arithmetic constraints for the output of the convolution, based on the convolution typing rule, again accounting for the possibility of the input e having a gradual type.

$$\begin{array}{c}
\frac{}{\vdash x : \tau : \tau \sqsubseteq x \wedge |x| \leq 4} \text{ (t-decl)} \quad \frac{}{\vdash x : x = \llbracket x \rrbracket} \text{ (t-var)} \\
\\
\frac{\vdash e : \psi}{\vdash \text{reshape}(e, \delta) : \psi \wedge \llbracket \text{reshape}(e, \delta) \rrbracket = \delta \wedge \text{can-reshape}(\llbracket e \rrbracket, \delta) \wedge |\llbracket e \rrbracket| \leq 4} \text{ (t-reshape)} \\
\\
\frac{\vdash e : \psi}{\vdash \text{Conv2D}(c_{in}, c_{out}, \kappa, e) : \psi \wedge \llbracket e \rrbracket \triangleright \text{TensorType}(\zeta_1, \zeta_2, \zeta_3, \zeta_4) \wedge c_{in} \sim \zeta_2 \wedge \llbracket \text{Conv2D}(c_{in}, c_{out}, \kappa, e) \rrbracket = \text{calc-conv}(\llbracket e \rrbracket, c_{out}, \kappa)} \text{ (t-conv)} \\
\\
\frac{\vdash e_1 : \psi_1 \quad \vdash e_2 : \psi_2}{\vdash \text{add}(e_1, e_2) : \psi_1 \wedge \psi_2 \wedge \llbracket \text{add}(e_1, e_2) \rrbracket = \langle e_1 \rangle \sqcup^* \langle e_2 \rangle \wedge (\langle e_1 \rangle, \langle e_2 \rangle) = \text{apply-broadcasting}(\llbracket e_1 \rrbracket, \llbracket e_2 \rrbracket) \wedge \langle e_1 \rangle \sim \langle e_2 \rangle \wedge |\llbracket e_1 \rrbracket| \leq 4 \wedge |\llbracket e_2 \rrbracket| \leq 4 \wedge |\llbracket \text{add}(e_1, e_2) \rrbracket| \leq 4} \text{ (t-add)}
\end{array}$$

■ **Figure 5** Constraint generation.

t-add contains least upper bound constraints and consistency constraints, similar to the *add* typing rule. We constrain the inputs e_1 and e_2 , as well as the expression itself, $\text{add}(e_1, e_2)$ to all be either *Dyn* or tensor of at most rank-4, via a \leq constraint. We use the function *apply-broadcasting*, which simulates broadcasting on the shapes, on dummy variables $\langle e_1 \rangle$ and $\langle e_2 \rangle$ (notice that the real shapes of e_1 and e_2 are represented by $\llbracket e_1 \rrbracket$ and $\llbracket e_2 \rrbracket$). We check $\langle e_1 \rangle$ and $\langle e_2 \rangle$ for consistency and obtain the least upper bound.

Let φ be a mapping from tensor-type variables to $\text{TensorType}(\text{list}(\zeta)) \cup \{\text{Dyn}\}$, and also from dimension-type variables to $\text{IntConst} \cup \{\text{Dyn}\}$. We define that a target constraint ψ has solution φ , written $\varphi \models \psi$, in the following way:

The following is true:	Provided:
$\varphi \models \psi \wedge \psi'$	$\varphi \models \psi \text{ and } \varphi \models \psi'$
$\varphi \models \psi \vee \psi'$	$\varphi \models \psi \text{ or } \varphi \models \psi'$
$\varphi \models \neg \psi$	$\text{not } (\varphi \models \psi)$
$\varphi \models \text{True}$	always
$\varphi \models v = \text{TensorType}(\zeta_1, \dots, \zeta_n)$	$\varphi(v) = \text{TensorType}(\varphi(\zeta_1), \dots, \varphi(\zeta_n))$
$\varphi \models v = \text{Dyn}$	$\varphi(v) = \text{Dyn}$
$\varphi \models v = v'$	$\varphi(v) = \varphi(v')$
$\varphi \models \zeta = n$	$\varphi(\zeta) = n$
$\varphi \models \zeta = \text{Dyn}$	$\varphi(\zeta) = \text{Dyn}$
$\varphi \models \zeta = \zeta'$	$\varphi(\zeta) = \varphi(\zeta')$
$\varphi \models \zeta = \zeta \cdot n + n'$	$\varphi(\zeta) = \varphi(\zeta') \cdot n + n'$
$\varphi \models (\zeta_1 \cdot \dots \cdot \zeta_m) \text{ mod } (\zeta'_1 \cdot \dots \cdot \zeta'_n) = 0$	$(\varphi(\zeta_1) \cdot \dots \cdot \varphi(\zeta_m)) \text{ mod } (\varphi(\zeta'_1) \cdot \dots \cdot \varphi(\zeta'_n)) = 0$

► **Definition 4.** $\varphi \leq \varphi'$ iff $\text{dom}(\varphi) = \text{dom}(\varphi') \wedge \forall x \in \text{dom}(\varphi) : \varphi(x) \sqsubseteq \varphi'(x)$

Let $\text{Gen}(P)$ be the constraint generation function and $\text{Sol}(C)$ be the set of solutions to constraints C . Then we can state the order-isomorphism theorem as follows:

► **Theorem 5** (Order-Isomorphism).

$\forall P : (\text{Mig}(P), \sqsubseteq)$ and $(\text{Sol}(\text{Gen}(P)), \leq)$ are order-isomorphic.

The order-isomorphism theorem states that we have captured the migration-space with our constraints such that, for a given program, the solution space and the migration-space are order-isomorphic. For the proof, see Appendix F.

Our algorithm for code annotation is shown in Algorithm 1.

Algorithm 1 Code annotation.

Input: Program P

Output: Annotated program P'

- 1: **Constraint Generation.** Generate constraints $C = \text{Gen}(P)$.
 - 2: **Constraint Solving.** Solve C and get a solution φ that maps variables to types.
 - 3: **Program Annotation.** In P , replace each declaration $x : \tau$ with $x : \varphi(x)$, to get P' .
-

Let us now revisit Listing 1 but this time with variable x annotated by `Dyn`. We will show how to migrate a calculus version of the program by generating constraints and passing them to an SMT solver. Let us recall that this listing had two expressions that map to the following expressions in our calculus: `Conv2D(2, 2, (2, 2), x)` and `Conv2D(4, 2, (2, 2), x)`.

The first step is to generate high-level constraints:

$$\text{Dyn} \sqsubseteq v_1 \quad (1)$$

$$v_1 \leq 4 \quad (2)$$

$$v_1 \triangleright \text{TensorType}(\zeta_3, \zeta_4, \zeta_5, \zeta_6) \quad (3)$$

$$2 \sim \zeta_4 \quad (4)$$

$$v_2 = \text{calc-conv}(v_1, 2, (2, 2), (2, 2), (2, 2), (2, 2)) \quad (5)$$

$$v_1 \triangleright \text{TensorType}(\zeta_9, \zeta_{10}, \zeta_{11}, \zeta_{12}) \quad (6)$$

$$4 \sim \zeta_{10} \quad (7)$$

$$v_8 = \text{calc-conv}(v_1, 2, (2, 2), (2, 2), (2, 2), (2, 2)) \quad (8)$$

Let us go over what each equation is for. Constraint (1) denotes that the type annotation for the variable x must be as precise or more precise than `Dyn`. Constraint (2) denotes that the type annotation for x could either be `Dyn` or a tensor with at most four dimensions. We use the \leq notation to denote this. Notice that the type variable for x is v_1 . Constraints (3), (4), and (5) are for `Conv2D(2, 2, (2, 2), x)`, while constraints (6), (7), and (8) are for `Conv2D(4, 2, (2, 2), x)`. More specifically, constraints (3) and (6) determine the input shape of a convolution while constraints (5) and (8) determine the output shape of a convolution.

The main differences between the constraints for our core calculus and the ones in our implementation is that `calc-conv` takes some additional parameters in our implementation because we have implemented the full version of convolution.

The constraints above are high-level constraints which are yet to be expanded. For example, \triangleright and \leq constraints get transformed to equality constraints. We will skip writing out the resulting constraints for simplicity. After expanding these constraints and running them through an SMT solver, we get a satisfying assignment. In case multiple satisfying assignments exist, we use the one that the SMT solver picks. The fact that we got a satisfying assignment lets us know that the migration space is non-empty, which means that the program is well-typed. Let us go through some of relevant assignments:

$$\begin{aligned} \varphi(v_1) &= \text{Dyn} \\ \varphi(v_2) &= \text{TensorType}(\text{Dyn}, 2, \text{Dyn}, \text{Dyn}) \\ \varphi(v_8) &= \text{TensorType}(\text{Dyn}, 2, \text{Dyn}, \text{Dyn}) \end{aligned}$$

Here, v_1 is the type of x , v_2 is the type of the first convolution and v_8 is the type of the second convolution. We can see that these assignments are a valid typing to the program because the outputs of both convolutions should be 4-dimensional tensors with the second dimension being 2, which stands for the output channel. And since the input x has been assigned `Dyn` by our SMT solver, we cannot determine the last two dimensions of a convolution output. While this is a reasonable output, it may not be helpful to the programmer. Furthermore, this program would not accept any concrete output. We know this from our constraints. From constraints (3) and (7), we have that $\zeta_4 = \zeta_{10}$. Then from (4), (8), which are $2 \sim \zeta_4$ and $4 \sim \zeta_{10}$, we can see that the only satisfying solution is `Dyn`. This means that the program cannot be statically typed. Next, we will see how to prove this formally.

Let us discuss how to extend our approach to solve Q(1) and Q(2). In the example above, the migration space is non-empty and we may want to know if we can statically type the program. We have established that we cannot. As a first step, we may want to take our core constraints above, which we will call C , and restrict the input to a rank-4 tensor. So we can consider the constraint $C \wedge x = \text{TensorType}(\zeta'_1, \zeta'_2, \zeta'_3, \zeta'_4)$ where $\zeta'_1, \dots, \zeta'_4$ are fresh variables. We can begin to impose restrictions on $\zeta'_1, \dots, \zeta'_4$ to make them concrete variables. For example, if we restrict the last dimension to be a number, we can add the constraint $\zeta'_4 \neq \text{Dyn}$. After running our constraints through the solver, we get the following assignments:

$$\begin{aligned}\varphi(v_1) &= \text{TensorType}(\text{Dyn}, \text{Dyn}, \text{Dyn}, 28470) \\ \varphi(v_2) &= \text{TensorType}(\text{Dyn}, 2, \text{Dyn}, 14236) \\ \varphi(v_8) &= \text{TensorType}(\text{Dyn}, 2, \text{Dyn}, 14236)\end{aligned}$$

To prove that no concrete assignment to the second dimension of x is possible, we simply add $\zeta'_2 \neq \text{Dyn}$ to our original constraints and the constraints will be unsatisfiable, so we conclude that the second dimension of x can only be `Dyn`.

We can also answer Q(2) by feeding the solver additional arithmetic constraints about dimensions. In our example, if we want the first dimension of x to be between 3 and 10, we can add the constraint $\zeta'_1 \leq 3 \wedge \zeta'_1 \geq 10$ to $C \wedge x = \text{TensorType}(\zeta'_1, \zeta'_2, \zeta'_3, \zeta'_4)$ and rerun our solver.

Our migration solution is based on a satisfiability problem: *is our migration problem decidable?* If so, what is the time complexity? The migration problem is decidable if the underlying constraints are drawn from a decidable theory. Those underlying constraints are the ones given by the grammar in Section 4. Let us for a moment ignore constraints of the form $(\zeta_1 \cdot \dots \cdot \zeta_m) \text{ mod } (\zeta'_1 \cdot \dots \cdot \zeta'_n) = 0$. We observe that all the other constraints are drawn from a well-known decidable theory. Specifically, the other constraints are drawn from quantifier-free Presburger arithmetic extended with uninterpreted functions and equality. The satisfiability problem for this theory is NP-complete [21]. Once we add constraints of the form $(\zeta_1 \cdot \dots \cdot \zeta_m) \text{ mod } (\zeta'_1 \cdot \dots \cdot \zeta'_n) = 0$, the decidability-status of the satisfiability problem is unknown, to the best of our knowledge. Fortunately, only three operations need this additional constraint: `Reshape`, `View`, or `Flatten`. All the other 47 operations that our implementation supports need only constraints in the NP-complete subset. Our implementation translates all of the constraints to Z3 format, and while our benchmarks do need constraints outside the NP-complete subset, our experiments terminated. In every case, Z3 terminated with either sat or unsat. Thus, the generated constraints are simple enough for Z3 to solve, even if the general case is undecidable.

The complexity of migration depends on the size of the constraint we generate. The bottleneck is the \leq constraint; let us see how to expand it.

From: $\|\llbracket e \rrbracket\| \leq 4$

To: $\llbracket e \rrbracket = \text{Dyn} \vee \llbracket e \rrbracket = \text{TensorType}(\zeta_1) \vee \dots \vee \llbracket e \rrbracket = \text{TensorType}(\zeta_1, \zeta_2, \zeta_3, \zeta_4)$

where ζ_1, \dots, ζ_4 are fresh variables. This yields a complexity of 4^n in the number of \leq constraints. So assuming that any additional constraints are drawn from the NP-complete subset, the problem will still be decidable. Note that if we are working with a fixed rank, then these constraints will be generated in polynomial time in the size of the program. Below we will see how solving the problem for a fixed rank has practical benefits.

5 Extending our approach to do Branch Elimination

We introduce our approach to branch elimination via the following example.

```

1  class ReshapeControlFlow(torch.nn.Module):
2      def __init__(self):
3          super().__init__()
4
5      def forward(self, x: Dyn):
6          if x.reshape(100).size()[0] < 100:
7              return torch.dropout(x, p=0.5, train=False)
8          else:
9              return torch.relu(x)

```

Listing 7 An example of graph-break elimination

In contrast to listing 5, where the conditional depends of the rank of the input, listing 7 has a conditional that depends on the value of one of the dimensions in the input shape. Listing 7 uses the `reshape` function, which takes a tensor and re-arranges its elements according to the desired shape. In this case, we reshape `x` to have the shape `TensorType([100])`. For reshaping to succeed, the initial tensor must contain the same number of elements as the reshaped tensor. Notice that since `x` is typed as `Dyn`, the program will type check. In the expression `x.reshape(100).size()`, the expression `size()` will return the shape of `x.reshape(100)`, which is `[100]`. We are then getting the first dimension of the shape in the expression `x.reshape(100).size()[0]`, which is 100. Thus, by inspecting the conditional `if x.reshape(100).size()[0] < 100`, we can see that the conditional should always evaluate to false. Thus, we can remove the true branch from the program and produce listing 8. In contrast, TorchDynamo breaks Listing 7 into two different programs: one for when the condition evaluates to true, and another for when the condition evaluates to false.

```

1  class ReshapeControlFlow(torch.nn.Module):
2      def __init__(self):
3          super().__init__()
4
5      def forward(self, x: Dyn):
6          return torch.relu(x)

```

Listing 8 An example of graph-break elimination

Let us see an example of how to extend our constraint-based solution to eliminate the extra branch. For listing 7, here are the constraints for `x.reshape(100).size()[0]` in line 6. The variable ζ_4 is for the result of the entire expression. Note that the PyTorch expression `x.reshape(100)` is the same as the calculus expression `reshape(x, TensorType(100))`.

$$\text{Dyn} \sqsubseteq v_1 \wedge v_1 \leq 4 \quad (1)$$

$$v_2 = \text{TensorType}(100) \wedge \text{can-reshape}(v_1, \text{TensorType}(100)) \quad (2)$$

$$v_2 = v_3 \quad (3)$$

$$(v_3 = \text{Dyn} \wedge \zeta_4 = \text{Dyn}) \vee ((\zeta_4 = \text{GetItem}(v_3, 1, 0) \vee \zeta_4 = \text{GetItem}(v_3, 2, 0) \vee \\ \zeta_4 = \text{GetItem}(v_3, 3, 0) \vee \zeta_4 = \text{GetItem}(v_3, 4, 0)) \quad (4)$$

Above, the constraint (1) is for x . Notice that v_1 is the type variable for x . Constraint (2) is for `reshape(x, TensorType(100))`. Next, when encountering the `size` function in a program, we simply propagate the shape at hand with an equality constraint, which is seen in equation (3). If we are indexing into a shape, we consider all the possibilities for the sizes of that shape and generate constraints accordingly. In particular, we have that ($v_3 = \text{Dyn} \wedge \zeta_4 = \text{Dyn}$) because a shape could be dynamic, which means that if we index into it, we get a `Dyn` dimension. But since we restricted our rank to 4, we can consider the possibilities of the index being 1, 2, 3 or 4, which is what the remaining constraints do.

We extend our constraint grammar with constructs that enable us to represent `size()` and indexing into shapes. This includes constraints of the form $\zeta = \text{GetItem}(v, c, i)$, where v is the shape we are indexing into, c is the assumed tensor rank, and i is the index of the element we want to get. We can map the new constraints to Z3 constraints easily.

Next we generate a constraint ($\zeta_4 < 100$) for the condition and a constraint $\neg(\zeta_4 < 100)$ for its negation. If C are the constraints for the program up to the point of encountering a branch, then we generate both $C \wedge \zeta_4 < 100$ and $C \wedge \neg(\zeta_4 < 100)$.

We evaluate both sets of constraints. One set must be satisfiable while the other must be unsatisfiable for us to remove the branch. If we are unable to remove the branch, this means that the input set is still too general such that for some inputs, the branch may evaluate to true and for other inputs, the branch may evaluate to false. In such case, we can ask the user to capture a stricter subset of the input by further constraining it. We can then re-evaluate our constraints again to see if we are able to remove the branch.

We extend our grammar with conditional expressions `if cond then e1 else e2`. Algorithm 2 describes how to eliminate a single branch.

Algorithm 2 Branch elimination.

Input: Program p .

Output: A possibly modified p with a branch eliminated.

- 1: Let C = the constraints for p up to encountering a branch `if cond then e1 else e2`.
 - 2: Let c_{cond} = the constraints for `cond`.
 - 3: **if** $(C \wedge c_{cond})$ is satisfiable and $(C \wedge \neg c_{cond})$ is unsatisfiable **then**
 - 4: Rewrite the branch to e_1
 - 5: **else if** $(C \wedge c_{cond})$ is unsatisfiable and $(C \wedge \neg c_{cond})$ is satisfiable **then**
 - 6: Rewrite the branch to e_2
 - 7: **else**
 - 8: Require the user to change the shape information
 - 9: **end if**
-

6 Implementation

PyTorch has three tool-kits that rely on symbolic tracers [3]. Let us go over each one. First, `torch.fx` [17] is a common PyTorch tool-kit and has a symbolic tracer. Symbolic tracing is a process of extracting a more specialized program representation from a program, for the purpose of analysis, optimization, serialization, etc. `torch.fx` does not accept programs containing branches and the `torch.fx` authors emphasize that “*most neural networks are expressible as flat sequences of tensor operations without control flow such as if-statements or loops*” [17]”. HFtracer [29] eliminates branches by symbolically executing on a single input. Finally, TorchDynamo [2] handles dynamic shapes by dividing the program into fragments.

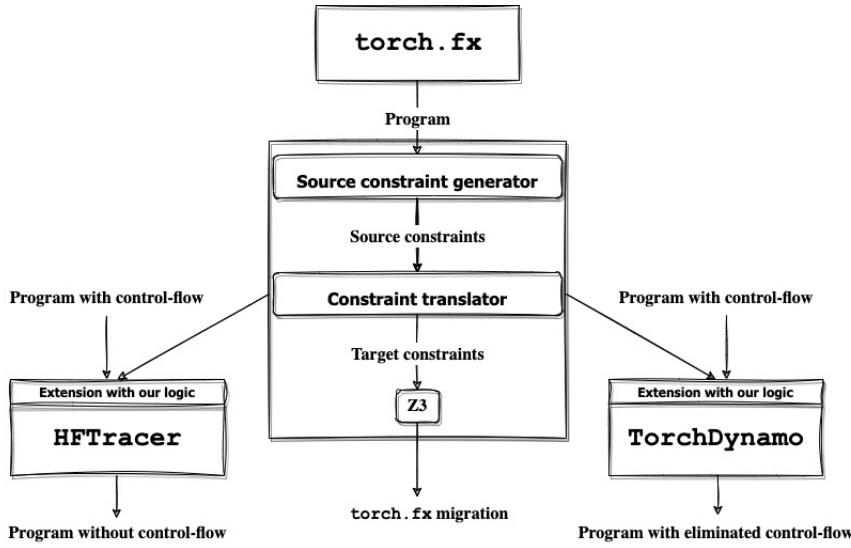

Figure 6 Our core tool and the three tracers.

This process is called a *graph-break*. Specifically, when encountering a condition that depends on shape information and where shape information is unknown, the program is broken into two parts. One fragment is for when the result of the condition is true, and another is for when the result of the condition is false. Graph-breaks result in multiple programs with no branches.

As a technical detail, code annotation for the purpose of program understanding and better documentation is meant to be performed on a source language; branch elimination is done at trace-time, on an intermediate representation. For the purpose of better readability, we presented all the examples in Section 2 in source code syntax. In some of our larger benchmarks, the source code is different from the intermediate representation because more high-level constructs were used, such as statements. However, statements do not influence our theoretical results. We did not include sequences in our theory because they did not introduce additional challenges to our problem. Finally, there are some constructs in PyTorch that propagate variable shapes, such as `dim()` and `size()`. There are also getters which index into shapes. Those constructs were used to write ad-hoc shape-checks. We dealt with them in our implementation by propagating shape information accordingly.

We have implemented approximately 6000 LOC across three different tracers. Figure 6 summarizes how our implementation works. First, we implement a core constraint generator. This generator takes a program (in our benchmarks case, a program is generated via `torch.fx`), and generates core, source constraints for it. Next is the constraint translator which consists of two phases. In the first phase, it encodes the gradual types found in the program then translates the source constraints into target constraints. Note that a program is annotated, possibly with a `Dyn` type for every variable. In the second phase, it translates the target constraints into `Z3` constraints, which is a 1:1 translation.

Next, we modify each of `TorchDynamo` and `HFtracer` to incorporate our reasoning and use it for branch elimination. We must incorporate our logic into the tracers because *branch elimination happens at trace-time*, unlike program migration which requires a whole program.

Our implementation faithfully follows our core logic, although we have made some practical simplifications. First, our implementation focuses on supporting 50 PyTorch operations that our benchmarks use. Each of those operations has its own constraints and supporting all 50

was multiple months of effort. Second, for the `view` operation (which is similar to `reshape` in terms of types, see <https://pytorch.org/docs/stable/generated/torch.Tensor.view.html>), we have skipped implementing dynamism and required the solver to provide concrete dimensions. This allowed us to carry out branch elimination without requiring an additional constraint that disables dynamism, although the same effect can be accomplished in this manner as well. Third, `Conv2D` may accept rank-3 or rank-4 inputs, but we have limited our implementation to the rank-4 case, since this is the case that is relevant to most of our benchmarks.

We ran our experiments on a MacBook Pro with an 8-Core CPU, 14-Core GPU and 512GB DRAM.

7 Experimental Results

We answer the following three questions.

- Q(1): Can our tool determine if the migration space is non-empty? If so, can it determine if the migration space contains a static migration and if so, can it find one? *Yes. Our tool is the first to affirmatively answer all three questions.*
- Q(2): Given an arithmetic constraint on a dimension, can our tool determine if there is a migration that satisfies it and if so, can it find one? *Yes. Our tool is the first to retrieve migrations that provably satisfy arbitrary arithmetic constraints.*
- Q(3): Can our tool prove that branch elimination is valid for an infinite set of inputs, not just for a single input? If so, does it allow us to represent the set of inputs for which a branch evaluates to true or false? *Yes. We incorporate our logic into two different tools and eliminate branches in all benchmarks we considered for infinite classes of input, characterized via constraints. Neither tool was able to achieve this without our logic.*

Figure 7 contains our benchmark names, the source of the benchmark, lines of code, and the number of `flatten` and `reshape` operations in each benchmark. The `flatten` and `reshape` operations are special because our analysis of them involves multiplication and modulo constraints. Our benchmarks are drawn from two well-known libraries, TorchVision and Transformers [30, 29], with the exception of two microbenchmarks that we use as examples in Section 2. We used different benchmarks for different experiments. The first four models do not contain branches, making them suitable for Q(1) and Q(2). They are interesting because `BmmExample` has a shape mismatch, `ConvExample` cannot be statically migrated, and `AlexNet` and `ResNet50` are well-known neural-network models. Our experience is that tensor programs are tricky to type, and that our tool offers feedback that helps the user narrow down the migration space by adding constraints. The next six models are suitable for our `HFTtracer` experiments. Those experiments required reasoning about whole programs and our tool was able to reason about them in under two minutes. The final four benchmarks are of a larger size. We do not support all the operations in those benchmarks. However, this did not pose a problem because in `TorchDynamo`, we were not required to reason about entire programs. Instead, we were required to reason about program fragments, which made our tool terminate in under three minutes.

We ran our tool in the following way to answer Q(1).

1. Generate the core constraints and check if they are satisfiable. If not, stop right away; The program is ill-typed.
2. Determine if the input variable can have a concrete rank by asking the solver for migrations of concrete ranks from one to four. If none exist, the input variable was used at different ranks throughout the program.

29:22 Generalizing Shape Analysis with Gradual Types

ResNet50	Yes	5	Yes	347

Figure 8 Q(1) and Q(2): static migration and migration under arithmetic constraints.

3. If the input variable can be assigned concrete ranks, pick one of them and ask the tool to statically annotate all dimensions.
4. If the solver cannot statically annotate all dimensions, relax this requirement for each dimension to determine which one cannot be statically annotated.

We first traced our benchmarks using `torch.fx`, then ran the above steps on the output. The first step simply involves running our tool, while the second and third steps require the user to pass constraints to the tool and rerun it. Determining if a variable has a certain rank requires a single run with our tool. Determining if a dimension can be static requires a single run with our tool. The final step involves removing constraints. Each time we remove a constraint from a dimension, we can run our tool once to determine a result.

The first part of Figure 8 summarizes our results. The first column in the figure is the benchmark name. The second column asks if the benchmark has a static migration and the third column measures the time it took to answer this question and retrieve a static migration. For ConvExample, the input can only be rank-4 and the second dimension can only be `Dyn`. BmmExample has a type error. Finally, ResNet50 and AlexNet can be fully typed and the inputs can only be rank-4 in both cases.

We ran our tool in the following way to answer Q(2). First we follow the steps for answering Q(1), and if any dimensions can be static, then we apply further arithmetic constraints on some of those dimensions and ask for a migration that satisfies them. We ran the steps above in our extension of `torch.fx`. The second part of Figure 8 summarizes our results. The fourth column asks if arithmetic constraints can be imposed on at least one

of the dimensions and the fifth column measures the time it took to answer this question and retrieve a migration that satisfies an arithmetic constraint. For ResNet50 and AlexNet, we added arithmetic constraints. For ConvExample, we fixed the example like we did in Section 2 then added arithmetic constraints. We obtained valid migrations that satisfy our constraints for all benchmarks, except for BmmExample which is ill-typed and thus has an empty migration space.

We ran our tool in the following way to answer Q(3). We ran our extension of **HFtracer**, starting with annotating the input with **Dyn** and then gradually increasing the precision of our constraints to provide the solver with more information to eliminate more branches. The number of times we run our tool here depends on how much information the user gives the tool about the input. If the tool receives static input dimensions, then this will be enough to eliminate all branches that depend on shapes. But since we aim to relax this requirement, we could start with a **Dyn** shape then gradually impose constraints, first with rank information, then with dimension information.

We were able to eliminate all branches this way. We followed similar steps in our **TorchDynamo** extension but we faced some practical concerns because **TorchDynamo** currently does not carry parameter information between program fragments. We had to resolve this issue manually by passing additional constraints at every new program fragment.

Figure 9 details our **HFtracer** experiments on 6 workloads. Figure 9 contains the original number of branches in the program, the remaining branches after running our extension, without imposing any constraints on the input, and the number of remaining branches after running our extension, with the constraints in Figure 9 on the input. The second-to-last column of the figure is the time it takes to perform branch elimination with constraints.

HFtracer also eliminates all branches from the 6 workloads. However, it does this by running the program on an input. We can obtain a similar result by giving a constraint describing the *shape* of the input because we observed that for all benchmarks we considered, an actual input is not needed to eliminate all branches, and we can relax this requirement much further. Specifically, for some benchmarks, no constraints are needed at all to eliminate all branches, while for others, it is enough to specify rank information. For one of the benchmarks, we can specify a range of dimensions for which branches can be eliminated. Figure 9 details the constraints.

Finally figure 10 represents branch elimination for **TorchDynamo**. There are two modes of operation in **TorchDynamo** called static and dynamic. In the static mode, the tracer traces the program with one input which is provided by the user. Branch elimination is therefore valid for a single input. In Dynamic mode, the tracer also takes an input but it only records *rank* information and ignores the values of the dimensions. So if a branch depends on dimension information, a graph-break will occur. We focused on benchmarks where branches depend on dimension information. In figure 10, we impose constraints on the dimensions and eliminate branches which decreases the number of times **TorchDynamo** breaks the program when tracing. The first column in the figure indicates the benchmark names. Next is the original number of branches with **TorchDynamo**. Then we have the remaining number of branches after incorporating our reasoning. Finally, we measure time in seconds. The input constraints are range and rank constraints, as exemplified by the constraints for XGLM shown in Figure 9.

From our experiments, we observed that slowdowns can be due to the kind of constraints involved and the number of constraints to solve. Our tool typically handles benchmarks that are under 1000 lines of code easily. However, range constraints impose overhead. For example, ResNet50 and XGLM contain such constraints and they were the slowest in Figure

M2M100	47	22	130
BlenderBot	35	19	40

Figure 10 Q(3): TorchDynamo number of remaining branches.

9. For the experiments under Q(1) and Q(2), we let the tools run more than 5 minutes, but for Q(3) we limit to 5 minutes. The benchmarks in figure 10 are over 1000 lines, and for some branches, branch elimination with TorchDynamo times out after 5 minutes.

There are two limitations to our TorchDynamo experiments. First, since PyTorch has various operations with many layers of abstractions and edge cases, not every edge case was implemented. Given that this only affected a few branches, we chose to skip those branches. This did not affect our experiments because TorchDynamo does not require all branches to be removed. Each branch removed will result in one less graph-break. TorchDynamo induces graph-breaks for reasons other than control flow. When graph-breaks happen, we have to re-write an input constraint for the resulting fragments because there is currently no clear mechanism in passing parameter information from one fragment to another. We manually passed input constraints to program fragments until eliminating at least 40% of branches and have stopped after that due to the large size of the benchmarks and program fragments. We leave parameter preservation during graph-breaks to the TorchDynamo developers.

8 Related work

We first discuss related work about shapes in tensor programs.

[15] show how to do shape checking based on assertions written by programmers. Their assertions can reason about tensor ranks and dimensions, with arithmetic constraints. Our work also supports such constraints. Their tool executes a program symbolically and looks for assertion violations. The more assertions programmers write, the more shape errors their tool can report. Their tool uses Z3 to solve constraints of a size that can be up to exponential in the size of the program. Our approach is similar in that it enables programmers to annotate a program with types and to type check the program and thereby catch shape errors. Another similarity is that we use Z3 to solve constraints of exponential size. Our approach differs by going further: we have tool support for annotating any program with types and for removing unnecessary runtime shape checks. Additionally, we have proved that our type system has key correctness properties.

[9] define a gradually typed system for tensor computations and, like us, they prove that it has key correctness properties. They use refinement types to represent tensor shapes, they enable programmers to write type annotations, and they do best-effort shape inference. Their refinements share some characteristics with the assertions used by [15], as well as with our constraints. They found that, for each of their benchmarks, few annotations are sufficient to statically type check the entire program. They focus on shape checking and shape inference, while we focus on generalizing shape analysis for various tasks including program migration and branch elimination. Their approach adds the traditional gradual runtime checks [22] in cases where annotations and shape inference fall short. Our work differs by enabling program optimizations through removing runtime checks, while we leave out gradual runtime checks. Conceptually, our approach and the one from [9] differ in that we define type migration syntactically, while they follow a semantic interpretation of gradual types. It is unclear how migration would be defined in their context. Another difference is that we have demonstrated scalability: their benchmark programs are up to 258 lines of code, while our benchmark programs are up to 2,380 lines of code. We were unable to do an experimental comparison because our tool works with PyTorch, while their tool works with OCaml-Torch.

[31] analyzed the root causes of bugs in TensorFlow programs by scanning StackOverflow and GitHub. They identified four symptoms and seven root causes for such bugs. The most common symptoms are functional errors, crashes, and build failure, while common root causes are data processing errors, type confusion, and dimension mismatches. Our type system can help spot those root causes because key parts of such code will have type `Dyn`, even after migration.

[11] use static analysis to detect shape errors in TensorFlow. Their approach statically detects 11 of the 14 TensorFlow bugs reported by [31], but has no proof of correctness. Our approach differs from [11] by being able to annotate a program with types and being able to remove unnecessary runtime checks. Our work can reason about programs without requiring any type annotations and only taking into account the shape information from the operations used in the program, while [11] requires a degree of type information. In contrast, we have proved that our type system has key migratory properties, such as that our constraints represent the entire migration space for a program, allowing us to extract and reason about all existing shape information from the program according to the programmer's needs.

[10] is a static analysis tool that detects shape errors in PyTorch programs. Their approach is different than ours in that it detects errors via symbolic execution. It considers all possible execution paths for a program to reason about shapes. The number of execution paths can be large. In contrast, our approach reasons about shapes which can be given in the form of type annotations or can be detected from the program.

[27] consider a dynamic analysis tool for TensorFlow, called ShapeFlow, to detect shape errors. The advantage of this approach is that, like our approach, it does not require type annotations, but their analysis holds for only particular inputs, in contrast to our approach, which reasons about programs across all possible inputs. Unlike our work, their approach has not been formalized, but there is empirical evidence to support that it detects shape errors in *most* cases. Because we reason about programs statically, our work is more suitable for compiler optimizations and program understanding. Our shape analysis approach can be used to annotate programs. In contrast, ShapeFlow is more suitable if a programmer desires a light-weight form for error detection that works in most cases.

[20] designed an intermediate representation called Relay. It is functional, like our calculus, but is statically-typed, unlike our gradual type system. Its goals are similar to ours in that it aims to balance expressiveness, portability, and compilation. Unlike our system, as a static

type system, Relay requires type annotations for every function parameter. Similar to our approach, their work focuses on the static aspect of the problem and has left the runtime aspect to future work.

[19] extends [20] by using a static polymorphic type system for shapes, which we leave to future work. This system has a type named `Any`, which enables partial annotations, but which appears to provide less flexibility than our `Dyn` type because of the absence of type consistency.

Next we discuss two closely related papers on migratory typing.

[12] defined the migration space for a gradually typed program as the set of all well-typed, more-precise programs. They represented the migration space for a given program by generating constraints where each solution represents a migration. The constraint-based approach enables them to solve migration problems for a λ -calculus. We adapted their definition of type migration and migration space to our context of a tensor calculus and rather different types. We use their idea of a migration space and constraints to give an algorithm that annotates a program with types and an algorithm that removes unnecessary runtime checks. In contrast to their approach, we use an SMT solver (Z3) because it can deal with the arithmetic nature of tensor constraints.

[16] build a tool which extends [12], by providing several criteria for choosing migrations from the migration space. Their work is about simple types, while our work is about tensor shapes. While their work is specifically focused on reasoning about the migration space for program annotation, we reason about the migration space more generally, by using it for general tensor reasoning tasks including program annotation and branch elimination. Their gradual language contains traditional gradual runtime checks, while we leave out runtime aspects.

9 Conclusion

We have presented a method that reasons about tensor shapes in a general way. Our method involves a gradual tensor calculus with key properties and support for decidable shape analysis for a large set of operations. Our algorithm is practical because it works on 14 non-trivial benchmarks across three different tracers. We expect that our approach to branch elimination can be extended to handle other forms of shape-based optimization.

Verifying Lock-Free Search Structure Templates

Nisarg Patel  New York University, NY, USA

Dennis Shasha  New York University, NY, USA

Thomas Wies  New York University, NY, USA

Abstract

We present and verify template algorithms for lock-free concurrent search structures that cover a broad range of existing implementations based on lists and skip lists. Our linearizability proofs are fully mechanized in the concurrent separation logic Iris. The proofs are modular and cover the broader design space of the underlying algorithms by parameterizing the verification over aspects such as the low-level representation of nodes and the style of data structure maintenance. As a further technical contribution, we present a mechanization of a recently proposed method for reasoning about future-dependent linearization points using hindsight arguments. The mechanization builds on Iris' support for prophecy reasoning and user-defined ghost resources. We demonstrate that the method can help to reduce the proof effort compared to direct prophecy-based proofs.

1 Introduction

A search structure is a key-based store that implements a mutable map of keys to values (or a mutable set of keys). It provides five basic operations: (i) create an empty structure, (ii) insert a key-value pair, (iii) search for a key and return its value, (iv) delete the entry associated with a key, and (v) update the value associated with a particular key. Because of their general usefulness, search structures are ubiquitous in data-intensive workloads.

Earlier works [19, 34, 18] developed a framework to verify a wide range of lock-based implementations of concurrent search structures. Specifically, they proved that these implementations are linearizable [11].

A core ingredient of the framework is the idea of template algorithms [39]. A template algorithm dictates how threads interact but abstracts away from the concrete layout of nodes in memory. Once the template algorithm is verified, its proof can be instantiated on a variety of search structures.

The template algorithms of [19, 34, 18] use locks as a synchronization technique. Locks ensure non-interference on portions of memory to guarantee that certain needed constraints hold in spite of concurrency.

The disadvantage of locks is that if a thread holding a lock on some portion of memory p stops, then no other thread can get a conflicting lock on p . For that reason, some practical implementations such as Java’s `ConcurrentSkipListMap` [33] use lock-free algorithms.

This paper shows how to capture multiple variants of concurrent lock-free skip lists and linked lists in the form of template algorithms. Thus, proving the correctness of such a template algorithm results in a proof that is applicable to many variants at once. Our template algorithms are parametric in the skip list height and allow variations along the following three dimensions: (i) maintenance style (eager vs lazy) (ii) node implementations and (iii) the order of maintenance operations on the higher levels of the skip lists.

By instantiating our template algorithm with appropriate maintenance operations and node implementations we obtain verified versions of existing (skip)list algorithms from the literature such as the Herlihy-Shavit skip list algorithm [10, § 14], the Michael set [31], and the Harris list algorithm [9]. We also obtain a new concurrent skip list algorithm that has not been considered before. The new algorithm is correct by construction thanks to our modular verification framework.

We mechanize our development in the concurrent separation logic Iris [14, 16]. One technical contribution of our work is a formalization of *hindsight reasoning* [32, 22, 6, 7, 26, 27] in Iris. Hindsight reasoning has shown its usefulness in dealing with future-dependent and external linearization points, a challenge that commonly arises in lock-free data structures.

Specifically, we build on the hindsight theory developed in [27], providing a mechanism in Iris where one can establish that a linearization point has passed by inferring knowledge about past states using a form of temporal interpolation.

To our knowledge, our development is the first formalization of hindsight theory in a foundational program logic. The usefulness of the developed theory extends beyond our lock-free template algorithms. In fact, we demonstrate that it can help to reduce the proof effort compared to alternative proof techniques in Iris. To this end, we reverify the multicopy template algorithms of [34] using our formalization of hindsight as opposed to our previous tailor-made proof argument for dealing with future-dependent linearization points. The new approach reduces the proof effort by 53%.

To summarize, our contributions are (i) template algorithms for a wide variety of lock-free search structure algorithms, (ii) mechanized proofs of linearizability based on hindsight reasoning in Iris. The result is, to our knowledge, the first formal verification of fully-functional lock-free algorithms for skip lists of unbounded height.

2 The Skip List Template Algorithm

A *skip list* is a search structure over a totally ordered set of keys \mathbb{K} . We focus our discussion on skip lists that implement mutable sets rather than maps. The extension of the presented algorithms to mutable maps is straightforward. The data structure is composed of sorted lists at multiple levels, with the base list determining the actual contents of the structure, while higher level lists are used to speed up the search. An example is shown in Figure 1. A

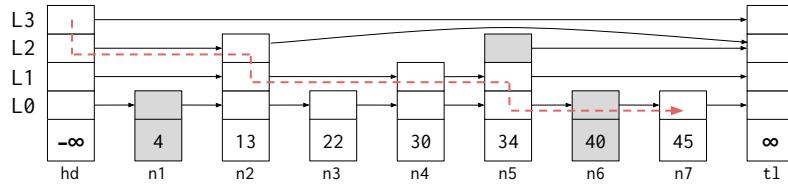

Figure 1 Skiplist with four levels. A node that is marked (logically deleted) at a level is shaded gray at that level. The red line indicates the path taken by a traversal searching for key 42.

skiplist node contains a key and has a height, determining how many higher level lists this node is a part of. Each node has a next pointer for each of its levels. Two sentinel nodes signify the head (*hd* with key $-\infty$) and the tail (*tl* with key ∞) of the skiplist. Lock-free linked lists often use the technique of logical deletion by *marking* a node before it is physically unlinked from the list. This involves storing a mark bit together with the next pointer, so as to allow reading and updating them together in a single (logically) atomic step. Lock-free skiplist implementations also use this technique. Since a skiplist node can be part of multiple lists, it has one mark bit per level.

The traversal for a key not only goes left to right as usual, but also top to bottom. The red line in Figure 1 depicts a traversal searching for key 42. The traversal begins at the highest level of the head node. At each non-base level, the traversal continues till it reaches a node with a key greater than or equal to the search key. Thereafter, the traversal drops down a level, and continues at the lower levels until it terminates on the bottom level at the first node whose key is greater than or equal to the search key.

The traversals in a concurrent skiplist perform *maintenance* in the form of physically unlinking encountered marked nodes. In Figure 1, node *n*₅ has been unlinked at level 2, thus the traversal does not visit it at that level. Operations that mark and change the next pointers at the higher levels do not affect the actual contents of the structure. We therefore consider them to be part of the maintenance.

Many variants of lock-free skiplist algorithms have been proposed in the literature and implemented in practice. These variants differ in (i) their node implementations, (ii) the styles of maintenance operations and/or (iii) the orders in which they perform maintenance operations with regard to other operations.

For example, node implementations in low-level languages often use bit-stealing [10] (or an equivalent of Java’s `AtomicMarkableReference`) so that both the next pointer and mark bit can be atomically read or updated. Other implementations use more complex solutions. For instance, the skiplists in [8] use nodes with back links to reduce traversal restarts due to marked nodes. Java’s `ConcurrentSkipListMap` [33] implements each node as a list of simpler nodes, one per level. The higher level nodes have both right pointers and down pointers, while the base nodes only have right pointers. Java’s implementation also uses *marker nodes* for marking, instead of bit-stealing.

In terms of style of maintenance, the traversal in the Michael Set [31] and Herlihy-Shavit lock-free skiplist [10, § 14] unlinks one marked node at a time. By contrast, the traversal in the Harris List [9] unlinks the entire sequence of marked nodes in one shot with a single CAS operation. The variants also differ in the order of marking of a node at higher levels. In the Herlihy-Shavit skiplist, the marking of a node goes from top level to the bottom level. This differs from skiplists in [33] and [8], whose marking goes from bottom to top.

Despite the differences in the skiplist algorithms described above (and others to be invented in the future), the bulk of their correctness reasoning remains the same. A goal of this paper is to show how to exploit that fact.

Template algorithm. Our template algorithm for skiplists abstracts away from node-level implementation details and the way in which traversals perform maintenance. As we shall see, the particular details regarding how the data is stored internal to the node does not affect the correctness of the core operations - `search`, `insert` and `delete`. Nor is the correctness affected by whether the traversal unlinks one marked node at a time or an entire sequence of marked nodes. We also show that the order in which maintenance operations are performed on the higher levels of the list does not matter for correctness. In summary, the template algorithm we present abstracts from: (i) node-level details; (ii) the style of unlinking marked nodes and (iii) the order of maintenance operations on higher levels.

The template algorithm is assumed to be operating on a set of nodes N that contains the two sentinel nodes head hd and tail tl . Let the maximum allowed height of a skiplist node be $L (> 1)$. Each node n is associated with (i) its key $\text{key}(n) \in \mathbb{K} = \mathbb{N} \cup \{-\infty, \infty\}$, (ii) its height $\text{height}(n) \in [1, L]$, (iii) the next pointers $\text{next}(n, i) \in N$ for each i from 0 to $\text{height}(n) - 1$, and (iv) its mark bits per level $\text{mark}(n, i) \in \{\text{true}, \text{false}\}$ for each i from 0 to $\text{height}(n) - 1$. When discussing $\text{next}(n, i)$ or $\text{mark}(n, i)$, we implicitly assume that i lies between 0 and $\text{height}(n) - 1$. We sometimes say a node n is unmarked to mean that it is unmarked at the base level, i.e., $\text{mark}(n, 0) = \text{false}$. The structural invariant maintains the following facts: $\text{key}(hd) = -\infty$, $\text{key}(tl) = \infty$, $\text{height}(hd) = \text{height}(tl) = L$, $\text{next}(tl, i) = tl$ for all i , $\text{next}(hd, L - 1) = tl$, $\text{mark}(hd, i) = \text{mark}(tl, i) = \text{false}$ for all i .

The core operations of the skiplist template are expressed using *helper functions* such as `findNext` and `markNode` that abstract from the details of the node implementation. We describe the behavior of these helper functions as and when we encounter them. The template is instantiated by implementing these functions. The helper functions are assumed to be *logically atomic*, i.e., appear to take effect in a single step during its execution.

Figure 2 shows the core operations of the skiplist template algorithm. (We omit the code for the data structure initialization as it is straightforward.) All three operations begin by allocating two arrays ps and cs via `allocArr`, each of size L and values initialized to hd and tl respectively. These arrays are then populated by the `traverse` operation as it computes the predecessor-successor pair for operation key k at each level. Intuitively, these pairs indicate where k would be inserted at each level. The template algorithm here abstracts away from the concrete `traverse` implementation. We later consider two implementations of `traverse` that differ in the way that maintenance is performed, as discussed earlier.

As far as the core operations are concerned, they rely on `traverse` to satisfy the following specification. First, it returns a triple (p, c, res) where p and c are nodes and res a Boolean such that $p = ps[0]$, $c = cs[0]$ and res is true iff k is contained in c . Second, the node c must have been unmarked at some point during the traversal; and third, for each $0 \leq i < L$, the traversal observes that $\text{key}(ps[i]) < k \leq \text{key}(cs[i])$.

Let us now describe the core operations, starting with the `search` operation. The `search` operation simply invokes the `traverse` function, whose result establishes whether k was in the structure. The `delete` operation starts similarly by invoking `traverse` and checking if the key is present in the structure. If it is, then `delete` invokes the maintenance operation `maintainanceOpDel`, which attempts to mark c at the higher levels (i.e. all levels except 0). We provide the implementation of `maintainanceOpDel` in a moment. Once `maintainanceOpDel` terminates, `delete` finally attempts to mark c via `markNode` at the base level. If marking succeeds, it terminates by invoking `traverse` (which performs the task of physically unlinking marked nodes at all levels) and returning `true`. Otherwise, a concurrent thread must have already marked c , in which case `delete` returns `false`.

```

1 let search k =
2   let ps = allocArr L hd in
3   let cs = allocArr L tl in
4   let _, _, res = traverse ps cs k in
5   res
6
7 let delete k =
8   let ps = allocArr L hd in
9   let cs = allocArr L tl in
10  let p, c, res = traverse ps cs k in
11  if not res then
12    false
13  else
14    maintainanceOp_del c;
15    match markNode 0 c with
16    | Success -> traverse ps cs k; true
17    | Failure -> false
18 let insert k =
19   let ps = allocArr L hd in
20   let cs = allocArr L tl in
21   let p, c, res = traverse ps cs k in
22   if res then
23     false
24   else
25     let h = randomNum L in
26     let e = createNode k h cs in
27     match changeNext 0 p c e with
28     | Success ->
29       maintainanceOp_ins k ps cs e; true
30     | Failure -> insert k

```

Figure 2 The template algorithm for lock-free skiplists. The template can be instantiated by providing implementations of `traverse` and the helper functions `markNode`, `createNode` and `changeNext`. The `markNode i c` attempts to mark node c at level i atomically, and fails if c has been marked already. `createNode k h cs` creates a new node e of height h containing k , and whose next pointers are set to nodes in array cs . Finally, `changeNext i p c cn` is a CAS operation attempting to change the next pointer of p from c to cn . `changeNext i p c cn` succeeds only if $\text{mark}(p, i) = \text{false}$ and $\text{next}(p, i) = c$. Other functions used here include `randomNum` to generate a random number and maintenance operations associated with `insert` and `delete`. `maintainanceOp_del` marks node c at the higher levels, while `maintainanceOp_ins` inserts a new node e at the higher levels.

The `insert` operation also begins with `traverse`. If the traversal returns *true*, then the key must already have been present. Hence, `insert` returns *false* in this case. Otherwise, a new node e is created using `createNode`. The node's height is determined randomly using `randomNum`, which generates a random number h such that $0 < h < L$. After creating a new node, the algorithm attempts to insert it into the list by calling `changeNext` at the base level (line 27). If the attempt succeeds, `insert` proceeds by invoking the maintenance operation `maintainanceOp_ins`, which also inserts the new node into the list at all higher levels. The `insert` then returns with *true*. If the `changeNext` operation fails, then the entire operation is restarted.

We now describe the maintenance operations for `insert` and `delete`, shown in Figure 3. The maintenance operations here differ from those in traditional skip list implementations in regards to the order in which maintenance is performed at higher levels. In traditional implementations, the marking of a node goes from top to bottom, while insertion of a new node goes from bottom to top. The skip list template presented here makes sure that the base level gets marked at the end and the insertion first happens at the base level, but it imposes no order on how it proceeds at higher levels. That is, when marking a node, a `delete` thread could for instance first mark odd levels, then even levels and finally the base level 0. The maintenance operations in the skip list template captures all such permutations. As our proof shows later, the order of maintenance at higher levels has no bearing on the correctness of the algorithm.

The `maintainanceOp_del` marks node c from levels 1 to $\text{height}(c)$. It begins by reading the height of c as h , and generating a permutation of $[1 \dots (h - 1)]$ stored in array pm via the `permute` function. The `maintainanceOp_del_rec` then recursively marks c in the order prescribed by pm . Note that the maintenance continues regardless of whether `markNode` succeeds or fails, because c will be marked at the end regardless.

30:6 Verifying Lock-Free Search Structure Templates

```

1 let maintainanceOp_del_rec i h pm c =
2   if i < h-1 then
3     let idx = pm[i] in
4     markNode idx c;
5     maintainanceOp_del_rec (i+1) h pm c
6   else
7     ()
8
9 let maintainanceOp_del c =
10  let h = getHeight c in
11  let pm = permute h in
12  maintainanceOp_del 0 h pm c
13 let maintainanceOp_ins_rec i h pm ps cs e =
14  if i < h-1 then
15    let idx = pm[i] in
16    let p = ps[idx] in
17    let c = cs[idx] in
18    match changeNext idx p c e with
19    | Success ->
20      maintainanceOp_ins_rec (i+1) h pm ps cs e
21    | Failure ->
22      traverse ps cs k;
23      maintainanceOp_ins_rec i h pm ps cs e
24  else
25    ()
26
27 let maintainanceOp_ins k ps cs e =
28  let h = getHeight e in
29  let pm = permute h in
30  maintainanceOp_ins 0 h pm ps cs e

```

 **Figure 3** The maintenance operations for the skip list. The `getHeight c` helper function returns $\text{height}(c)$. The `permute` function generates a permutation of $[1 \dots (h-1)]$ as an array.

The `maintainanceOp_ins` begins in the same way by reading the height, generating the permutation and invoking `maintainanceOp_ins_rec`. The `maintainanceOp_ins_rec` first collects the predecessor-successor pair at the current level from arrays `ps` and `cs`, respectively. Then it tries to insert the new node `e` using `changeNext` on predecessor node `p`. If `changeNext` succeeds, then the recursive operation continues. Otherwise, it recomputes the predecessor-successor pairs using `traverse`. After the recomputation, the insertion is retried at the same level.

We can now finally turn to the implementations of `traverse`. We consider two implementations that differ in their treatment of marked nodes. The *eager* traversal attempts to unlink every marked node it encounters, while the *lazy* traversal simply walks over the marked nodes till it reaches an unmarked node. The traversal then attempts to unlink the entire marked segment at once. The two implementations are similar in other aspects, so we discuss only the eager traversal in detail here.

The eager traversal is shown in Figure 4. The `traverse` function is implemented using mutually-recursive functions `eager_rec` and `eager_i`¹. The function `eager_rec` populates the arrays `ps` and `cs` with the predecessor-successor pair at level `i` computed by `eager_i`. The `eager_i` performs a traversal at level `i` by first reading the mark bit and next pointer of `c` using `findNext`. If `c` is found to be marked, then `eager_i` attempts to physically unlink the node using `changeNext`. In the case that `changeNext` fails (because either `p` is marked or it does not point to `c` anymore), `eager_i` simply restarts the `traverse` function. In the case of `Success` of `changeNext`, the traversal continues. If `c` is unmarked, then `traverse_i` proceeds by comparing `k` to `key(c)`. For $\text{key}(c) < k$, the traversal continues with `c` and `cn`. Otherwise, `eager_i` ends at `c`, returning (p, c, true) if $\text{key}(c) = k$ and (p, c, false) otherwise. As mentioned before, `eager_i` attempts to unlink immediately whenever a marked node is encountered.

¹ For ease of exposition, the implementation of the eager traversal shown in Figure 4 differs slightly from the version we have verified in Iris. The Iris version uses option return types instead of mutually-recursive functions in order to obtain a more modular proof of the eager traversal. We use the mutually recursive implementation here for clarity of exposition.

```

1 let eager_i i k p c =
2   match findNext i c with
3   | cn, true ->
4     match changeNext i p c cn with
5     | Success -> eager_i i k p cn
6     | Failure -> traverse ps cs k
7   | cn, false ->
8     let kc = getKey c in
9     if kc < k then
10       eager_i i k c cn
11     else
12       let res = (kc = k ? true : false) in
13       (p, c, res)
14 let eager_rec i ps cs k =
15   let p = ps[i+1] in
16   let c, _ = findNext i p in
17   let p', c', res = eager_i i k p c in
18   ps[i] <- p';
19   cs[i] <- c';
20   if i = 0 then
21     (p', c', res)
22   else
23     eager_rec (i-1) ps cs k
24 let traverse ps cs k =
25   eager_rec (L - 2) ps cs k
26

```

Figure 4 The eager traversal for the skip list template. `findNext i k c` returns a pair $(\text{next}(c, i), \text{mark}(c, i))$. The `getKey c` helper function returns $\text{key}(c)$.

3 Proof Intuition

Our goal is to show that the skip list template is linearizable. That is, we must prove that each of the core operations take effect in a single atomic step during its execution, the *linearization point*, and satisfies the sequential specification shown in Figure 5. For the skip list template, we define the abstract state $C(N)$ to be the union of the *logical contents* $C(n)$ of all nodes in N , where $C(n) := (\text{mark}(n, 0) ? \emptyset : \{\text{key}(n)\})$. In other words, the abstract state of the structure is a collection of keys contained in unmarked nodes at the base level. There are existing techniques from the literature that help us analyze the skip list

$$\Psi_{\text{op}}(k, C, C', \text{res}) := \begin{cases} C' = C \wedge (\text{res} \Leftrightarrow k \in C) & \text{op} = \text{search} \\ C' = C \cup \{k\} \wedge (\text{res} \Leftrightarrow k \notin C) & \text{op} = \text{insert} \\ C' = C \setminus \{k\} \wedge (\text{res} \Leftrightarrow k \in C) & \text{op} = \text{delete} \end{cases}$$

Figure 5 Sequential specification of a search structure. k refers to the operation key, C and C' to the abstract state before and after operation op , respectively, and res is the return value of op .

template. The two main techniques that we rely on are the *Edgeset Framework* [39] and *Hindsight Reasoning* [32, 22, 6, 7, 26, 27]. We begin by giving a brief overview of the two techniques, proceeded by the analysis of the skip list template using these techniques.

3.1 The Edgeset Framework

The Edgeset Framework provides a common terminology to capture how search operations navigate in a variety of search structures. We view each search structure as a mathematical graph whose edges are associated with an *edgeset*, a label that is a set of keys. We denote the edgeset from n to n' by $\text{es}(n, n')$, and $k \in \text{es}(n, n')$ signifies that a search for key k will proceed from node n to n' . In the context of the skip list template, we define the edgeset leaving n to be all values greater than the key in n if n is unmarked. If node n is marked, then the edgeset leaving n is the entire keyspace. Formally: $\text{es}(n, n') := (n' = \text{next}(n, 0) \wedge \text{mark}(n, 0) = \text{false} ? (\text{key}(n), \infty) : \mathbb{K})$. Note that, our definition of edgesets in the skip list template depends only on the base list, and not on higher level mark bits and next pointers.

30:8 Verifying Lock-Free Search Structure Templates

A notion defined in terms of edgesets is the *inset* of a node, denoted by $\text{inset}(n)$, signifying a set of keys for which a search will arrive at n . In order to understand the concept of inset intuitively, consider Figure 6. The inset of node n_4 is $(2, \infty)$, because, for all keys greater than 2, the search will enter n_4 . We say node n_1 is the *logical predecessor* of n_4 if it is the first unmarked predecessor of n_4 . The inset of the root is \mathbb{K} and the inset of n is the intersection of \mathbb{K} with the edgesets of all nodes between the root and n . For sorted linked lists in general, a more local notion gives the same result: the inset of an unmarked node n is $(\text{key}(n'), \infty)$, where n' is the logical predecessor of n .

In contrast to inset, we define the *outset* as the union of all its outgoing edgesets: $\text{outset}(n) := \bigcup_{n' \in N} \text{es}(n, n')$.

We can now define the *keyset* of a node n as $\text{keyset}(n) := \text{inset}(n) \setminus \text{outset}(n)$, i.e. intuitively, the set of keys for which a search enters n but never leaves. The importance of keysets is that if k is in $\text{keyset}(n)$, then k is either in the contents of n or is nowhere in the structure. In Figure 6, the keyset of n_4 is $(2, 9]$ and in general, the keyset of an unmarked node n is $(\text{keyset}(n'), \text{key}(n)]$ where n' is its logical predecessor. The keyset of a marked node is \emptyset because its outset is the set of all keys \mathbb{K} .

The technical definition of inset relies on the global data structure graph, defined as a solution to the following fixpoint equation

$$\forall n \in N. \text{inset}(n) = \text{in}(n) \cup \bigcup_{n' \in N} \text{es}(n', n) \cap \text{inset}(n')$$

where $\text{in}(n) := (n = \text{hd} ? \mathbb{K} : \emptyset)$. Thus, the inset is a global quantity and hence difficult to reason about. Fortunately, this is where the Flow Framework [20, 21, 28] comes in handy. It allows us to reason about quantities that can be expressed as a solution to a fixpoint equation (like inset) in a local manner by attaching *flow* values to the node. The framework then provides tools to track changes to the flow values that are induced by changes to the underlying graph. Our approach to encoding keysets in Iris using the Flow Framework is borrowed from [18]. We defer further details on this matter to the later sections.

As mentioned above, $\text{keyset}(n)$ intuitively is the set of all keys that n is responsible for. Consider Figure 6 again, a thread executing `search(6)` without any interference will reach node n_4 and terminate, concluding that 6 is not present in the structure. In this sense, we say n_4 is responsible for key 6 and therefore 6 is part of n_4 's keyset. The keysets of all nodes partition the set of all keys and provide the crucial *Keyset Property*:

$$\forall n \in N, k \in \mathbb{K}. k \in \text{keyset}(n) \Rightarrow (k \in C(N) \Leftrightarrow k \in C(n)) \quad (\text{KeysetPr})$$

This property enables one to lift a proof of the specification at the node level to a proof of the sequential specification Ψ_{op} . A particular situation where (KeysetPr) proves indispensable is when `search` fails to find the search key. Note that `search` observes only the nodes it visited, and hence has only a partial view of the structure. When `search` fails to find the key, the proof has to reconcile this partial view of the structure with the global view. In essence, if a concurrent invocation of `search` on key k fails to find the key, can we conclude that there was a point in time during its execution when k was in fact not present in the structure? Here, the property (KeysetPr) helps us reconcile facts gathered by `search` with the global state of the structure. Specifically, if `search` can determine a node n such that $k \in \text{keyset}(n)$ and $k \notin C(n)$, then we can immediately infer that k was not present in the structure at that point in time.

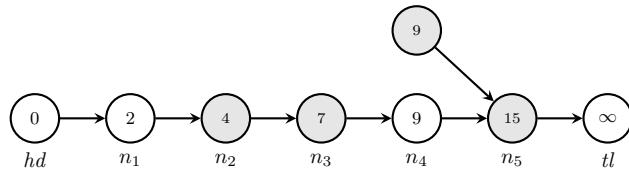

Figure 6 Possible state of the base list in the skip list template. Nodes are labeled with the value of their `key` field. Edges indicate `next` pointers. Marked (logically deleted) nodes are shaded gray. $\text{keyset}(hd) = \{0\}$, $\text{keyset}(n_1) = (0, 2]$, $\text{keyset}(n_4) = (2, 9]$ and $\text{keyset}(tl) = (9, \infty)$. The keyset of a marked node is always \emptyset .

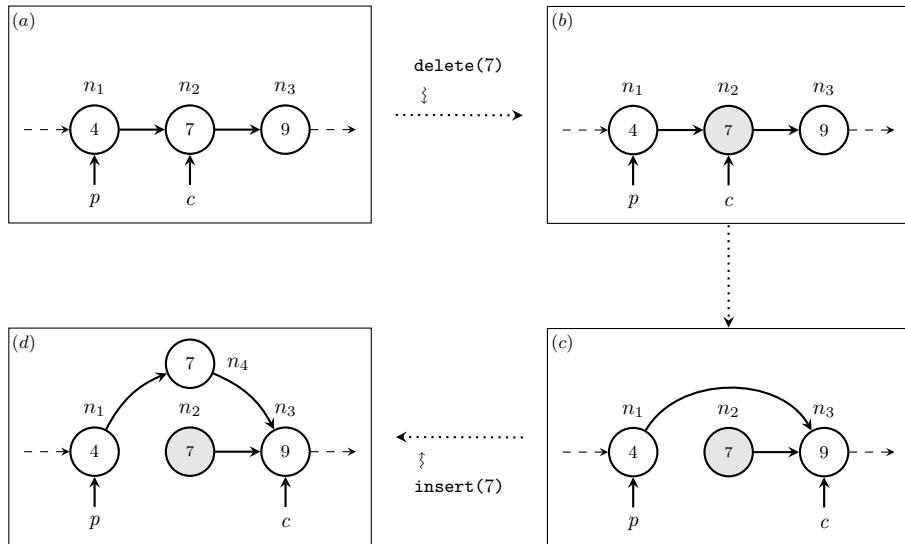

Figure 7 Possible states of `search(7)` on the base level in presence of interference from concurrent `delete(7)` and `insert(7)`.

3.2 Hindsight Reasoning

Lock-free structures often exhibit future-dependent linearization points. That is, the linearization point of an operation cannot be determined at any fixed moment, but only at the end of the execution, once any interference of other concurrent operations has been accounted for. To understand the interference issue, consider the `search` operation. Since, `search` returns the result of `traverse`, let us look at the eager traversal implementation. To simplify the explanation further, let us assume that the maximum height allowed for every non-sentinel node is one. Then, we can ignore the `eager_rec` function and focus on `eager_i` called at the base level.

Let there be a thread T executing `search(7)`. Concurrently, there is a thread T_d executing `delete(7)` and a thread T_i executing `insert(7)`. Figure 7 shows interesting scenarios that thread T might potentially observe. Box (a) captures the state of the structure at the beginning of the `eager_i` call processing n_2 . Let **Scenario 1** be the situation when thread T faces no interference from T_d and T_i . Here, thread T finds the key 7 in n_2 and `eager_i` returns `true`. The point when `eager_i` finds n_2 to be unmarked becomes the linearization point for this scenario.

Now consider **Scenario 2** to be the situation where thread T_d marks n_2 before `eager_i` processes it, as shown in Box (b). Thread T will attempt to unlink n_2 , and assuming no further interference, the unlink will result in the structure in Box (c). Thread T will process

n_3 next, finding n_3 to be unmarked with key greater than 7, and will terminate with result *false*. So when is the linearization point in this scenario? It cannot be when T finds n_3 unmarked when processing it. Because there could be further interference from thread T_i which inserts key 7 in a new node as shown in Box (d). The new node could be added right before T reads the mark bit of n_3 . Thus, when `eager_i` finds n_3 unmarked and returns *false*, key 7 could actually be present in the structure at that point in time.

The linearization point is actually the point in time shown in Box (c), i.e., right after n_2 is unlinked. However, thread T cannot confirm this when n_2 is unlinked because `eager_i` may not terminate at n_3 with *false* as the result. The reason is that by the time T processes n_3 , it could get marked in a manner similar to n_2 in Box (b), resulting in the unlinking of n_3 and potentially a restart. That Box (c) is the linearization point is confirmed when T has found n_3 to be unmarked later. The structure maintains the invariant that once a node is marked, it remains marked. Using this invariant, an analysis of thread T 's history concludes that n_3 must have been unmarked at the point when n_2 was unlinked. Once `eager_i` terminates at n_3 with *false*, an analysis can *establish in hindsight* that Box (c) indeed was the linearization point.

Hindsight reasoning as formalized in [26, 27] is designed to deal with situations like the `search` in Figure 7. It enables temporal reasoning about computations using a *past predicate* $\diamond q$, which expresses that proposition q held true at some prior state in the computation (up to the current state). For instance, $\diamond(\text{next}(n_1, 0) = n_2)$ holds in Box (c) even though $\text{next}(n_1, 0) = n_3$ at that point. The reason is that $\text{next}(n_1, 0) = n_2$ was true at an earlier point in time, namely in Box (b). Note that the past operator \diamond abstracts away the exact time point when the predicate held true. Note also that a past predicate is not affected by concurrent interferences, as it merely records some fact about a past state.

There are two ways to establish a past predicate that are relevant for our proofs. The first is to establish the predicate in the current state directly. That is, $\diamond q$ holds if q holds in the current state. As an example, we obtain $(\text{next}(n_1, 0) = n_2)$ when `findNext` on n_1 returned n_2 in Box (a). Thus, for all subsequent states including Box (b) and (c), we get $\diamond(\text{next}(n_1, 0) = n_2)$. The second way to establish a past predicate is through the use of *temporal interpolation* [27]. That is, one proves a lemma of the form: if there existed a past state that satisfied property q and the current state satisfies r , then there must have existed an intermediate state that satisfied o . Such lemmas can then be applied, e.g., to prove that if thread T finds n_3 to be unmarked in Scenario 2, then it must have been unmarked when n_2 was unlinked in Box (c).

Equipped with the Edgeset Framework and hindsight reasoning, we are now ready to analyze the core operations of the skip list template.

3.3 Proof Outline for Core Operations

We refer to a linearization point as *modifying* if the operation changes the abstract state of the data structure (like in the case of a succeeding `delete` and `insert`) and otherwise refer to it as *unmodifying* (like `search` and in the case of a failing `delete` or `insert`). The modifying linearization points of the skip list template are easier to reason about because they are not future-dependent. For `delete`, the linearization point occurs when `markNode` succeeds, and similarly, for `insert` the linearization point occurs when the call to `changeNext` on line 27 succeeds. The proof strategy for unmodifying linearization points is to combine (`KeysetPr`) with the \diamond operator from hindsight reasoning. Let us expand on this proof strategy in detail and show why the skip list template is linearizable.

We begin by describing the specification for `traverse` that is assumed for analyzing the core operations of the template. Then, we analyze each of the operations in detail. Finally, we show how the eager implementations of `traverse` satisfies the specification that was assumed in the beginning. Along the way, we introduce (as and when necessary) invariants maintained by the skiplist template that are crucial for proving linearizability.

Specification of `traverse`. The function `traverse ps cs k` updates arrays `ps` and `cs` with predecessor-successor pairs for each level and returns a triple (p, c, res) that satisfies the following past predicate regarding node c : $\Diamond(k \in \text{keyset}(c) \wedge (res \Leftrightarrow k \in C(c)))$. Recall that our definition of edgesets in Section 3.1 implies the following invariant:

Invariant 1 For all nodes n , if $\text{mark}(n, 0)$ is set to *true* then $\text{keyset}(n) = \emptyset$.

Using Invariant 1, we can establish that c is unmarked at the base level at the time point when $k \in \text{keyset}(c)$ holds. Note that `traverse` may physically unlink marked nodes. However, this step does not change the abstract state of the structure. Hence, the specification for `traverse` involves no change of the abstract state.

We now consider each of the core operations in detail.

Proof of search. Function `search` returns `res` out of the triple (p, c, res) returned by `traverse`. The specification of `traverse` says $res \Leftrightarrow k \in C(c)$ at some point, say t , during its execution. The specification additionally guarantees $k \in \text{keyset}(c)$ at time t . These two facts, combined with the (`KeysetPr`) at time point t , allow us to immediately infer that `res` is *true* iff k was in the structure at that point. Hence, we can establish that $(res \Leftrightarrow k \in C(c))$ was true at some point during the execution of `search`.

Proof of delete. We analyze `delete` by case analysis on the value `res` returned by `traverse`. If `res` is *false*, then again we can establish that k was not in the structure at some point during `traverse`'s execution by the same reasoning used in the proof of `search`. So let us consider the case that `res` is *true*. By the specification of `traverse`, we can establish a time point when c was unmarked and contained k . The `delete` operation then calls `maintainanceOpDel` which marks c at all the higher levels. Finally, the `markNode` on Line 15 attempts to mark c at the base level. If `markNode` succeeds, then this step becomes the linearization point of `delete` and k can be considered to be deleted from the structure. But if `markNode` fails, then we gain the knowledge that $\text{mark}(c, 0) = \text{true}$. Hindsight reasoning allows us to infer that c was marked at the base level by a concurrent thread between the end of `traverse` and the invocation of `markNode`. The point right after c was marked by a concurrent thread becomes the linearization point of `delete` in this case, as we can determine that k was not present in the structure at that point.

This hindsight reasoning relies on two facts: first, the key of a node never changes and second, once a mark bit is set to *true* by a successful `markNode` operation (at line 15 in `delete` or line 4 in `maintainanceOpDel`), no other operation will set it back to *false*. In fact, these two facts are invariant for the skiplist template:

Invariant 2 For all nodes n and level i , once $\text{mark}(n, i)$ is set to *true*, it remains *true*.

Invariant 3 For all nodes n , $\text{key}(n)$ remains constant.

Proof of `insert`. Similar to `delete`, we begin by case analysis on `res` returned by `traverse`. If `res` is true, then we can establish that k was already present in the structure at some point. Otherwise, `res` is `false` and `insert` creates a new node e with key k . Using `changeNext`, an attempt is made to insert node e between nodes p and c . If the attempt succeeds, then k is now part of the structure and this becomes the linearization point. The following `maintainanceOp_ins` operation does not change the abstract state of the structure, and thus, has no effect in terms of linearizability. If the `changeNext` fails, then `insert` simply restarts.

As is evident with the proof outline for the core operations, the specification assumed for `traverse` plays a critical role in case the operation exhibits an unmodifying linearization point. Let us now turn to `traverse` and show how its specification can be proved. We analyze the eager traversal in detail in the following section. The proof argument for the lazy version is similar.

3.4 Proof Outline for Eager Traversal

As stated earlier, `traverse` returns (p, c, res) such that $\diamondsuit(k \in \text{keyset}(c) \wedge (res \Leftrightarrow k \in C(c)))$. Since the returned triple is the result of a call to `eager_i` at the base level, let us begin by analyzing the behavior of this call.

In the sequential setting, the traversal in a search structure maintains the invariant that the search key is always in the inset of the current node. This invariant holds by the design of the Edgeset Framework. Unfortunately, this invariant no longer holds for the skiplist template in the concurrent setting as evidenced by Box (c) in Figure 7. However, we argue first that `eager_i` does maintain the invariant that the search key was in the inset of the current node c between the start of the traversal and the point at which the `eager_i` accesses c . We call this the *inset in hindsight* invariant.

We prove this invariant inductively. We make use of the following locally maintained invariants: (i) At all times, there is one list, denoted the *reachable list*, from the head node that includes all unmarked and some marked nodes. (This list is characterized by the set of nodes with non-empty inset, see Figure 6 for intuition). (ii) The keys in the reachable list are sorted. A consequence of these two invariants is that if a node n is in the reachable list (whether n is marked or not) and has a key less than k , then k is in the inset of n .

To prove that *inset in hindsight* is an invariant, we have to show that (a) it is an invariant when `eager_i` takes a step (Line 2) when traversing the base level, and (b) that we can establish *inset in hindsight* when `eager_rec` initiates `eager_i` (Line 17) at the base level.

To show (a), observe that if a node n becomes unlinked from the reachable list, then it will never again be part of the reachable list. Hence, if n is not in the reachable list when `eager_i` begins executing at the base list, then `eager_i` will never visit n . The contrapositive of this statement allows us to say that if `eager_i` reaches some node c , then it must have been part of the reachable list at some point during the execution of `eager_i`. Additionally, `eager_i` proceeds to the node following c only when $\text{key}(c) < k$. With the help of invariants (i) and (ii) above, we can thus establish that k was in the inset of n at some point.

To show (b), we must do a case analysis on whether node p (Line 16) is marked. If it is unmarked, then it is straightforward to establish that k is in the inset of c currently. However, if p is marked, then we require temporal interpolation based on the following invariant:

Invariant 4 For all nodes n and level i , once `mark(n, i)` is set to `true`, `next(n, i)` does not change.

This invariant tells us that if p was known to be unmarked in the past, and it is marked currently, then p must have been pointing to c right before it got marked. At that point in time, we can establish that k must have been in the inset of c .

This completes the inductive proof that inset in hindsight is indeed an invariant maintained by the traversal. The inset in hindsight invariant is sufficient to prove the `traverse` specification by the following simple argument. If the traverse encounters k in an unmarked node n , then `traverse` will return *true* as it should. If, by contrast, `traverse` encounters an unmarked node n such that $\text{key}(n) > k$, then by the inset in hindsight invariant, k must have been in the inset of n at some point t in the past and k cannot be in the outset of n (because $\text{key}(n) > k$ and n is unmarked), so therefore k must have been in the keyset of n at time t .

4 Hindsight Reasoning in Iris

Linearizability in Iris is defined via (*logically*) *atomic triples* [4, 16]. Intuitively, an atomic triple $\langle x. P \rangle e \langle v. Q \rangle$ says that at some point during the execution of e , the resources described by the precondition P will be updated to satisfy the postcondition Q for return value v in one atomic step. The variable x can be thought of as the abstract state of the data structure before the update at the linearization point.

Linearizability of a search structure operation op can be expressed by an atomic triple of the form

$$\boxed{\text{Inv}(r)} \dashv\ast \langle C. \text{CSS}(r, C) \rangle \text{op} r k \langle \text{res}. \exists C'. \text{CSS}(r, C') * \Psi_{\text{op}}(k, C, C', \text{res}) \rangle. \quad (\text{ClientSpec})$$

Here, r is the pointer to the head of the data structure. The predicate $\text{CSS}(r, C)$ is the *representation predicate* that relates the head pointer with the contents C of the structure. The predicate $\text{Inv}(r)$ is the shared data structure invariant. It can be thought of as a thread-local precondition of the atomic triple, which we express using separating implication. The invariant ties $\text{CSS}(r, C)$ to the data structure's physical representation and may contain other resources necessary for proving the atomic triple. The predicate $\Psi_{\text{op}}(k, C, C', \text{res})$ captures the sequential specification of the structure. The specification essentially says there is a single atomic step in op where the abstract state changes from C to C' according to the sequential specification $\Psi_{\text{op}}(k, C, C', \text{res})$ (Figure 5). This step is op 's linearization point. We call (ClientSpec) the *client-level* atomic specification for the data structure under proof.

Proving atomic triples. The proof of establishing an atomic triple involves a *linearizability obligation* that must be discharged directly at the linearization point. However, it can be challenging to determine the linearization point precisely and to discharge the linearizability obligation exactly at that point. When the program execution reaches a potential linearization point that depends on future interferences by other threads, then the proof will fail if it is unable to determine whether the linearizability obligation should be discharged now or later. In Iris, this challenge is overcome using *prophecy variables* [15], which enable the proof to reason about the remainder of the computation that has not yet been executed.

Another challenge is that the linearization point of an operation may be an atomic step of another operation that is executed by a different thread (like in Scenario 2 discussed in Section 3.2). Data structures that demonstrate such behavior are said to deploy *helping*. This behavior complicates thread modular reasoning. The conventional solution to this challenge in Iris is to use a *helping protocol* [15, 34, 13]. The helping protocol is specified as part of the shared data structure invariant and consists of a registry that tracks which threads are expected to be linearized by other threads as well as conditional logic that governs the correct transfer and discharge of the associated linearizability obligations.

Both the use of prophecy variables and the helping protocol need to be tailored to the specific data structure at hand, which adds considerable overhead to the proof. To reduce this overhead, we present an alternative proof method that enables linearizability proofs based on hindsight arguments in Iris. Rather than identifying the linearization point precisely, the proof can establish linearizability in hindsight using temporal interpolation in the style of the intuitive proof argument for the skiplist template presented in Section 3.2.

Hindsight specification. Our proof method offers an intermediate specification, a Hoare triple specification, which in essence expresses that linearizability has been established in hindsight. In our Iris formalization, we show that any data structure whose operations satisfy the hindsight specification also satisfy the client-level atomic specification. This proof relates the two specifications via prophecy variables and a helping protocol. However, the helping protocol is data structure agnostic, making our proof method applicable to a broad class of structures exhibiting future-dependent unmodifying linearization points.

From the perspective of a proof author using our method to prove linearizability of some structure, one has to only establish the hindsight specification to obtain the proof of the client-level atomic specification. To this end, our method provides further guidance to the proof author.

In order to use hindsight reasoning, one has to have the history of computation at hand. Here, we offer a shared state invariant with a mechanism to store the history. The shared state invariant has three main components: a mechanism to store the history, the helping protocol, and finally, an abstract predicate that can be instantiated with invariants specific to the structure at hand. The first two components are data structure agnostic. The proof author only needs to specify the data structure-specific invariant and what information about the data structure state should be tracked by the history.

In the rest of this section, we discuss our method in detail. We begin with the hindsight specification, followed by a discussion of the shared state invariant and how to use it.

4.1 Linearizability in Hindsight

We motivate the hindsight specification using the challenges we face when proving the client-level atomic specification for the `delete` operation of the skiplist template. Let us recall the intuitive proof argument for `delete` from Section 3.3. As per the observation regarding the modifying and unmodifying linearization points, a `delete` thread with modifying linearization point can fulfill the obligation at the point when the structure is modified. However, a `delete` thread with an unmodifying linearization point requires helping.

Prophecy reasoning. An important detail of our proof method is how it determines whether a thread requires helping. In the following, we refer to the operation that a thread performs at its linearization point as its *decisive operation*. In `delete`, the traversal observes node c to be unmarked at some point during execution. In the case where c is marked by the time that the thread calls its decisive operation `markNode` (in Line 15), the thread requires helping from the thread that marks c .

In order to determine in advance whether a thread requires helping, our proof method attaches a prophecy to each thread. A prophecy in Iris can predict a sequence of values and is treated as a resource that can be owned by a thread. Ownership of a prophecy p is captured by the predicate `Proph(p, pvs)`, where pvs is the list of predicted values. The predicate signifies the right to resolve p when the thread makes a physical step that produces some result value v . The resolution of p establishes equality between v and the head of the

list pvs (i.e., the next value predicted by p). The resolution step yields the updated predicate $\text{Prop}(p, pvs')$ where pvs' is the tail of pvs . This mechanism enables the proof to do a case analysis on the predicted values pvs before these values have been observed in the program execution².

The prophecy attached to a thread predicts the results of the thread's decisive operation. In case of `delete`, the decisive operation is the call to `markNode` in the base list, while for `insert`, it is the call to `changeNext` in the base list. Note that a thread may restart if its decisive operation fails (like in the case of `insert`). Therefore, the prophecy needs to predict a sequence of result values, one for each attempted call to the thread's decisive operation.

For the purpose of this discussion, we assume that the prophecy predicts a sequence of **Success** or **Failure** values. If the sequence contains a **Success** value, then the decisive operation will succeed and the thread will modify the structure. Otherwise, the thread's linearization point is unmodifying. Let predicate $\text{Upd}(pvs)$ hold when pvs contains at least one **Success** value.

The proof author only needs to identify the decisive operations that potentially change the abstract state of the structure (like `markNode` as discussed above) by resolving the prophecy around these decisive calls.

Hindsight specification. Before we can present the hindsight specification, we need to provide necessary details regarding the atomic triples in Iris. An atomic triple $\langle x.P \rangle e \langle v.Q \rangle$ is defined in terms of standard Hoare triples of the form $\forall \Phi. \{AU_{x,P,Q}(\Phi)\} e \{v.\Phi(v)\}$. The predicate $AU_{x,P,Q}(\Phi)$ is the *atomic update token* and represents the linearizability obligation of the atomic triple. At the beginning of each atomic step that the thread takes up to its linearization point, the token offers the resources in P and the token itself transforms into a choice. That is, at the end of the atomic step, the prover has to choose to either *commit* the linearization or *abort*. When committing, the prover has to show that the thread's atomic step transforms the resources in P to those in Q , receiving $\Phi(v)$ from the update token in return, which serves as the receipt of linearization of the atomic triple. In case of an abort, the prover needs to show that the thread's atomic step reestablishes P .

We also need to introduce two more auxiliary predicates:

- $\text{Thread}(tid, t_0)$: this predicate is used to *register* the thread with identifier tid in the shared invariant. The argument t_0 denotes the time when thread tid began its execution.
 - $\text{PastLin}(op, k, res, t_0)$: this predicate holds if there was a past state in the history between time t_0 and the point when this predicate is evaluated for which the sequential specification Ψ_{op} held with result res . It essentially captures whether the sequential specification was true for any point after time t_0 .

We now have all the ingredients to present the hindsight specification:

$$\begin{aligned} & \forall tid t_0 pvs. \boxed{\text{Inv}(r)} \rightarrow \text{Thread}(tid, t_0) \rightarrow \\ & \left\{ \begin{array}{l} \{\text{Proph}(p, pvs) * (\text{Upd}(pvs) \rightarrow \text{AU}_{\text{op}}(\Phi))\} \text{ op } r k \\ \left\{ \begin{array}{l} \text{res. } \exists pvs'. \text{Proph}(p, pvs') * pvs = (_\circledast pvs') \\ * (\text{Upd}(pvs) \rightarrow \Phi(\text{res})) \end{array} \right\} \\ * (\neg \text{Upd}(pvs) \rightarrow \text{PastLin}(\text{op}, k, \text{res}, t_0)) \end{array} \right\} \end{aligned} \quad (\text{HindSpec})$$

² For further details on prophecies in Iris, we refer to [15].

We explain it piece by piece. The local precondition $\text{Thread}(tid, t_0)$ ties the thread to its identifier tid and provides knowledge that tid begins executing at time t_0 . The Hoare triple can be best understood by observing how prophecy resources are allowed to change (highlighted in brown) and what are the obligations when $\text{Upd}(pvs)$ holds (in teal) versus when it does not hold (in magenta). Let us look at each of these in detail. First, the prophecy resource $\text{Proph}(p, pvs)$ in the precondition changes to $\text{Proph}(p, pvs')$ in the postcondition where pvs' is a suffix of pvs . It basically says that operation op is allowed to resolve the prophecy p as many times as it needs and then return the remaining resource at the end.

Now let us consider the case when $\text{Upd}(pvs)$ holds. The precondition here provides the atomic update token $\text{AU}_{op}(\Phi)$ to op , expecting the receipt of linearization $\Phi(res)$ in return. Thus, the responsibility of linearization is delegated to op when $\text{Upd}(pvs)$ holds. We can gain better insight by relating this situation to the `delete` operation from the skip list template as before. This case corresponds to when `markNode` (from line 15) succeeds as $\text{Upd}(pvs)$ holds here. The point when `markNode` succeeds becomes the linearization point and so the thread does not require help from other threads to linearize. The hindsight specification simply asks for the receipt from linearization $\Phi(res)$ at the end.

Finally, let us consider the case when $\text{Upd}(pvs)$ does not hold. The precondition provides no additional resources here, while the postcondition requires the predicate $\text{PastLin}(op, k, res, t_0)$. In simple terms, this means that if $\text{Upd}(pvs)$ is not true, i.e., the prophecy says the thread is not going to modify the structure, then the hindsight specification allows exhibiting a past state from history when the sequential specification was true. Relating again to `delete`, if the `markNode` fails, then the thread can look at the history of the structure and exhibit precisely the point when the decisive node got marked.

The proof argument for establishing the hindsight specification is significantly simpler than if one were to attempt a direct proof of the client-level atomic specification. In particular, the proof author does not need to reason about helping and atomic update tokens in last case discussed above. Instead, they only need to reason about the structure-specific history invariant.

Soundness of the hindsight specification. Our proof that relates the hindsight specification for op to the atomic triple specification involves a helping protocol. The details of the helping protocol and the soundness proof for the hindsight specification are similar to those of the proofs presented in [15, 34]. We therefore provide only a brief summary here. Additional details regarding the proof and the helping protocol can be found in [36].

Before op begins executing, the proof creates the prophecy resource $\text{Proph}(p, pvs)$ assumed in the precondition of the hindsight specification. If the prophecy determines that the thread requires helping, then its client-level atomic triple is registered to a predicate which encodes the helping protocol as part of the shared state invariant $\text{Inv}(r)$. The registered atomic triple serves as an obligation for the helping thread to commit the atomic triple. This obligation will be discharged by the appropriate concurrent operation determined by the op 's sequential specification Ψ_{op} . The proof then uses the hindsight specification to conclude that it can collect the committed triple from the shared predicate. The committed triple serves as a receipt that the obligation to linearize has been fulfilled.

To govern the transfer of linearizability obligations and fulfillment receipts between threads via the shared invariant, the helping protocol tracks a *registry* of thread IDs with unmodifying linearization points that require helping from other concurrent threads. Each thread registered for helping is in either *pending* state or *done* state, depending on whether the thread has already been linearized. A thread registered for helping must be able to

determine its current protocol state in order to be able to extract its committed atomic triple from the registry. For this purpose, the helping protocol includes a *linearization condition* that holds iff a registered thread *tid* has linearized (and is, hence, in *done* state).

From the point of view of a thread which *does* the helping, the linearization condition forces its proof to scan over the pool of uncommitted triples registered in the helping protocol and identify those that need to be linearized at its linearization point, changing their protocol state from *pending* to *done*. This step involves a proof obligation for the helping thread to show that the sequential specification of *tid*'s operation is indeed satisfied at the linearization point.

One crucial innovation in our helping protocol is that we have formulated a linearization condition that is parametric in the sequential specification of the data structure operations, making the soundness proof for the hindsight specification applicable to many structures at once. In particular, we deal with the aspect of scanning and updating the registry in the proof of the helping thread, the proof author simply invokes a lemma provided by our method at the identified linearization points. Therefore, the helping protocol mechanism remains fully opaque to the proof author.

4.2 Invariant for Hindsight Reasoning

Hindsight arguments involve reasoning about past program states. Our encoding therefore tracks information about past states using *computation histories*. We define computation histories as finite partial maps from *timestamps*, \mathbb{N} , to *snapshots*, \mathbb{S} . A snapshot describes an abstract view of a program state. It is a parameter of our method. For instance, a snapshot may capture the physical memory representation of the data structure under proof, while abstracting from the remainder of the program state. Another parameter is a function $|\cdot|$ that computes the abstract state of the data structure from a given snapshot.

$$\begin{aligned} \text{Inv}(r) &:= \exists H T C. \overline{\text{CSS}}(r, C) * |H(T)| = C \\ &\quad * \text{Hist}(H, T) * \text{Inv}_{\text{help}}(H, T) * \text{Inv}_{\text{tpl}}(r, H, T) \\ \text{Inv}_{\text{tpl}}(r, H, T) &:= \text{resources}(r, H(T)) \\ &\quad * (\forall t, 0 \leq t \leq T \Rightarrow \text{per_snapshot}(H(t))) \\ &\quad * (\forall t, 0 \leq t < T \Rightarrow \text{transition_inv}(H(t), H(t + 1))) \end{aligned}$$

Figure 8 Definition of the shared state invariant encoding the hindsight reasoning. Variable H represents the history, T the current timestamp in use and C the abstract state of the structure.

Figure 8 shows a simplified definition of the invariant that encodes the hindsight reasoning. For sake of brevity, we provide only a high-level overview of the predicates used in the invariant. The predicate $\text{Hist}(H, T)$ contains the mechanism to track the history of snapshots. That is, H denotes the history that has been observed so far and T is the current time stamp. Using appropriate ghost resources, it ensures that the timestamps are non-decreasing and past states recorded in H are preserved by future updates to the history. This allows us to define a *past predicate* $\diamondsuit_{s,t_0}(q)$ with the intuitive meaning that the history contains state s recorded after (or at) time t_0 for which proposition q holds true. The exact definition of the past predicate uses the ghost resources used to preserve the past states. The predicate $\text{Hist}(H, T)$ also guarantees that $\text{dom}(H) = \{0 \dots T\}$, ensuring that there are no gaps in the history.

The conjunct $|H(T)| = C$ and the predicate $\overline{\text{CSS}}(r, C)$ together tie the abstract state C of the data structure to the latest snapshot in the history. The predicate $\overline{\text{CSS}}(r, C)$ is the dual of the representation predicate $\text{CSS}(r, C)$ used in the client-level atomic specification. Both represent one half of an ownership over the abstract state of the structure, keeping the abstract state defined by $\text{Inv}(r)$ synchronized with the representation predicate $\text{CSS}(r, C)$.

The helping protocol predicate $\text{Inv}_{\text{help}}(M, T)$ contains a *registry* of thread IDs with unmodifying linearization points that require helping from other concurrent threads. For each thread ID tid in the registry, the protocol stores information such as the start time of the thread, whether it has been linearized or not, etc.

The predicate $\text{Inv}_{\text{tpl}}(r, H, T)$ captures invariants particular to the data structure under proof. It is further composed of three abstract predicates that are meant to be instantiated with the structure specific invariants. The three predicates serve the following purpose. The first predicate $\text{resources}(r, H(T))$ ties the current snapshot to the physical representation of the structure. The predicate $\text{Hist}(H, T)$ contains a conjunct $(\forall t, t < T \Rightarrow H(t) \neq H(t+1))$. Together with the predicate resources , this conjunct forces a thread to update the history whenever the structure is modified.

The predicate $\text{per_snapshot}(H(T))$ captures the structural invariants that hold for any given snapshot. For instance, when proving the skip list template, this predicate holds facts about the nodes hd and tl having maximum height, etc. The predicate $\text{transition_inv}(s, s')$ captures a transition invariant on snapshots observed in the history. That is, it constrains how certain quantities evolve over time. Again as an example from the skip list template proof, the fact that a node marked in s remains marked in s' is included here. Crucially, the facts in $\text{transition_inv}(s, s')$ allow temporal interpolation required to establish facts about past states in the history (like in Section 3.2).

To summarize, the proof author defines the snapshot of the structure, the function $|\cdot|$, and instantiates the three abstract predicates in Inv_{tpl} appropriately. The resulting shared state invariant then tracks the history and handles the helping protocol without requiring further fine-tuning to the data structure at hand.

5 Verifying the Skip List Template

We relate the intuitive proof argument from Section 3 to the development on hindsight reasoning in Iris in Section 4 to obtain a complete proof of the skip list template. To achieve this, we must perform three tasks required by the proof method in Section 4. The first task is to determine the decisive operations that potentially alter the structure, and resolve the prophecy around those operations. As discussed previously, the decisive operations are `markNode` for `delete` and `changeNext` for `insert`. The `search` operation does not modify the abstract state and hence, it has no decisive operation.

The second task is to define a snapshot in the context of the skip list template and instantiate Inv_{tpl} appropriately. This includes the predicate resources that ties the concrete state of the structure to the latest snapshot, as well as invariants that allow temporal interpolation. The third and the final task is to prove the hindsight specification for the core operations.

In this section we focus on the second task of defining the snapshot and providing invariants necessary to formalize the intuitive proof argument. Once, we have set up the right invariants, the formalized proof follows the intuitive proof very closely. We explain this with `delete` as an example.

```

 $\text{Inv}_{\text{tpl}}(r, H, T) := \text{resources}(r, H(T))$ 
    *  $(\forall t, 0 \leq t \leq T \Rightarrow \text{per\_snapshot}(H(t)))$ 
    *  $(\forall t, 0 \leq t < T \Rightarrow \text{transition\_inv}(H(t), H(t + 1)))$ 
 $\text{resources}(s) := \bigstar_{n \in \text{FP}(s)} \text{Node}(n, \text{mark}(s, n), \text{next}(s, n), \text{key}(s, n), \text{height}(s, n))$ 
    *  $\text{resources\_keyset}(s)$ 
 $\text{transition\_inv}(s, s') := (\text{FP}(s) \subseteq \text{FP}(s'))$ 
    *  $(\forall n, \text{key}(s', n) = \text{key}(s, n) \wedge \text{height}(s', n) = \text{height}(s, n))$ 
    *  $(\forall n i, \text{mark}(s, n, i) = \text{true} \Rightarrow \text{mark}(s', n, i) = \text{true})$ 
    *  $(\forall n i, \text{mark}(s, n, i) = \text{true} \Rightarrow \text{next}(s', n, i) = \text{next}(s, n, i))$ 

```

■ **Figure 9** Instantiating Inv_{tpl} with invariants of the skip list template.

5.1 Snapshot and the Skip list Template Invariant

Recall that the notion of keysets are central to the intuitive proof argument for the core operations of the skip list template. Hence, a snapshot of the structure must contain information about the keysets. For encoding keysets in Iris, we borrow heavily from [18], especially the *keyset camera* and the representation of keysets via the Flow Framework.

We define the snapshot of the skip list template as a tuple containing the following components:

- the set of nodes N comprising the structure (also referred to as the *footprint* below)
- the abstract state of the structure (a set of keys)
- the mark bits (a map from N to $\mathbb{N} \rightarrow \text{Bool}$, i.e., a Boolean per level)
- the next pointers (a map from N to $\mathbb{N} \rightarrow N$)
- the keys (a map from N to K)
- the height of nodes (a map from N to \mathbb{N})
- the representation of flow values

We reparameterize the $\text{mark}(n, i)$ function introduced earlier to take the snapshot as an argument. Thus, we use $\text{mark}(s, n, i)$ to mean the mark bit of node n at level i in snapshot s . We redefine $\text{next}(\cdot)$, $\text{key}(\cdot)$, $\text{keyset}(\cdot)$ and other such functions similarly by adding the snapshot s as an additional parameter. We also use $\text{FP}(s)$ to represent the footprint of the snapshot s .

We now present the skip list template invariant in Figure 9. The `resources` predicate ties the snapshot to the concrete state through an intermediary node-level predicate `Node`. This predicate actually ties the physical representation of a node in the heap to the abstract quantities ($\text{key}(\cdot)$, $\text{height}(\cdot)$, $\text{mark}(\cdot)$ and $\text{next}(\cdot)$, respectively) that the skip list template relies on. The `Node` predicate also owns all the resources needed to execute the helper functions. The skip list template proof is parametric in the definition of `Node`. Thus, we achieve proof reuse across skip list variants that follow the same high-level skip list algorithm, but implement the node differently. We provide more details on this matter later. We discuss some concrete node implementations in Section 6.

The predicate `resources_keyset` captures the ownership resources required for keyset reasoning. Using the ghost resources in Iris and the keyset camera from [18], it ensures that the keysets and the logical contents of nodes in s satisfy (`KeysetPr`).

```

1 〈 k h mk nx. Node(n, k, h, mk, nx) 〉 getKey n 〈 k. Node(n, k, h, mk, nx) 〉
2 〈 k h mk nx. Node(n, k, h, mk, nx) 〉 getHeight n 〈 h. Node(n, k, h, mk, nx) 〉
3 〈 k h mk nx. Node(n, k, h, mk, nx) * (i < h) 〉 findNext i n 〈 n'. Node(n, k, h, mk, nx) * (nx(i) = n') 〉
4
5 〈 k h mk nx. Node(n, k, h, mk, nx) * (i < h) 〉 markNode i n
6 〈 x. Node(n, k, h, mk', nx) * (mk(i) = true ⇒ x = Failure * mk' = mk) 〉
7 〈 x. Node(n, k, h, mk', nx) * (mk(i) = false ⇒ x = Success * mk' = mk[i ↦ true]) 〉
8 〈 k h mk nx. Node(n, k, h, mk, nx) * (i < h) 〉 changeNext i n n' e
9 〈 x. Node(n, k, h, mk, nx') * ((mk(i) = true ∨ nx(i) ≠ n') ⇒ x = Failure * nx' = nx) 〉
   〈 ((mk(i) = false ∧ nx(i) = n') ⇒ x = Success * nx' = nx[i ↦ e]) 〉

```

Figure 10 Specifications of the helper functions used by the skiplist template.

The predicate `per_snapshot` captures structural invariants that hold for all snapshots recorded in the history. This includes invariants of three kinds: first, invariants to ensure that each component of the snapshot is of the correct type and the maps (from nodes to mark bits, next pointers, etc.) are defined for all nodes in the footprint; second, the node-level invariants relating the node's inset, outset, mark bit, etc (like Invariant 1); and third, invariants about the `hd` and `tl` nodes, such as $\text{key}(s, \text{hd}) = -\infty$, $\text{height}(\text{tl}) = L$, etc.

The predicate `transition_inv(s, s')` captures invariants about how certain quantities evolve over time, such as that mark bits once set to true remain true. The invariants 2, 3, and 4 presented in Section 3 are part of this predicate. These invariants form the crux of the hindsight reasoning, as they enable temporal interpolation.

Before we go into the formal proof argument for `delete`, we must discuss how to reason about the node-level helper functions. Figure 10 shows the specification for the helper functions assumed by the skiplist template. The specifications are logically atomic, i.e., they behave like a single atomic step in the template. The preconditions for all of the functions rely solely on the predicate `Node`. The functions `getKey`, `getHeight` and `findNext` read various components of the node. Note that `findNext` reads both the mark bit and the next pointer together.

The specification for functions `markNode` and `changeNext` is slightly more complex because they potentially change the structure. Let us explain them briefly. For `markNode` on node n at level i , the return value (`Success` or `Failure`) is determined by whether n is already marked at i . If it is, then the function returns `Failure` without modifying the node. If it is unmarked, then `markNode` successfully marks it, and updates the node accordingly. The specification for `changeNext` can be interpreted similarly. Here, the return value hinges upon the mark bit being false and the next pointer of n pointing to n' at i .

5.2 Proof of `delete`

We now have all the ingredients to show that `delete` satisfies `(HindSpec)`. We provide only a high-level summary of the proof here. Please see [36] for more details.

The precondition provides access to the invariant $\text{Inv}(r)$ and knowledge that the thread ID is tid with start time t_0 . Additionally, the thread has the right to resolve prophecy p around the decisive operations, and if the thread observes a successful decisive operation, then the atomic update $\text{AU}(\Phi)$ is available to help with the linearization. The `delete` operation begins with `traverse`. Using the \diamond operator defined in Section 4.2, we express the postcondition of `traverse` as

$$\Diamond_{s,t_0}(k \in \text{keyset}(s, c) \wedge (\text{res} \Leftrightarrow k \in C(s, c))).$$

Intuitively, this assertion captures that there is a past state s in the history (after time point t_0) in which k is in the keyset of c and res is true iff k is in the logical contents of c .

The argument here proceeds by case analysis on res . Let us first consider the case that res is *false*. The `delete` operation also terminates with *false*. Since the thread terminates without any calls to the decisive operations, this case corresponds to the $\neg\text{Upd}(pvs)$ case in the postcondition of (HindSpec). The postcondition requires `delete` to establish the predicate `PastLin(del, k, false, t0)`. In this context, establishing this predicate amounts to identifying a witness past state in which k was not part of the abstract state. Clearly, this is witnessed by state s from the specification of `traverse`. Applying (KeysetPr) in state s , we can establish the predicate `PastLin(del, k, false, t0)`.

Now, let us consider the case that res is *true*. The `maintainanceOp_del` marks node c at the higher level, but the interesting part of the proof is when the decisive operation `markNode` is called at the base level (Line 15). Again there are two cases to consider, depending on whether `markNode` succeeds. If `markNode` succeeds, then we can establish `Upd(pvs)` as we see a `Success` value being resolved. In this case, the precondition of (HindSpec) provides the atomic update $\text{AU}(\Phi)$. Since, the thread has modified the abstract state, this becomes the linearization point. The thread can linearize with $\text{AU}(\Phi)$ to obtain the receipt Φ and satisfy its postcondition. The proof also has to update the history with the new snapshot of the structure, as c goes from being unmarked to marked.

The final (and most interesting) case is when `markNode` fails. Here again, we must establish `PastLin(del, k, false, t0)` to complete the proof of (HindSpec). Two facts are useful: (i) in the past state s referred to in the `traverse` spec, we can establish that $\text{mark}(s, c) = \text{false}$; and (ii) since the `markNode` has failed, in the current state say s_0 , $\text{mark}(s_0, c) = \text{true}$. Hence, by using the second conjunct of `transition_inv` in Figure 9 and temporal interpolation on the two facts above, we can infer the existence of two consecutive states s_1 and s_2 , such that $\text{mark}(s_1, c) = \text{false}$ and $\text{mark}(s_2, c) = \text{true}$. Clearly, a concurrent `delete` thread marked c in state s_2 . Hence, this state becomes the witness to establish the predicate `PastLin(del, k, false, t0)`. This completes the proof that `delete` satisfies (HindSpec).

6 Proof Mechanization and Evaluation

We now shed light on the mechanization of the hindsight methodology, as well as its application to the skip list template. We additionally reverify the multicopy template from [34] using our new hindsight specification to modularize the proof effort. Although the multicopy algorithms are lock-based, hindsight reasoning is helpful in their verification. The case study demonstrates a substantial reduction in proof size due to the encoding of hindsight reasoning in Iris, illustrating the generality of our contribution. Our development is available as a VM and docker image on Zenodo [37].

All of the proofs we discuss below are mechanized in Iris/Coq. The templates, traversals and the node implementations are written in Iris's default programming language HeaPLang. In order to correctly capture the dependence between different layers of the proofs (such as hindsight specification and the templates, the templates and the `traverse`/node implementations), we heavily make use of Coq's module system.

The organization of our proofs is shown in Figure 11. Going from left to right, the first column relates to the formalization of hindsight reasoning in Iris. The box "Hindsight" captures the assumptions regarding the hindsight specification from Section 4. These

30:22 Verifying Lock-Free Search Structure Templates

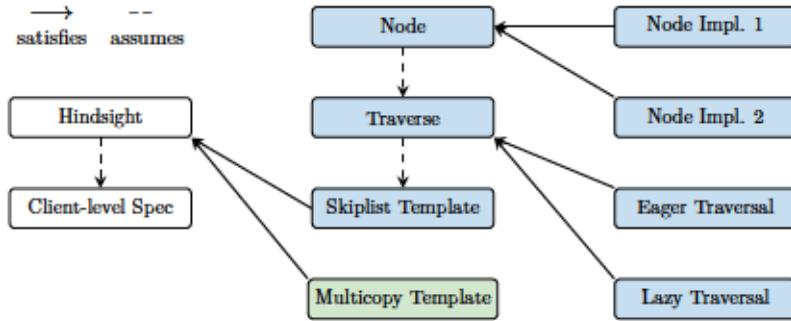

Figure 11 The structure of our proofs. Each box represents a collection of modules relevant to the label. The dashed arrows represent module dependence, i.e., assumption of specifications. The normal arrows represent implementation of the target module (fulfillment of the assumptions).

assumptions not only include the hindsight specification itself but also the relevant definitions of snapshots, histories, etc. The module “Client-level Spec” relates the client-level specification expressed in terms of atomic triples to the hindsight specification used for the template-level proofs. The corresponding proof involves the reasoning about prophecies and the helping protocol, which is done once and for all and applicable to all data structures that fulfill the assumptions made in the “Hindsight” module.

The middle column consists of modules for the two verified templates (skiplist and multicopy) and the associated proofs verifying the template operations against the hindsight specification. We discuss them in turn.

Skiplist template case study. The skiplist template, as described in Figure 2, abstracts from the concrete implementations of nodes and the `traverse` operation. Hence, we package their specifications into separate modules. To ensure that the specified data structure invariant for the skiplist template is not vacuous, we also verified an `init` routine that initializes the data structure and establishes the invariant.

The final column shows modules for the two node implementations of the skiplist template, as well as the eager and lazy traversal discussed in Section 2. The helper functions `markNode` and `changeNext` are implemented using an atomic CAS operation in both of the node implementations. The crux of the node implementation for the skiplist template is to determine a memory representation of the mark bit and the next pointer (at some level) such that both values can be read or written together with one atomic CAS operation. The first node implementation does this by using a sum type. The second node implementation is conceptually similar but uses more low-level data types instead of a sum type.

The traversal and node implementations above correspond to several existing lock-free (skip)list algorithms from the literature. The Herlihy-Shavit skiplist algorithm [10, § 14] is obtained by instantiating our template with the eager traversal, the node implementation 2, and maintenance operations that link higher-level nodes in increasing order of level and unlink nodes in the opposite order. The Michael set [31] is obtained as a degenerate case of the Herlihy-Shavit template instantiation where the skiplist is restricted to $L = 2$ (For $L = 2$, Level 1 consists of only a fixed single edge between the sentinel nodes. So, conceptually, Level 1 can be ignored in this case.)

We obtain a novel variant of a skiplist by replacing the eager traversal in the Herlihy-Shavit instantiation with the lazy traversal. The lazy traversal is inspired by the Harris list algorithm [9], which is obtained as a degenerate case of this new lazy skiplist algorithm by restricting it to $L = 2$.

Table 1 Summary of the proof effort. For each module, we show the number of lines of program code, lines of proof, total number of lines, and the proof-checking time in seconds. The code for the initialization and the core operations of the skiplist (entries with (*)) is technically defined in the “Skiplist” module, however here we present them separately for each operation to provide a better picture. The count for Herlihy-Shavit is the summation of rows “Hindsight”, “Client-level Spec”, all “Skiplist” modules, “Node Impl. 2” and “Eager Traversal”.

Skiplist Template (Iris/Coq)				
Module	Code	Proof	Total	Time
Flow Library	0	5330	5330	33
Hindsight	0	950	950	11
Client-level Spec	9	329	338	18
Skiplist	12	1693	1705	26
Skiplist Init(*)	6	319	325	15
Skiplist Search(*)	7	62	69	6
Skiplist Insert(*)	37	3457	3494	111
Skiplist Delete(*)	28	2401	2429	72
Node Impl. 1	118	908	1026	35
Node Impl. 2	106	836	942	35
Eager Traversal	38	1165	1203	96
Lazy Traversal	47	2063	2110	145
Total	408	19513	19921	603
Herlihy-Shavit	243	11212	11455	390

We present a summary of the proof effort for the skiplist template in Table 1. The proof-checking time was measured on the Docker image running on an Apple M1 Pro chip with 16GB RAM. The flow library contains the Iris formalization of the Flow Framework developed in [18, 34]. As a minor contribution, we extend this library with general lemmas for reasoning about graph updates that have an affect on an unbounded number of nodes. These lemmas are useful for the proofs of `insert`, `delete` and lazy `traverse`. The unbounded updates, as well as the maintenance operations, are the reason for the relatively high number of proof lines for the `insert` and `delete` operations.

Multicopy template case study. The multicopy template from [34] generalizes search structures such as the lock-based Log-Structured Merge (LSM) tree used widely in modern database systems. It satisfies the Map ADT specification, with `search` and `upsert` (for insert/update) as its core operations. To deal with the complexity of future-dependent external linearization points, the original proof relies on an intermediate template-level specification based on the concept of *search recency*.

Table 2 presents a detailed comparison of the multicopy template proofs from [34] versus the new proof based on the hindsight framework. The original proof consists of a total of 2779 lines. By contrast, the definitions (“Defs”) and “Client-level Spec” proofs can be factored out of the total cost of the hindsight-based proof, because it is part of the hindsight library itself. Hence, the new proof based on hindsight reasoning consists of only 1310 lines, which is a reduction of 53%. To summarize, the improvement stems from the fact that the original proof relies on an intermediate specification and a helping protocol that is tailored to multicopy structures, while our new proof uses a helping protocol that is shared among all proofs that build on the new hindsight proof method.

Table 2 Comparison of multicopy template proofs. The column “Original” shows the number of lines from the proofs in [34], while “Hindsight” shows them for our new proof effort. Module “Defs” represents definitions required for proving the client-level specification (helping invariant, history predicate, etc). Module “Client-level Spec” contains the proof relating the intermediate specification (Search Recency Specification from [34] and Hindsight Specification in our paper) to the client specification. Module “LSM” contains definitions required to instantiate the frameworks for LSM trees. Modules “Search” and “Upsert” refer to the proofs for the search and upsert operations, respectively. Entries in “()” for the “Hindsight” column are not included in the total due to being part of the hindsight library.

Multicopy Template (Iris/Coq)		
Module	Original	Hindsight
Defs	866	(950)
Client-level Spec	434	(338)
LSM	741	540
Search	411	399
Upsert	327	371
Total	2779	1310

While the majority of the reduction in the proof size stems from the elimination of structure-specific specifications and helping protocol proofs, we also saw a minor reduction in the size of the remainder of the proof. One outlier is the proof of `upsert`. Here, the increase is attributed to the fact that the proof has to construct a fresh snapshot when the operation succeeds. However, this construction is conceptually simple and could be factored out into more abstract lemmas that are provided directly by the hindsight library.

7 Related Work

The formal verification of linearizability has received much attention in recent years. We refer to [5] for a survey of relevant techniques and focus our discussion to the most closely related works.

Our work builds on the idea of template algorithms for lock-based concurrent search structures of [19, 34, 18], which we extend to the setting of lock-free implementations. A common challenge when verifying linearizability of lock-free data structures is the prevalence of future-dependent and external linearization points. Hindsight theory [32, 22, 6, 7, 26, 27] has emerged as a suitable technique to address this challenge in the context of concurrent search structures. To our knowledge, we are the first to formalize hindsight reasoning within a foundational program logic. Tools like `Poling` [40], `plankton` [26, 27], and `nekton` [25] automate hindsight reasoning at the expense of an increased trusted code base. However, these tools currently cannot handle complex data structures with unbounded outdegree like skip lists. Also, they do not aim to characterize the design space of related concurrent data structures like our template algorithms do.

Other techniques for dealing with future-dependent linearization points include arguments based on forward simulation (e.g., by tracking all possible linearizations of ongoing operations [12], tracking a partial order [17], or using commit points [3]) and backward simulation (e.g., using prophecy variables [1, 23, 15]). Our encoding of hindsight reasoning in Iris combines forward reasoning (by tracking the history of the data structure state) and backward reasoning (by using prophecies). However, the details of this encoding are for the most part hidden from the proof engineer by providing a higher-level reasoning interface

based on past predicates and temporal interpolation as proposed in [27]. Our comparison with a prior proof of multicopy structure templates [34] suggests that this abstraction helps to reduce the proof complexity.

Several works propose techniques for automatically verifying concurrent skiplists. Abdulla et al. [2] propose a technique for verifying linearizability of lock-free list-based data structures using forest automata. The evaluation considers bounded skiplists with up to 3 levels. However, the implementation does not scale to larger bounds and the unbounded case is outside the scope of the technique. We note that the height of the skiplist is tied to the expected runtime of the skiplist operations. To guarantee the expected worst-case runtime bounds, the skiplist’s height must be of order $O(\log(n))$ where n is the expected maximal number of entries in the list. For this reason, real-world skiplist implementations are also parametric in the height. Heights up to 63 levels are feasible in deployed skiplists [24], so the restriction to height 3 in [2] is unrealistic. By contrast, our proofs cover skiplists of arbitrary height.

Sánchez and Sánchez [38] present an SMT-based approach towards an automated verification of concurrent lock-based skiplists. The approach is based on a decidable theory of unbounded skiplists. However, it does not consider lock-free implementations and focuses on establishing *shape invariants* preserved by the structure instead of proving linearizability.

Unlike these automated tools, our approach does not rely on data-structure specific decidable theories for reasoning about inductive properties of heap graphs. Instead, we build on the Flow Framework [20, 21, 28], which enables local reasoning about such properties over general graphs in separation logic. As a minor contribution, we extend the mechanization of the Flow Framework from [19] with lemmas to reason about graph updates that affect properties of an unbounded number of nodes.

There are some skiplist algorithms that are not immediately covered by our template algorithm. For example, skiplists based on the algorithm presented in [8] such as Java’s `ConcurrentSkipListMap` [33] use *backlinks* to avoid restarts when a traversal fails. However, we believe that our template algorithm can be extended to subsume such algorithms by abstracting from the restart policy, similarly to how the present template abstracts from the maintenance policy.

In this paper, we assume a programming language with a garbage collected semantics. The rationale for this assumption is that issues arising from manual memory reclamation can be addressed by orthogonal means. For instance, [29, 30] propose a technique that decouples the proof of data structure correctness from that of the underlying memory reclamation algorithm, allowing the correctness proof of the data structure to be carried out under the assumption of garbage collection. Recent work also showed how to carry out such modular proofs in program logics like Iris [13].

8 Conclusions and Future Work

This paper shows how to verify some of the most challenging concurrent data structure algorithms in existence. The accompanying proofs are fully mechanized in the foundational program logic Iris. The proofs are modular and cover the broader design space of the underlying algorithms by parameterizing the verification over aspects such as the low-level representation of nodes and the style of data structure maintenance.

Besides being the first work to verify unbounded lock-free skiplists, the work has developed technologies for Iris, particularly hindsight reasoning, that can be useful in many applications.

Our proofs guarantee safety but not liveness. This limitation is shared by the algorithms they verify: in any highly concurrent (minimal or no locking) setting, a thread t may never complete because of other threads that overtake it. Fortunately, this never happens in practice where threads all advance more or less at the same pace. Verifying liveness under such fairness assumptions remains an interesting direction for future work.

Another area of future work is to verify algorithms that mix locking parts with lock-free parts both for single copy and multicopy search structures. We believe that the present framework will be a good basis for that effort.

Abstract

Choreographic programming is a paradigm for writing distributed applications. It allows programmers to write a single program, called a choreography, that can be compiled to generate correct implementations of each process in the application. Although choreographies provide good static guarantees, they can exhibit high latency when messages or processes are delayed. This is because processes in a choreography typically execute in a fixed, deterministic order, and cannot adapt to the order that messages arrive at runtime. In non-choreographic code, programmers can address this problem by allowing processes to execute out of order – for instance by using futures or reactive programming. However, in choreographic code, out-of-order process execution can lead to serious and subtle bugs, called *communication integrity violations (CIVs)*.

In this paper, we develop a model of choreographic programming for out-of-order processes that guarantees absence of CIVs and deadlocks. As an application of our approach, we also introduce an API for safe non-blocking communication via futures in the choreographic programming language Choral. The API allows processes to execute out of order, participate in multiple choreographies concurrently, and to handle unordered data messages. We provide an illustrative evaluation of our API, showing that out-of-order execution can reduce latency and increase throughput by overlapping communication with computation.

1 Introduction

Choreographic programming [25] is a paradigm that simplifies writing distributed applications. In contrast to a traditional development style, where one implements a separate program for each type of process in the system, choreographic programming allows a programmer to define the behaviors of all processes together in a single program called a *choreography* [26]. Through *endpoint projection (EPP)*, a choreography can be compiled to generate the programs implementing each process that would otherwise need to be written by hand. Aside from convenience, the advantage of this approach is that certain classes of bugs (such as deadlocks)

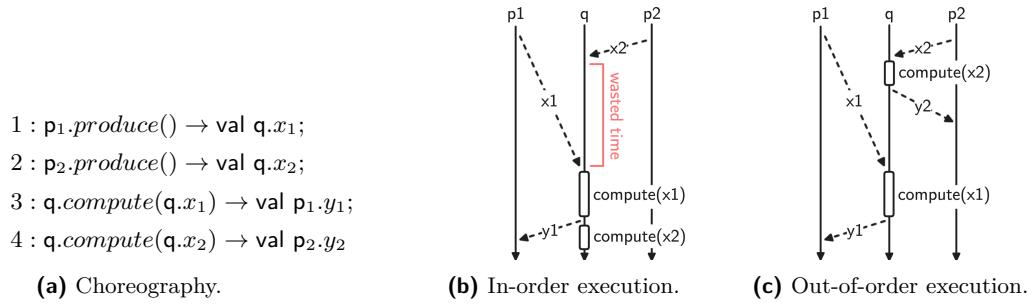

Figure 1 A choreography where out-of-order execution can improve performance.

are impossible *by construction* [8]. Choreographic programming has been applied to popular languages such as Java [16] and Haskell [32], and has been used to implement real-world protocols such as IRC [23].

Processes in choreographic programs typically execute in a fixed, sequential order. Consider Figure 1a, which shows a simple choreography performed by processes p_1 , p_2 , and q . The syntax $p.e \rightarrow \text{val } q.x$ means “ p evaluates expression e and sends the result to q , which binds the result to a local variable x ”. Under the usual semantics for choreographies, $p_1.produce()$ and $p_2.produce()$ can be evaluated in parallel because p_1 and p_2 are distinct processes. However, q must execute each step sequentially: first q waits until it receives x_1 ; then q waits until it receives x_2 ; and only then can q send p_1 the result of processing x_1 .

Figure 1b depicts an execution of the choreography, showing the drawback of a fixed processing order: if x_2 arrives before x_1 , q wastes time waiting for x_1 instead of processing x_2 . Ideally, q would evaluate $compute(q.x_1)$ and $compute(q.x_2)$ according to the arrival order of x_1 and x_2 , as shown in Figure 1c. Assuming these two expressions are safe to reorder, such an optimization would allow q to overlap computation with communication and reduce the average latency experienced by p_1 and p_2 . We are therefore interested in studying choreographic programming models where processes may execute some statements out of order, or even concurrently. We call such processes *out-of-order processes* and the corresponding choreographies (*fully*) *out-of-order choreographies*.

Processes with out-of-order features have been considered in prior work. Process models such as the actor model [2] or the π -calculus with delayed receive [24] are expressive enough to implement the behavior in Figure 1c, but these models lack the static guarantees of choreographic programming. More recently, Montesi gave a semantics for *nondeterministic choreographies* [26], i.e., choreographies with nondeterministic choice. Nondeterministic choreographies can implement the execution in Figure 1c, but they are unwieldy when it comes to expressing out-of-order process execution: they require explicitly writing all possible schedulings, lest getting a suboptimal program. For our example, we would get a choreography twice the size of the one in Figure 1a (cf. Section 6). Consequently, nondeterministic choreographies are both hard to write and brittle – a typical drawback when using syntactic operators to express interleavings. This raises the question:

Can we develop a choreographic programming model for out-of-order processes that marries the simple syntax of Figure 1a with the semantics of Figure 1c?

The simplicity of this problem is deceptive, since common-sense approaches can lead to pernicious compiler bugs. For instance, consider Figure 2: two microservices cs (a “content service”) and ks (a “key service”) send values txt, key to a server s (lines 1 and 2). The server

in turn forwards those values to a client c (lines 3 and 4). Notice that if s is an out-of-order process, then it can forward the results in any order, as shown in Figures 2b and 2c. This causes a problem for c : since both txt and key were sent by s , and since both values have the same type (`String`), c has no way to determine whether the first message contains txt (as in Figure 2b) or key (as in Figure 2c). This problem is easy for compiler writers to miss, leading to disastrous nondeterministic bugs where variables are bound to the wrong values. We call such bugs *communication integrity violations (CIVs)*.

In this paper, we investigate CIVs and other complications that arise from mixing choreographies with out-of-order processes. Our investigation brings forward necessary elements that are missing from previous research on choreographic programming [26] and the neighbouring approach of multiparty session types (which use simpler choreographies without data or computation) [19, 15, 1, 33]. Although the problem in Figure 2 can easily be solved by attaching static information (such as variable names) to each message, we show in Section 2 that a general solution requires mixing static and dynamic information, replicated across multiple processes. We also find that formalizing fully out-of-order choreographies requires several features uncommon in standard choreographic programming models, such as scoped variables and an expanded notion of well-formedness.

We make the following key contributions:

1. We present O_3 , a formal model for asynchronous, fully out-of-order choreographies.¹ Our model prevents CIVs by attaching *integrity keys* to messages. A nice consequence of our solution is that messages no longer need to be delivered in FIFO order. We prove that O_3 choreographies ensure deadlock-freedom (Theorem 2) and communication integrity (Theorem 4).
2. We present an EPP algorithm to project O_3 choreographies into out-of-order processes. We prove an operational correspondence theorem, which states that a choreography and its projection evolve in lock-step (Theorem 6). The key to making this proof tractable is a new notion of well-formedness that formalizes a communication integrity invariant. The theorem implies that a correct compiler will not generate code with deadlocks or CIVs.
3. We demonstrate the applicability of our approach by developing *Ozone*, a non-blocking communication API for the choreographic programming language Choral [16].² Choreographies implemented with Ozone can use futures [4] to process messages concurrently (as in Figure 1c) without violating communication integrity. We evaluate Ozone with microbenchmarks and a model serving pipeline [34]. Our results confirm that out-of-order execution can dramatically reduce latency and increase throughput for choreographies, putting the performance of hand-written reactive processes within reach of choreographic programmers (we compare to actors written in the popular *Akka* framework [3]).

The paper is structured as follows. Section 2 explores CIVs and other issues in out-of-order choreography models. Section 3 presents our formal model O_3 . Section 4 presents our model for out-of-order processes and our EPP. Section 5 presents our non-blocking API for Choral and our evaluation. We conclude with related work in Section 6 and discussion in Section 7.

2 Overview

In this section we explore the challenges that must be solved to develop a fully out-of-order choreography model, along with our approach.

¹ The name O_3 derives from our model being *Out Of Order*.

² The name *Ozone* derives from O_3 being the chemical formula for ozone.

31:4 Ozone: Fully Out-of-Order Choreographies

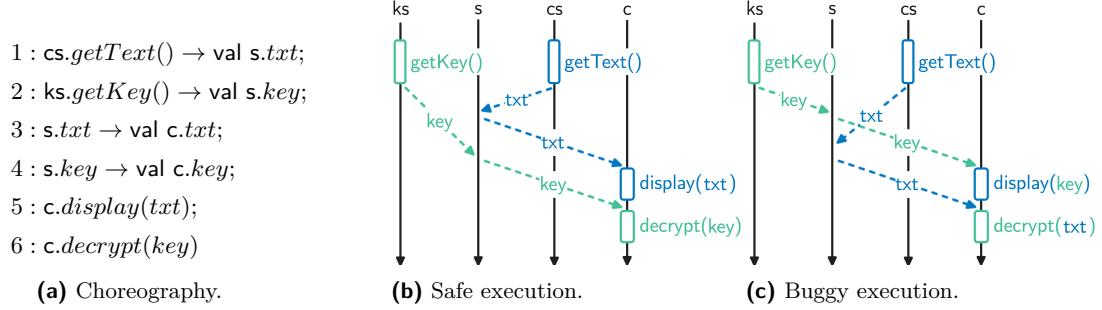

Figure 2 A choreography where naïve out-of-order execution is unsafe. Process **c** cannot distinguish whether the first message it receives represents *key* or *txt*.

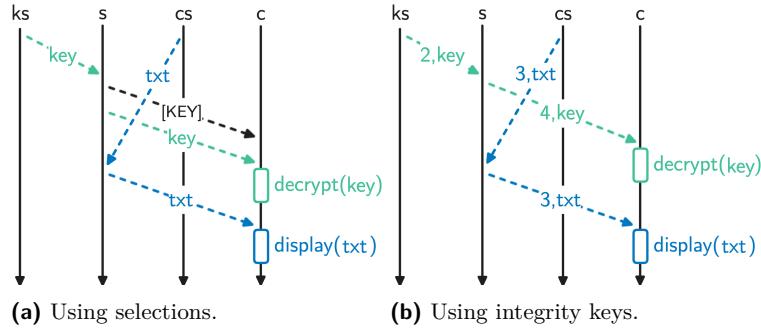

Figure 3 Two approaches to prevent CIVs: selections and integrity keys.

2.1 Intraprocedural Integrity

Informally, communication integrity is the property that messages communicated in a choreography are bound to the correct variables. To ensure this, processes might need extra information; in Figure 2, process **c** needs to know which value will arrive first: *txt* or *key*.

A traditional solution would be for **s** to send a *selection* to **c**. Selections are communications of constant values, used in choreography languages when one process makes a control flow decision that other processes must follow. Figure 3a shows how **s** could send the selection [KEY] to inform **c** that *key* will arrive before *txt*. Indeed, this is the approach used by nondeterministic choreographies [26]. However, selections impose overhead: any time nondeterminism could occur, the programmer would need to insert new selection messages. These extra messages would have both a cognitive cost for the programmer (as programs become littered with selections) and a runtime cost in the form of an extra message.

Instead, we opt to pair each message with a disambiguating tag called an *integrity key*. When **c** receives a message, it checks the integrity key to find the meaning of the message. Figure 3b uses *line numbers* as integrity keys. For example, the *txt* message is tagged with the number 3 because it was produced by the instruction on line 3 in Figure 2. Equivalently, one could use variable names (assuming that all variables have distinct names), message types (assuming that all messages have distinct types), or operators [7]; essentially these are all ways to combine messages with selections. However, as we will see in the next section, none of these solutions will suffice once we introduce procedures and recursion.

Integrity keys have another advantage over selections: they make it safe for the network to reorder messages. For instance, the selection in Figure 3a will only prevent CIVs if *key* and *txt* are delivered in the same order they were sent. Thus previous theories and implementations

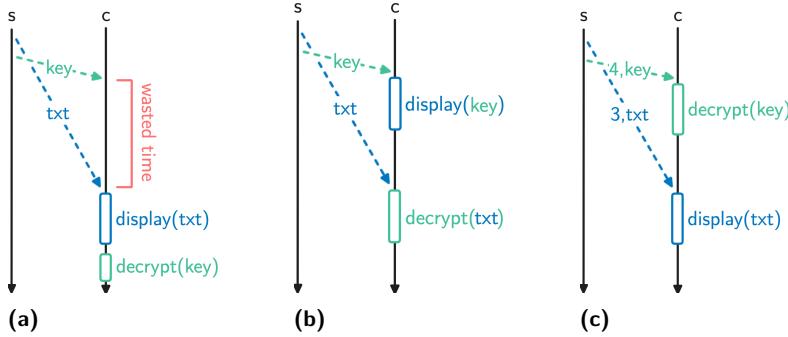

Figure 4 The challenges of non-FIFO delivery. Part (a) depicts head-of-line blocking when using a FIFO transport protocol: The message containing k arrives first, but it cannot be processed until t arrives. Part (b) depicts a CIV caused by using an unordered transport protocol without integrity keys. Part (c) depicts how the processes can use integrity keys to prevent CIVs.

of choreographic languages require a transport protocol that ensures reliable FIFO communication [16, 26]. These models are therefore susceptible to head-of-line blocking [31], where one delayed message can prevent others from being processed (Figure 4a). Figure 4b shows why FIFO is necessary in these models: unordered messages can cause CIVs. Because our model combines unordered messages, integrity keys, and out-of-order processes, it circumvents the head-of-line blocking problem – as shown in Figure 4c.

2.2 Procedural Choreographies

Choreographies can use procedures parameterised on processes for modularity and recursion [11, 26]. Figure 5a shows an example: a procedure X with three *roles* (i.e., process parameters) a, b, c . The procedure X is invoked twice – once with processes p, q, r_1 (line 7) and again with p, q, r_2 (line 8). In the body of X , role a produces a value and sends it to b ; then b transforms the value and sends it to c ; finally, c processes the value and sends it to a . As usual in most programming languages, we will assume the variables $a.w, b.x, c.y$, and $a.z$ are locally scoped – this is in contrast to many choreography models, where variables at processes are all mutable fields accessible anywhere in the program.

In existing choreography models, a process can only participate in one choreographic procedure at a time. This is no longer the case with fully out-of-order choreographies. Consider Figure 5a, where process p invokes procedure X twice. The process may begin by invoking the first procedure call (line 7), computing $p.w$ (line 2), and sending $p.w$ to r_1 (line 3). Then, instead of executing its next instruction – i.e. becoming blocked by waiting for a message on line 5 – p can skip the instruction and proceed to invoke the second procedure call (line 8). Thus, we can have an execution like in Figure 5b, in which p sends a message to r_1 as part of the first procedure call and immediately sends a message to r_2 as part of the second procedure call. This unusual semantics is exactly what we would expect in a choreography language with non-blocking receive – such as in Choral, when using the Ozone API to bind the result of a communication to a future (Section 5).

2.2.1 Interprocedural Integrity

Concurrent choreographic procedures add another dimension of complexity to the communication integrity problem. Figures 5b and 5c show why: depending on the order that r_1 and r_2 's messages arrive at q , the messages from q may arrive at p in any order. (This occurs even

if we assume reliable FIFO delivery!) Like in the previous section, p cannot distinguish which message pertains to which procedure invocation. But now static information is insufficient to ensure communication integrity: both messages from q pertain to the same variable in the same procedure, so the integrity keys fail to distinguish the different procedure calls. We call this the *interprocedural CIV problem*.

The example above shows that integrity keys need dynamic information prevent CIVs. We can solve the problem by combining the line numbers used in Section 2.1 with some *session token* t that uniquely identifies each procedure invocation. Applied to Figures 5b and 5c, p could inspect the session token to determine whether the messages pertain to the first procedure call (line 7) or the second (line 8). But this requires p and q to somehow achieve *a priori* agreement about which tokens correspond to which procedure invocations.

One solution to the interprocedural CIV problem would be to select a “leader” process for each procedure call, and let the leader compute a session token for all the other roles to use. However, this would make the leader a bottleneck: until the other participants receive the token, senders would not be able to send messages, and recipients would not be able to discern which procedure invocation their incoming messages pertain to. We therefore propose a method for processes to compute session tokens independently, using only local data, such that they still agree on the same value of the token for each procedure invocation.

Observe that a procedure call is uniquely identified by its caller (i.e. the procedure call that called it) and its line number l. Assuming the caller already has a unique token t, the callee’s token can be computed as some injective function $\text{nextToken}(l, t)$. This function would need to satisfy two properties:

- **Determinism:** For any input pair l, t , $\text{nextToken}(l, t)$ always produces the same value t' .
- **Injectivity:** Distinct input pairs l, t produce distinct output tokens.

Determinism ensures that if two processes in the same procedure call (with token t) invoke the same procedure (on line l) then both processes will agree on the value of $\text{nextToken}(l, t)$. *Injectivity* ensures that if a process concurrently participates in two different procedure calls (with distinct tokens t_1, t_2) and invokes two procedures (on lines l_1, l_2 – possibly $l_1 = l_2$) then the resulting session tokens will be distinct ($\text{nextToken}(l_1, t_1) \neq \text{nextToken}(l_2, t_2)$). In the next section, we realize these constraints by representing tokens as lists of line numbers and defining nextToken to be the list-prepend operator.

3 Choreography Model

In this section we present O_3 , a formal model for asynchronous, fully out-of-order choreographies. Statements can be executed in any order (up to data dependency) and messages can be delivered out of order. The section concludes with proofs of deadlock-freedom and communication integrity.

3.1 Syntax

The syntax for choreographies in O_3 is defined by the grammar in Figure 6. Two example choreographies are shown in Figure 7; we explain their semantics in Section 3.2.2.

A choreography C is executed in the context of a collection of *procedures* \mathcal{C} . Each procedure $X_i(\bar{p}, \bar{p}.x) = C_i$ is parameterized by a list of *roles* $\bar{p} = p_1, \dots, p_n$ and role-local *parameters* $\bar{p}.x = p_{j_1}.x_1, \dots, p_{j_m}.x_m$ where every parameter $p_{j_k}.x_k$ is located at one of the roles in \bar{p} . We assume that procedures do not contain runtime terms (such as $l, t : p \rightsquigarrow q.x$).

A choreography C consists of a sequence of *instructions* I , followed by the end symbol 0 which is often omitted. Each instruction is prefixed with a *line number* l and a *token* t . We call this pair an *integrity key*. If C_i is the body of a procedure in \mathcal{C} , then the token t on every instruction in C_i must be a *token placeholder* t . When the procedure is invoked, all token placeholders t in C_i will be replaced with a fresh *token value* τ .

We assume that line numbers in \mathcal{C} are similar to line numbers in a real computer program: Each instruction I in \mathcal{C} has a distinct line number l . When a procedure $X_i(\bar{p}, \bar{p}.x) = C_i$ is invoked, the line numbers in C_i will remain unchanged. This will allow us to access the static location of an instruction at runtime in order to compute the integrity key.

There are five kinds of instructions. A communication $p.e \rightarrow \text{val } q.x; C$ instructs process p to evaluate expression e and send it to process q , which will bind the result to $q.x$ in the continuation C . A selection $p \rightarrow q[L]; C$ conveys knowledge of choice [26]: it instructs p to send a value literal L to q , informing q that a decision (represented by L) has been made. A local computation $\text{val } p.x = e; C$ instructs p to evaluate e and bind the result to $p.x$ in C . A conditional $\text{if } e@p \text{ then } C_1 \text{ else } C_2; C$ instructs p to evaluate e and for the processes to proceed with C_1 or C_2 according to the result. A procedure call $X_i(\bar{p}, \bar{a}); C$ instructs processes \bar{p} to invoke procedure $X_i(\bar{q}, \bar{q}.y) = C_i$ defined in \mathcal{C} , with processes \bar{p} playing roles

$BuyItem(s, b, b.itemID) =$ 1, t : b.itemID → val s.itemID; 2, t : val s.item? = sell(s.itemID); 3, t : s.item? → val b.item? 4, $\tau_0 : BuyItem(\text{seller}, \text{buyer}_1, 123@\text{buyer}_1)$; 5, $\tau_0 : BuyItem(\text{seller}, \text{buyer}_2, 543@\text{buyer}_2)$	$StreamIt(p, c) =$ 1, t : p.produce() → val c.x; 2, t : val c.z = consume(c.x); 3, t : if (itemsLeft() > 0)@p then 4, t : p → c[MORE] 5, t : StreamIt(p, c) else 6, t : p → c[DONE] 7, $\tau_0 : StreamIt(p_1, c)$; 8, $\tau_0 : StreamIt(p_2, c)$
(a)	(b)

Figure 7 Two example choreographies. On the left, processes buyer_1 and buyer_2 concurrently attempt to buy products from seller . On the right, producers p_1 and p_2 concurrently send streams of data to a shared consumer c .

\bar{q} and arguments \bar{a} (which may take the form of values $v@p$ or variables $p.x$) substituted for parameters $\bar{q}.\bar{y}$ in C_i . In addition to these basic instructions, a choreography may contain blocks $\{C\}; C'$ which limit the scope of variables defined in C so they do not extend to C' .

In addition, choreographies can contain *runtime instructions* that represent an instruction in progress; these terms are an artifact of the semantics, not written explicitly by the programmer. A communication-in-progress $p \rightsquigarrow q.x$ indicates that p sent a message to q , which q has not yet received. Similarly, a selection-in-progress $p \rightsquigarrow q[L]$ indicates that p sent a selection. A procedure-call-in-progress $\bar{p}.X(\bar{q}, \bar{a})\{C\}$ indicates that some processes have invoked X , and others have not – we leave the details to Section 3.2.

Expressions e are composed of *atoms* a (i.e. variables $p.x$ and values $v@p$) and function applications $f(\bar{e})$. Although the variables $p.x$ are immutable, we assume that a function f evaluated by p can mutate p 's state as a side-effect. Technically, having side-effects in our theory is not necessary. However, most choreographic programming theories and implementations equip processes with mutable state [26]; this includes Choral, the language we use to implement the Ozone API in Section 5.

3.2 Semantics

We now give a fully out-of-order semantics for choreographies in O_3 . The semantics is a labelled transition system on *configurations* $\langle C, \Sigma, K \rangle$, where C is a choreography, Σ is a mapping from process names p to process states σ , and K is a mapping from process names p to multisets of messages M yet to be delivered to p . We also assume there exists a set of unchanging procedure declarations \mathcal{C} , not shown explicitly in the configuration.

An *initial configuration* is a configuration $\langle C, \Sigma, K \rangle$ where Σ maps each p to an arbitrary state, K maps each p to the empty set, and all instructions in C use the same token τ_0 , called the *initial token*. We assume initial configurations to be well-formed, cf. Section 3.3. The transition relation (\xrightarrow{p}) is on configurations, where p identifies which process took a step.

Messages in our semantics are represented as triples (l, τ, v) . Here l is the line number of the communication that sent the message, τ is the token associated with the procedure invocation that sent the message, and v is a value called the *payload*. Together, the pair (l, τ) is called the *integrity key* of the message; the line number prevents intraprocedural CIVs (Section 2.1) while the token prevents interprocedural CIVs (Section 2.2).

3.2.1 Transition rules

Figure 8 defines the semantics for O_3 , which extends textbook models for procedural and asynchronous choreographies to allow full out-of-order execution [26]. That is, in a choreography of the form $I_1; I_2; C$, the statement I_2 can always be executed before I_1 unless:

1. (*Data dependency*) I_1 binds a variable $p.x$ that is used in I_2 ; or
2. (*Control dependency*) I_1 is a selection of the form $p \rightarrow q[L]$ or $p \rightsquigarrow q[L]$, and I_2 is an action performed by q .

The semantics for communication is defined by rules C-SEND and C-RECV. In C-SEND for the communication term $l, \tau : p.e \rightarrow val q.x$, the expression e is evaluated in the context of p 's state using the notation $\Sigma(p) \vdash e \Downarrow (v, \sigma)$. Evaluating e produces a value v and a new state σ for p ; we assume that (\vdash) is defined for any e that contains no free variables and for any state $\Sigma(p)$. The C-SEND rule transforms the communication term into a communication-in-progress term $l, \tau : p \rightsquigarrow q.x$ and adds the message (l, τ, v) to q 's set of undelivered messages. The message can subsequently be received by q using the C-RECV rule. This rule removes the communication-in-progress term and substitutes the message payload v into the continuation C . Notice that the integrity key l, τ of the message is matched against the integrity key of the communication-in-progress, $l, \tau : p \rightsquigarrow q.x$. Notice also that the semantics for communication is not defined if the token t is merely a placeholder t – it must be a token *value* τ . Indeed, in Section 3.3 we show that placeholders only appear in \mathcal{C} , never in C .

Rules C-SELECT and C-ONSELECT closely mirror the semantics of C-SEND and C-RECV – the key difference is that a label L is communicated instead of a value. Rules C-COMPUTE and C-IF are standard, except for changes made to use lexical scope instead of global scope: C-COMPUTE substitutes the value v into the continuation C (instead of storing it in the local state Σ) and C-IF places the continuation C_i in a block to prevent variable capture. To garbage collect empty blocks, C-IF uses a concatenation operator (\circ) defined as:

$$\{I; C\} \circ C' = \{I; C\}; C' \quad \{0\} \circ C' = C'$$

The C-DELAY rule is used in choreography models to enable a limited form of out-of-order execution, where unrelated processes execute concurrently: given a choreography $I; C$, C-DELAY would ordinarily prevent any q from executing in C if q is somehow involved in I . Our formulation of the rule is weakened: q is only prevented from executing in C if I is a selection at q , i.e. a control dependency. The rule still respects data dependencies, however, by design of the other rules – for instance, $l, \tau : p.x \rightarrow val q.y$ cannot be evaluated until x is bound to a value. Thus our version of C-DELAY enables *full* out-of-order execution.

The rules C-FIRST, C-ENTER, C-LAST, and C-DELAY-PROC model procedure calls, with extra machinery to model how processes can execute their roles in a choreographic procedure in parallel until they need to interact. Given a procedure call $l, \tau : X(\bar{p}, \bar{a})$, C-FIRST models how $p \in \bar{p}$ has entered the procedure before any of the other processes. The rule replaces the procedure call with a procedure-call-in-progress $l, \tau : \bar{p} \setminus p. X(\bar{p}, \bar{a}) \{ C'_1 \}$ to reflect this fact; the choreography C'_1 is the body of the procedure, which p may begin executing via the C-DELAY-PROC rule. The remaining processes can enter the procedure via the C-ENTER rule, and the last process to enter the procedure uses the C-LAST rule. As we explain below, these rules also compute new integrity keys for the callee procedure to prevent CIVs.

The key novelty of our semantics for procedures is the use of `nextToken`. In C-FIRST, the body C'_1 is obtained by computing the token $\tau' = \text{nextToken}(l, \tau)$ and substituting τ' for all occurrences of the token placeholder t . Notice that the semantics makes it appear as if the processes have synchronized to compute the next token; in Section 4, we give a semantics where each process computes the next token independently and in Theorem 6 we prove that the two models correspond. Hence the apparent synchronization has no runtime cost.

As discussed in Section 2.2.1, $\text{nextToken} : \mathbb{N} \times \text{Token} \rightarrow \text{Token}$ is a pure injective function for computing new tokens (of type `Token`) using integrity keys (of type $\mathbb{N} \times \text{Token}$). To ensure the integrity keys from two concurrent procedures never collide, `nextToken` must produce unique, non-repeating keys upon iterated application. One way this can be realized is by representing `Token` = \mathbb{N}^* as lists of numbers, the initial token τ_0 as an empty list $[]$, and implementing $\text{nextToken}(l, \tau) = l :: \tau$, i.e. prepending the line number l to the list. Intuitively, this means the token associated with a procedure invocation is a simplified *call stack* of line numbers from which the procedure was called.

3.2.2 Discussion

Figure 7a expresses a choreography in which two buyer processes concurrently buy items from a seller process. In the initial configuration, `buyer1` can enter the procedure on line 4, `buyer2` can enter the procedure on line 5, and `seller` can enter either procedure. If `buyer2` enters first (using C-DELAY and C-ENTER), it can proceed to send 543@`buyer2` to `seller` (using C-COM). Then `seller` can enter the procedure on line 5 (using C-DELAY and C-LAST) and proceed to receive the message from `buyer2` (using C-RECV). This execution would be impossible in a standard choreography model because `seller` would need to complete the procedure invocation on line 4 before it could enter the procedure on line 5. The added concurrency ensures that slowness in `buyer1` does not prevent `buyer2` from making progress.

Notice the out-of-order semantics of Figure 7a also adds nondeterminism. Suppose `buyer1` and `buyer2` attempt to buy the same item and the `seller` only has one copy. One of the buyers will receive the item, and the other will receive a null value. In a standard choreography model, the item would always go to `buyer1`. In O_3 , the item will be sold nondeterministically according to the order that messages arrive to the seller. This nondeterminism can be problematic – it makes reasoning about choreographies harder – but also increases expressivity: nondeterminism is essential in distributed algorithms like consensus and leader election. Reasoning about nondeterminism in choreographies is an important topic for future work.

Figure 7b shows we can also express recursive choreographies. In each iteration of the procedure *StreamIt*, a producer `p` sends a value to a consumer `c` (line 1) and decides whether to start another iteration (line 3). Then the producer asynchronously informs the consumer about its decision (lines 4 and 6) and can proceed with the next iteration (line 5) without waiting for the consumer. Because messages in O_3 are unordered, the consumer can consume items (line 2) from different iterations in any order; this prevents head-of-line blocking [31].

In the initial choreography of Figure 7b, producers `p1, p2` and a consumer `c` invoke two instances of *StreamIt*. As in Figure 7a, the two procedures evolve concurrently; a slowdown in `p1` will not prevent `c` from consuming items produced by `p2`.

3.3 Properties

In this section we prove that O_3 choreographies are deadlock-free and we formalize the communication integrity property. Combined with the EPP Theorem presented in Section 4, these results imply that projected code inherits the same properties.

\end{array}$$

 **Figure 9** Well-formedness (representative rules).

To prove these properties we need an invariant that characterizes how the rules of O_3 preserve the intuition from Section 2. For example, consider the following configurations:

$$\langle l, \tau_0 : p \rightsquigarrow q.x, \Sigma, \{p \mapsto \emptyset, q \mapsto \emptyset\} \rangle \tag{1}$$

$$\langle l, \tau_0 : p.e \rightarrow val q.x, \Sigma, \{p \mapsto \emptyset, q \mapsto \{(l, \tau, v)\}\} \rangle \tag{2}$$

$$\langle \{1, \tau : p.e \rightarrow val q.x\}; \{1, \tau : p.e' \rightarrow val q.x\}, \Sigma, \{p \mapsto \emptyset, q \mapsto \emptyset\} \rangle \tag{3}$$

$$\langle 3, \tau_0 : p.X(p, q) \{1, \tau_0 : p.e \rightarrow val q.x\}, \Sigma, \{p \mapsto \emptyset, q \mapsto \emptyset\} \rangle \tag{4}$$

Configuration (1) is not reachable because $l, \tau : p \rightsquigarrow q.x$ never occurs unless q has an undelivered message from p . Dually, configuration (2) is not reachable because p has a message in its queue that, according to the choreography, has not yet been sent. Configuration (3) is unreachable because the two instructions share the same integrity key; we will show that `nextToken` ensures such configurations never arise. Likewise, `nextToken` also forbids configuration (4), since the token of the instruction $1, \tau_0 : p.e \rightarrow val q.x$ must have been derived from the integrity key of the enclosing call $3, \tau_0 : p.X(p, q) \{ \dots \}$. Specifically, $\tau_0 \neq \text{nextToken}(3, \tau_0)$. To specify this last property, recall that tokens are represented as lists of integers $l_1 :: l_2 :: \dots$. We say (l_1, t_1) is a *prefix* of (l_2, t_2) – written $(l_1, t_1) \prec (l_2, t_2)$ – if the list $l_1 :: t_1$ is a prefix of $l_2 :: t_2$ and that the keys are *disjoint* if neither is a prefix of the other.

Following convention, we formalize the properties of reachable configurations by defining which configurations and procedures are *well-formed*. Figure 9 highlights the most interesting rules that define well-formedness, where \checkmark reads “well-formed” – the rest can be found in the full version of this paper [27]. In particular, well-formedness ensures that:

1. (C-WF-SEND) $l, \tau : p \rightsquigarrow q.x$ occurs in C if and only if $(l, \tau, v) \in K(q)$ for some v .
2. (C-WF-SELECT) $l, \tau : p \rightsquigarrow q[L]$ occurs in C if and only if $(l, \tau, L) \in K(q)$.
3. (C-WF-DEF) Each I in C has a distinct integrity key l, t , where t is not a placeholder.
4. (C-WF-CALLING) If the integrity key of I is a prefix of the integrity key of I' then I is a communication-in-progress $l, t : \bar{p}. X(\bar{p}, \bar{a}) \{ C' \}$ and I' is in C' .

Well-formedness also guarantees other properties seen in other choreography models, e.g., that procedures contain no free variables and that processes waiting to enter a procedure have the same local behaviour in the original procedure body and the current choreography [26]. As in prior work [26, 13], the latter check is made by using endpoint projection ($\llbracket C \rrbracket_p$), which returns the local behaviour of a process in a choreography and is defined later in Section 4.3.

► **Theorem 1** (Preservation). *If $\langle C, \Sigma, K \rangle$ is well-formed and $\langle C, \Sigma, K \rangle \xrightarrow{P} \langle C', \Sigma', K' \rangle$, then $\langle C', \Sigma', K' \rangle$ is well-formed.*

Proof. By induction on the rules of \xrightarrow{P} . We focus on the rules for communication and procedure invocation.

C-SEND replaces $l, \tau : p.e \rightarrow \text{val } q.x$ with $l, \tau : p \rightsquigarrow q.x$ and adds a message (l, τ, v) . By the induction hypothesis, (l, τ, v) is not already in K .

C-RECV eliminates $l, \tau : p \rightsquigarrow q.x$ and removes a message (l, τ, v) . Since each instruction has a distinct integrity key by hypothesis, no other $l, \tau : p \rightsquigarrow q.x$ term occurs in C .

C-FIRST introduces new terms into the choreography by invoking the call $l_1, \tau_1 : X(\bar{p}, \bar{a})$. By the induction hypothesis, for any other instruction $l_2, t_2 : I$ in C , either (a) keys l_1, t_1 and l_2, t_2 are disjoint; or (b) $l_2, t_2 : I$ is a call-in-progress containing $l_1, \tau_1 : X(\bar{p}, \bar{a})$. In case (a), disjointness implies any instruction in the body of the procedure $C'[\bar{q}, \bar{q}.y, t \mapsto \bar{p}, \bar{p}.x, \tau']$ will also have a key that is disjoint from l_2, t_2 . In case (b), notice $\forall l, (l_2, t_2) \prec (l_1, t_1) \prec (l, \text{nextToken}(l_1, t_1))$; hence any interaction in the body has a key where (l_2, t_2) is a prefix. ◀

► **Theorem 2** (Deadlock-Freedom). *If $\langle C, \Sigma, K \rangle$ is well-formed, then either $C \equiv 0$ or $\langle C, \Sigma, K \rangle \xrightarrow{P} \langle C', \Sigma', K' \rangle$ for some p, C', Σ', K' .*

Proof. By induction on the structure of C , making use of the full definition of well-formedness [27]. In each case, we observe the first instruction I of C can always be executed. For instance, if $I \equiv l, \tau : p.e \rightarrow \text{val } q.x$ then the C-SEND rule can be applied because well-formedness implies e has no free variables. If $I \equiv l, \tau : p \rightsquigarrow q.x$, there must be a message $(l, \tau, v) \in K(q)$ because the configuration is well-formed. The other cases follow similarly. ◀

We end this section with a formalization of communication integrity. Consider the buggy execution in Figure 2: in a model without integrity keys, the execution reaches a configuration

$$\langle s \rightsquigarrow c.txt; s \rightsquigarrow c.key; \dots, \Sigma, c \mapsto v_{key}, v_{txt} \rangle,$$

where v_{key} is the value produced by $ks.getKey()$ and v_{txt} is the value produced by $cs.getText()$. A CIV occurs if the configuration can make a transition that consumes $s \rightsquigarrow c.txt$ and v_{key} together, binding $c.txt$ to v_{key} . We therefore want to ensure:

- There is only one way a communication-in-progress instruction can be consumed; and
- The instruction is consumed together with the correct message.

► **Definition 3** (Send/receive transitions). A send transition $\langle C, \Sigma, K \rangle \xrightarrow{P} \langle C', \Sigma', K' \rangle$ is a transition with a derivation that ends with an application of C-SEND. Likewise, a receive transition is a transition with a derivation that ends with C-RECV.

► **Theorem 4** (Communication Integrity). Let $e = c_0 \xrightarrow{p_1} \dots \xrightarrow{p_{k+1}} c_{k+1}$ be an execution ending with a send transition $c_k \xrightarrow{p} c_{k+1}$, which produces instruction $l, \tau : p \rightsquigarrow q.x$ and message m . Let $e' = c_0 \xrightarrow{p_1} \dots \xrightarrow{p_n} c_n$ ($n > k$) be an execution extending e , where $l, \tau : p \rightsquigarrow q.x$ has not yet been consumed. Then there is at most one receive transition $c_n \xrightarrow{q} c_{n+1}$ consuming $l, \tau : p \rightsquigarrow q.x$. Namely, it is the transition that consumes $l, \tau : p \rightsquigarrow q.x$ and m together.

Proof. By definition of C-SEND, m has the form (l, τ, v) . By definition of C-RECV, if there exists a transition $c_n \rightarrow c_{n+1}$ that consumes $l, \tau : p \rightsquigarrow q.x$, then the transition also consumes a message (l, τ, v') , for some v' . It therefore suffices to show the message (l, τ, v') is unique and that $v' = v$. This follows by induction on the length m of the extension:

- *Base case:* Well-formedness implies there is no message (l, τ, v') in c_k . Hence the message (l, τ, v) in c_{k+1} is unique.
- *Induction step:* Observe that the transition $c_m \rightarrow c_{m+1}$ cannot remove (l, τ, v) ; this would require consuming $l, \tau : p \rightsquigarrow q.x$, which cannot happen in e' by hypothesis. Also observe that the transition cannot add a new message with integrity key (l, τ) ; this would require consuming an instruction $l, \tau : p'.e \rightarrow \text{val } q.x'$, which cannot exist in c_m by well-formedness. Hence (l, τ, v) is unique in c_{m+1} . ◀

4 Process Model and Endpoint Projection

4.1 Syntax

Figure 10 presents the syntax for out-of-order processes. A term $p[P]$ is a process named p with behavior P . Networks, ranged over by N, M , are parallel compositions of processes. Compared to prior work, certain process instructions need to be annotated with integrity keys (for instance, message send $p!_{l,t} e$ and procedure call $l, t : X(\bar{p}, \bar{a})$). In addition, when receiving a message it is no longer necessary to specify a sender – it suffices to write $?_{l,t} x; P$ instead of the more traditional $p?_{l,t} x; P$ – because integrity keys functionally determine the variable to which the message payload should be bound.

$\mathcal{P} ::= \{X_i(\bar{p}_i, \bar{x}_i) = C_i\}_{i \in \mathcal{I}}$	(decls)	
$P, Q ::= I; P$	(seq)	$\{P\}$ (block)
0	(end)	
$I ::= p!_{l,t} e$	(send)	$?_{l,t} x$ (receive)
$\text{val } x = e$	(expr)	$p \oplus_{l,t} L$ (choice)
$\&\{(l, \tau, L_i) \Rightarrow P_i\}_{i \in \mathcal{I}}$	(branch)	if e then P else Q (cond)
$l, t : X(\bar{p}, \bar{a})$	(call)	
$e ::= f(\bar{e})$	(app)	a (atom)
$a ::= x$	(var)	v (val)
$N, M ::= p[P]$	(proc)	$(N \mid M)$ (par)

Figure 10 Syntax for out-of-order processes.

4.2 Semantics

The semantics for out-of-order processes appears in Figure 11. It is a labelled transition system on *process configurations* $\langle N, \Sigma, K \rangle$, where N is a network and Σ, K have the same meaning as in Section 3.2. We also assume an implicit set of procedure declarations \mathcal{P} .

The transition rules of Figure 11 are similar to prior work. P-SEND adds a message (l, τ, v) to the undelivered messages of q , whereas P-RECV removes the message and substitutes it into the body of the process. Similarly, P-SELECT adds (l, τ, L) to the message set and P-ONSELECT selects a branch from the set of options $\&\{(l_j, \tau_j, L_j) \Rightarrow P_j\}_{j \in \mathcal{J}}$. P-CALL invokes a procedure, locally computing the next token and substituting the body of the procedure into the process. Rules P-COMPUTE, P-IF, and P-PAR are standard.

The key novelty of out-of-order processes is the P-DELAY rule, which allows a process to perform instructions in *any* order, up to data- and control-dependencies. The latter implies processes cannot evaluate instructions nested within an if or $\&$ -expression.

4.3 Endpoint Projection

Figure 13 defines the *endpoint projection* (EPP) $\llbracket C \rrbracket$ of a choreography C , translating it into a network. The rules follow from simple modifications to the textbook definition of EPP [26]. Projecting a conditional on a process that does not evaluate the guard uses the auxiliary partial operator \sqcup , which produces a term that can react to the different branches by receiving different selections (this is standard).

Figure 12 shows networks projected from the choreographies of Figure 7. Notice the choreographic procedures *BuyItem* and *StreamIt* are each split into two process procedures – one for each role. Communications in the choreography are, as usual, projected into send and receive instructions. Conditionals in the choreography are projected into an if-instruction at one process and a branch-instruction at the other processes awaiting its decision.

Below we formulate the hallmark *EPP Theorem*, which states that a choreography C and its projection $\llbracket C \rrbracket$ evolve in lock-step, up to the usual (\sqsupseteq) relation from Montesi [26] (given in Figure 14). Importantly, we update the theorem to restrict our attention to *well-formed* networks and choreographies. We say that a network N is well-formed if the keys in each process are distinct, i.e., $\text{keys}(P)$ is distinct for each $p[P]$ in N ($\text{keys}(P)$ is given in Figure 14). The restriction allows us to ignore processes such as $p[\&\{(1, \tau, L) \Rightarrow P_1\}; \&\{(1, \tau, L) \Rightarrow P_2\}]$, which could only be projected from a choreography where two distinct instructions have the same integrity key $(1, \tau)$. This leads to the following lemma:

► **Lemma 5.** *Let C, Q be well-formed. If $Q \sqsupseteq \llbracket C \rrbracket_q$ then $\text{keys}(Q) \supseteq \text{keys}_q(C)$, where*

$$\text{keys}_q(C) = [(l, t) \mid (l, t : p \rightsquigarrow q.x) \in \text{stats}(C)], [(l, t) \mid (l, t : p.e \rightarrow \text{val } q.x) \in \text{stats}(C)].$$

The key difficulty of proving the EPP Theorem was finding the right definition of well-formedness (Theorems 1 and 4). With the definition established, the entire proof follows directly from textbook induction principles (*c.f.* [26]). We sketch the proof in the full version of this paper [27].

► **Theorem 6 (EPP Theorem).** *Let $\langle C, \Sigma, K \rangle$ be a well-formed configuration.*

1. (Completeness) *If $\langle C, \Sigma, K \rangle \xrightarrow{p} \langle C', \Sigma', K' \rangle$ then $\langle \llbracket C \rrbracket, \Sigma, K \rangle \xrightarrow{p} \langle N', \Sigma', K' \rangle$ for some well-formed N' where $N' \sqsupseteq \llbracket C' \rrbracket$.*
2. (Soundness) *If $\langle N, \Sigma, K \rangle \xrightarrow{r} \langle N', \Sigma', K' \rangle$ for some well-formed N where $N \sqsupseteq \llbracket C \rrbracket$, then $\langle C, \Sigma, K \rangle \xrightarrow{p} \langle C', \Sigma', K' \rangle$ for some C' where $N' \sqsupseteq \llbracket C' \rrbracket$.*

5 A Non-Blocking Communication API for Choral

In this section, we show how the ideas in O_3 can be applied in practice. To this end, we consider Choral [16]: a state-of-the-art choreographic programming language based on Java. Choral is designed to support real-world programming and interoperate with Java, so it is much more sophisticated than our minimalistic theory. Data locations in Choral are lifted to the type level and communication is expressed by invoking methods of *channel* objects.

Choral’s intended programming model consists of sequential processes that block to receive messages. However, to improve performance programmers can use Java’s `CompletableFuture` API, thereby introducing intraprocess concurrency and out-of-order execution. This breaks the programming model and introduces CIVs (cf. Section 2) that could cause crashes or silent memory corruption. Motivated by our formal model, we developed *Ozone*: an API for Choral programmers to safely mix choreographies with futures. In the remainder of this section, we introduce Choral and Ozone and we show how programmers can mix choreographies with futures achieve significant speedups in practical applications.

5.1 Concurrent Messages

We introduce the Ozone API with an implementation of the choreographic procedure from Figure 2. The implementation is shown in Figure 15, which defines a class called `ConcurrentSend` parameterized by four roles (i.e. process parameters): `KS`, `CS`, `S`, and `C`. In this class, the `start` method implements the procedure itself. As in our formal model, the procedure is parameterized by distributed data: On line 3, parameter `key` is a `String` located at `KS`; `txt` is a `String` located at `CS`; and `client` is a `Client` object at `C`, representing the client’s user interface. The `start` procedure is also parameterized by session tokens, which we introduced in Figure 15, on line 4. The parameter `Token@(KS, CS, S, C) tok` is

$$\begin{aligned}
 \llbracket \mathcal{C} \rrbracket &= \bigcup_{i \in \mathcal{I}} \llbracket X_i(\bar{\mathbf{p}}, \bar{\mathbf{p}}.\bar{x}) = C_i \rrbracket \\
 \llbracket X_i(\bar{\mathbf{p}}, \bar{\mathbf{p}}.\bar{x}) = C_i \rrbracket &= \{X_{i,j}(\bar{\mathbf{p}} \setminus \mathbf{p}_j, \llbracket \bar{\mathbf{p}}.\bar{x} \rrbracket_{\mathbf{p}_j}) = \llbracket C_i \rrbracket_{\mathbf{p}_j} \mid \bar{\mathbf{p}} = \mathbf{p}_1, \dots, \mathbf{p}_n, j \leq n\} \\
 \llbracket l, t : \mathbf{p}.e \rightarrow \mathbf{val} \quad \mathbf{q}.x; \quad C \rrbracket_r &= \begin{cases} \mathbf{q} !_{l,t} e; \llbracket C \rrbracket_r & \text{if } r = \mathbf{p} \\ ?_{l,t} x; \llbracket C \rrbracket_r & \text{if } r = \mathbf{q} \\ \llbracket C \rrbracket_r & \text{otherwise} \end{cases} \\
 \llbracket l, t : \mathbf{p} \rightsquigarrow \mathbf{q}.x; \quad C \rrbracket_r &= \begin{cases} ?_{l,t} x; \llbracket C \rrbracket_r & \text{if } r = \mathbf{q} \\ \llbracket C \rrbracket_r & \text{otherwise} \end{cases} \\
 \llbracket l, t : \mathbf{val} \quad \mathbf{p}.x = e; \quad C \rrbracket_r &= \begin{cases} \mathbf{val} x = \llbracket e \rrbracket_r, \llbracket C \rrbracket_r & \text{if } r = \mathbf{p} \\ \llbracket C \rrbracket_r & \text{otherwise} \end{cases} \\
 \llbracket l, t : \mathbf{p} \rightarrow \mathbf{q}[L]; \quad C \rrbracket_r &= \begin{cases} \mathbf{q} \oplus_{l,t} \llbracket e \rrbracket_r; \llbracket C \rrbracket_r & \text{if } r = \mathbf{p} \\ \&\{(l, t, L) \Rightarrow \llbracket C \rrbracket_r\} & \text{if } r = \mathbf{q} \\ \llbracket C \rrbracket_r & \text{otherwise} \end{cases} \\
 \llbracket l, t : \mathbf{p} \rightsquigarrow \mathbf{q}[L]; \quad C \rrbracket_r &= \begin{cases} \&\{(l, t, L) \Rightarrow \llbracket C \rrbracket_r\} & \text{if } r = \mathbf{q} \\ \llbracket C \rrbracket_r & \text{otherwise} \end{cases} \\

```

1  public class ConcurrentSend@(KS, CS, S, C) {
2      public void start(
3          String@KS key, String@CS txt, Client@C client,
4          Token@(KS, CS, S, C) tok,
5          AsyncChannel@(KS, S) ch1, AsyncChannel@(CS, S) ch2, AsyncChannel@(S, C) ch3
6      ) {
7          // Services send data to the server.
8          CompletableFuture@S keyS = ch1.fcom(key, 1@(KS,S), tok);
9          CompletableFuture@S txtS = ch2.fcom(txt, 2@(CS,S), tok);
10
11         // Server forwards data to the client.
12         ch3.fcom(keyS, 3@(S,C), tok)
13             .thenAccept(client::decrypt);
14         ch3.fcom(txtS, 4@(S,C), tok)
15             .thenAccept(client::display);
16     }
17 }
```

Figure 15 An implementation of the choreography in Figure 2 using Choral and the Ozone API.

syntactic sugar for the parameter *list* `Token@KS tok_KS, ..., Token@C tok_C`.³ The last three parameters on line 5 are *channels*. In Choral, channels are used to communicate data from one role to another. If `ch` is a channel of type `Channel@(A,B)<T>` and `e` is an expression of type `T@A`, then the expression `ch.com(e)` is a communication that produces a value of type `T@B`.

Our main contribution in the Ozone API is a custom channel `AsyncChannel@(A,B)<T>` with a method `fcom` for safely communicating data with non-blocking semantics. The `fcom` method is similar to `com`, but with the following differences:

- Whereas `com` takes one argument, `fcom` takes three: a payload, a line number, and a session token. The latter two arguments form an integrity key, of which both the sender and receiver have a copy.

³ This syntactic sugar is provided for readability and is not currently supported by the Choral compiler. We will also use syntactic sugar for lambda expressions and omit obvious type annotations later in this section. Our actual implementation uses desugared versions of the syntax.

31:20 Ozone: Fully Out-of-Order Choreographies

```

1  public class ConcurrentSend_KS {
2      public void start(
3          String key, Token tok_KS,
4          AsyncChannel ch1
5      ) {
6          ch1.fcom(key, 1, tok_KS);
7      }
8  }
9  public class ConcurrentSend_S {
10     public void start(
11         Token tok_S, AsyncChannel ch1,
12         AsyncChannel ch2, AsyncChannel ch3
13     ) {
14         CompletableFuture keyS =
15             ch1.fcom(1, tok_S);
16         CompletableFuture txtS =
17             ch2.fcom(2, tok_S);
18
19         ch3.com(keyS, 3, tok_S);
20         ch3.com(txtS, 4, tok_S);
21     }
22 }
```

```

23  public class ConcurrentSend_CS {
24      public void start(
25          String txt, Token tok_CS,
26          AsyncChannel ch2
27      ) {
28          ch2.fcom(txt, 2, tok_CS);
29      }
30  }
31
32  public class ConcurrentSend_C {
33      public void start(
34          Client client, Token tok_C,
35          AsyncChannel ch3
36      ) {
37          ch3.fcom(3, tok_C)
38              .thenAccept(client::decrypt);
39          ch3.fcom(4, tok_C)
40              .thenAccept(client::display);
41      }
42 }
```

 **Figure 16** Endpoint projection of Figure 15.

- When the receiver B executes a `com` instruction, its thread becomes blocked until the value (of type `T@B`) has been delivered. In contrast, `fcom` creates a Java *future* (of type `CompletableFuture@B<T>`) which is a placeholder at B that will hold a value of type T once the message is delivered. Instead of blocking, `fcom` immediately returns that future to the calling thread. The thread can then assign a callback to handle the message and proceed with other useful work.

Lines 8 and 9 of Figure 15 show `fcom` being used to transport `key` and `txt` to the server S. The expression `1@(KS, S)` is sugar for the list `1@KS, 1@S` and we assume the replicated value `tok` is expanded into the list `tok_KS, tok_S`. Thus both sender and receiver pass integrity keys as arguments to `fcom`.

Lines 12-15 of Figure 15 show how the server S and client C use the future values. On line 12, the server uses an overloaded version of `fcom` that takes `CompletableFuture@S` instead of `T@S`. The method assigns to the future a callback, which forwards the result to the client once the future has been completed. The result of `fcom` on line 12 is a `CompletableFuture@C`, to which the client binds a callback on line 13: when the key from S finally arrives at C, the client will proceed to invoke the method `client.decrypt` with the key as an argument. Lines 14 and 15 do the same, but with the value of `txt`. As we will see below, the values of `key` and `txt` can arrive at the client in any order, so the callbacks on lines 13 and 15 can execute in any order – even in parallel.

5.1.1 Endpoint projection

By running the Choral compiler, `ConcurrentSend@(KS,CS,S,C)` is *projected* to generate four Java classes, shown in Figure 16. Each class implements the behavior of its corresponding role. For example, `ConcurrentSend_KS` implements the behavior of KS. Its `start` method is parameterized by: `key`, which corresponds to the `key` in Figure 15; `tok_KS`, the copy of the token `tok` belonging to KS; and `ch1`, a channel endpoint that connects KS to S. Following the reasoning in Figure 13, these behaviors will not exhibit deadlocks or communication integrity errors when composed (assuming the implementations of Choral and Ozone are correct).

```

1  public class ConcurrentClients@{KS, CS, S, C1, C2} {
2      public void start(
3          AsyncChannel@{KS, S} ch1, AsyncChannel@{CS, S} ch2,
4          AsyncChannel@{S, C1} ch3, AsyncChannel@{S, C2} ch4,
5          KeyService@{KS} keyService, ContentService@{CS} contentService,
6          Client@{C1} client1, String@{KS, CS} clientID1,
7          Client@{C2} client2, String@{KS, CS} clientID2,
8          Token@{KS, CS, S, C1, C2} tok
9      ) {
10         (new ConcurrentSend2()).start(ch1, ch2, ch3,
11             keyService.getKey(clientID1), contentService.getContent(clientID1),
12             client1, tok.nextToken(0@{KS,CS,S,C1}) );
13
14         (new ConcurrentSend2()).start(ch1, ch2, ch4,
15             keyService.getKey(clientID2), contentService.getContent(clientID2),
16             client2, tok.nextToken(1@{KS,CS,S,C2}) );
17     }
18 }
```

Figure 17 A Choral choreography invoking ConcurrentSend2.

```

1  public class ConcurrentClients_KS {
2      public void start( ... ) {
3          (new ConcurrentSend2_KS()).start(ch1,
4              keyService.getKey(clientID1),
5              tok.next(0));
6
7          (new ConcurrentSend2_KS()).start(ch1,
8              keyService.getKey(clientID2),
9              tok.next(1));
10     }
11 }
```

```

12  public class ConcurrentClients_S {
13      public void start( ... ) {
14          (new ConcurrentSend2_S()).start(
15              ch1, ch2, ch3, tok.next(0));
16
17          (new ConcurrentSend2_S()).start(
18              ch1, ch2, ch3, tok.next(1));
19      }
20 }
```

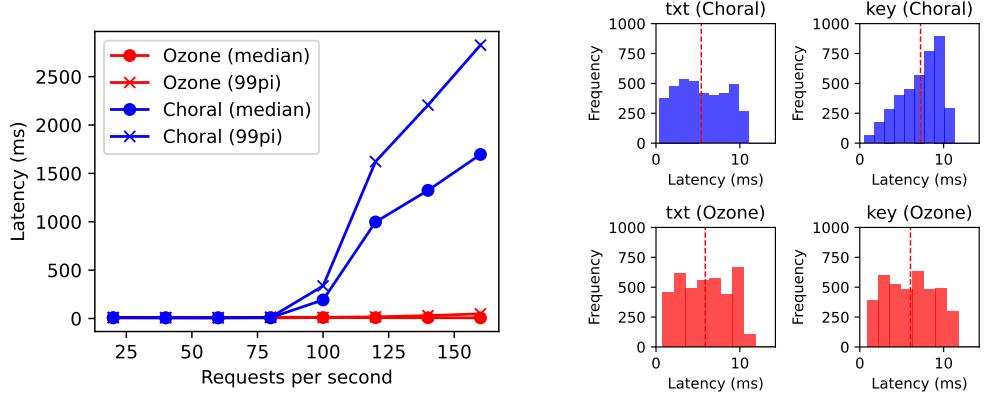

Figure 18 Endpoint projection of Figure 17 (representative examples).

Let us see how integrity keys prevent CIVs in Figure 16. Notice that the Choral instruction `CompletableFuture@S keyS = ch1.fcom(key, 1@{KS,S}, tok);` on line 8 of Figure 15 is projected into two instructions:

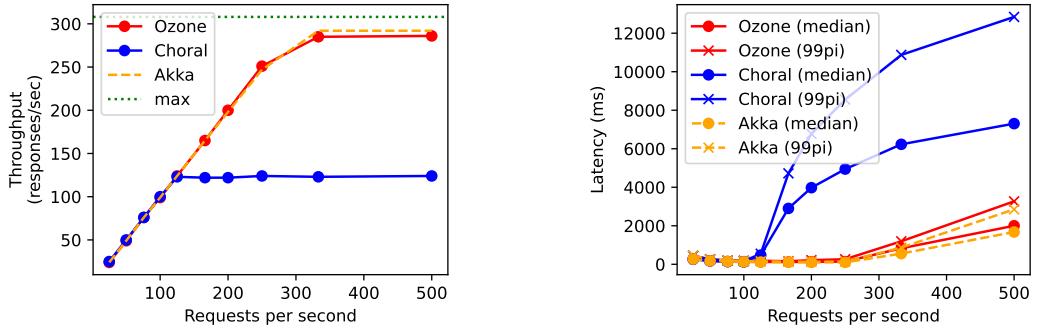

1. `ch1.fcom(key, 1, tok_KS)` at the sender KS; and
2. `CompletableFuture keyS = ch1.fcom(1, tok_S)` at the receiver S.

The former instruction is parameterized by a payload and an integrity key and produces nothing. The latter instruction is parameterized only by an integrity key (with no payload) and produces a future. When KS sends `key` to S, it combines the payload with integrity key `(1, tok_KS)`. Dually, S creates a future that will only be completed when a message with the integrity key `(1, tok_S)` is received. Since `tok_KS` and `tok_S` have the same value, the send- and receive-operations are guaranteed to match.

On lines 14-17 of Figure 16, the server S sets listeners for `key` and `txt`. On lines 19-20, S schedules the values to be forwarded to C; notice that even with FIFO channels, `key` and `txt` may arrive in any order. Consequently, S may forward their values to C in any order. On lines 37-40 of Figure 16, the client creates futures to hold the values of `key` and `txt` and sets callbacks to be invoked when the values arrive. Here we see the importance of integrity keys: the client uses `(3, tok_C)` and `(4, tok_C)` to disambiguate the `key` message from the `txt` message. Without integrity keys, mixing Choral choreographies with Java Futures would be unsafe. As shown in Section 4.3, our solution is correct even when the underlying transport protocol can deliver messages out of order.

(a) Concurrent producers latency (lower is better). (b) Concurrent senders latency (further left is better).

Figure 19 Microbenchmark.

(a) Throughput (higher is better).

(b) Latency (lower is better).

Figure 20 Model serving.

5.2 Procedure calls

Section 5.1 showed how the line numbers in an integrity key could prevent CIVs. We now briefly show how the *tokens* in an integrity key prevent *interprocedural* CIVs. Figure 17 depicts a choreography that invokes two instances of `ConcurrentSend2`: the first instance with client `C1`, and the second instance with client `C2`. On lines 12 and 16, the roles all compute fresh tokens for each procedure they're involved in, like in our formal model; the syntax `tok.nextToken(0@KS,CS,S,C1)` is sugar for `tok_KS.nextToken(0@KS), ..., tok_C1.nextToken(0@C1)`, and the method `t.nextToken(l)` implements the function `nextToken(l,t)`. These fresh tokens ensure that, even if messages from `KS` to `S` are delivered out of order there is no chance that messages from the first procedure invocation will be confused for messages from the second invocation.

5.3 Evaluation

We evaluated Ozone with microbenchmarks based on Figures 1 and 2 and with a model serving benchmark from Wang et al [34]. The experiments were carried out on a six-node Linux cluster, with two Intel Xeon Gold 6130 CPUs and 384 GB of memory per node and an average bandwidth of 15 Gbps.

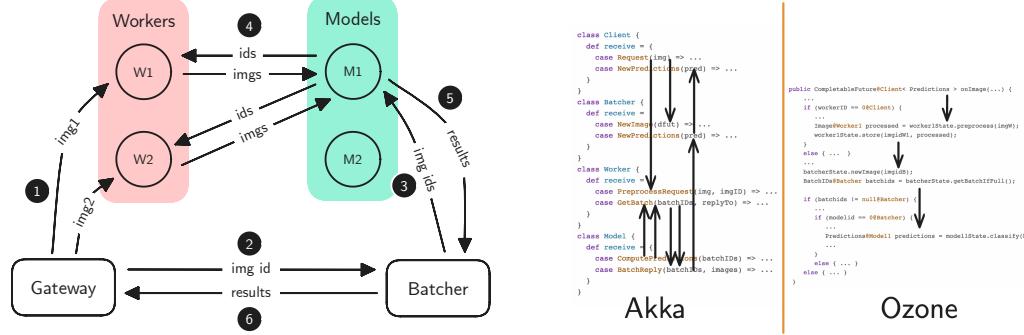

Figure 21 Architecture for the image classification pipeline.

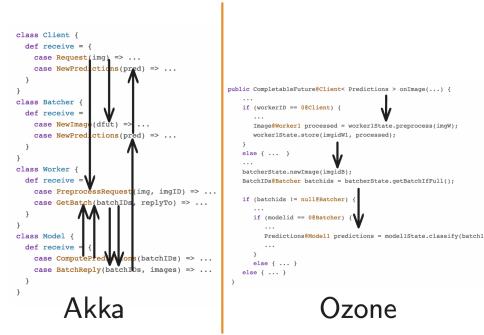

Figure 22 Control flow comparison between hand-written Akka processes and Ozone.

The first microbenchmark is a version of Figure 1 from the introduction. Each producer iteratively invokes the choreography at a fixed rate and, in response to each request, the server simulates computation by sleeping for 0–5 milliseconds. Figure 19a shows the median and 99th percentile latency for server responses to worker requests. In the Choral implementation, the server quickly becomes a bottleneck because of its fixed processing order: a request from p_1 must be handled before a request from p_2 , and both requests must be handled for the i -th iteration before they can be handled for the $(i+1)$ -th iteration. In the Ozone implementation, requests from different producers can be handled out of order and producers can start a new instance of the choreography without waiting for the second one to complete. Consequently the server spends less time waiting for requests, so it can handle much higher request rates.

The second microbenchmark is a version of Figure 2 from Section 2, in which the server sends messages to the microservices ks and cs and forwards their responses to the client. Each microservice takes 0–5 milliseconds to compute its response. The latency histogram for the Choral implementation (top) shows how the time for the client to receive txt depends on the time to compute txt , but the time to receive key depends on *both* the time to compute txt and the time to compute key . In contrast, the Ozone implementation (bottom) allows the server to forward key to the client without waiting for txt – thereby reducing the average latency for key by more than 30%.

To measure the impact of Ozone on a realistic application, we ported the image classification pipeline of Wang et al [34] to Choral (Figure 21). In this pipeline, images are received by a Gateway that performs load balancing and forwards the images to a pair of Worker services for preprocessing. A Batcher service collects requests and sends them as a batch to a Model service, which fetches the processed images and performs image classification. This architecture allows applications to harness *intra*-GPU parallelism by increasing the batch size (at the cost of latency) and *inter*-GPU parallelism by increasing the number of Model services. Figure 20 shows the performance for Choral and Ozone implementations of the pipeline, using sleeps to simulate computation. The plots also show the performance of an implementation in the Akka actor framework [3] and the theoretical maximum throughput of the Model services.

The Choral implementation has a bottleneck: after the Batcher sends work to a Model, it waits for the Model’s response and becomes blocked. In the Ozone implementation, the Batcher binds the Model service’s response to a `CompletableFuture` and continues receiving requests from the Gateway. Consequently, the throughput and latency for the Ozone implementation can scale with the number of requests until both Models become saturated with work. Figure 20 shows our library scales similarly to hand-written reactive processes in Akka, though the latter perform slightly better under high load because the

Akka framework is heavily optimized to handle network congestion; these same optimizations can be applied to Choral, but they are orthogonal to our present work. We conclude that our methodology can achieve good performance while providing the benefits of choreographic programming: (i) absence of bugs like deadlocks and mismatched communications (e.g., sending a message with the wrong type or at the wrong time) [16, 26, 23]; (ii) and improved readability, since control flow is easier to follow in choreographies than in processes (see Figure 22), as discussed in [32, 21, 23, 16].

6 Related Work

In early choreographic languages, the sequencing operator $I; C$ had strict sequential semantics; concurrency could only be introduced via an explicit parallel operator $C \parallel C'$ [30, 22, 7]. Explicit parallelism was later replaced by a relaxed sequencing operator $I; C$ that would allow instructions in C to be evaluated before I under certain conditions [8]. This presents the benefits of offering a simple syntax for choreographies and, at the same time, automatically inferring what can be safely executed concurrently. For these reasons, relaxed sequencing has been adopted in most recent works on choreographic programming (e.g., [18, 16, 17, 13, 20, 21]) and its textbook presentation [26]. Our present work makes the sequencing operator even more relaxed, allowing all instructions to be executed out of order, up to data- and control-dependency. To the best of our knowledge, our model is the first to support non-FIFO communication in the setting of choreographic programming.

Our work is closely related to choreographic *multicomms*: sets of communications that can be executed out of order, up to data dependency [12]. However, multicomms do not allow *computation* to be performed out of order, as in Figure 1c. Multicomms therefore do not need to address the communication integrity problem, which we focus on in this work. Relatedly, previous work investigated modeling asynchronous communication by making send actions non-blocking [8, 19, 10, 28, 18, 26], but none of considered non-blocking receive. Thus, they are not expressive enough to capture the behaviors that we are interested in here.

In terms of expressivity, there is some overlap between our model and *nondeterministic choreographies* [26], which use an explicit *choreographic choice* operator $C +_p C'$. Nondeterministic choreographies can implement the execution in Figure 1c with:

$$\left(\begin{array}{l} \text{buyer}_1.id \rightarrow \text{val seller}.id_1; \\ \text{buyer}_2.id \rightarrow \text{val seller}.id_2; \\ \dots \end{array} \right) +_{\text{seller}} \left(\begin{array}{l} \text{buyer}_2.id \rightarrow \text{val seller}.id_2; \\ \text{buyer}_1.id \rightarrow \text{val seller}.id_1; \\ \dots \end{array} \right)$$

Figure 2 can also be expressed with nondeterministic choreographies:

$$\left(\begin{array}{l} 1 : \text{cs.getText()} \rightarrow \text{val s.txt}; \\ 2 : \text{s} \rightarrow \text{c[TXTFIRST]}; \\ 3 : \text{s.txt} \rightarrow \text{val c.txt}; \\ 4 : \text{c.display(c.txt)}; \\ 5 : \text{ks.getKey()} \rightarrow \text{val s.key}; \\ 6 : \text{s.key} \rightarrow \text{val c.key}; \\ 7 : \text{c.decrypt(c.key)} \end{array} \right) +_{\text{s}} \left(\begin{array}{l} 8 : \text{ks.getKey()} \rightarrow \text{val s.key}; \\ 9 : \text{s} \rightarrow \text{c[KEYFIRST]}; \\ 10 : \text{s.key} \rightarrow \text{val c.key}; \\ 11 : \text{c.decrypt(c.key)}; \\ 12 : \text{cs.getText()} \rightarrow \text{val s.txt}; \\ 13 : \text{s.txt} \rightarrow \text{val c.txt}; \\ 13 : \text{c.display(c.txt)} \end{array} \right)$$

Compared to O_3 , these implementations are much larger because they require programmers to statically encode all desired schedules. One can easily forget to include some schedules or encode them incorrectly: for instance, if one moved line 12 up to line 10 above, it would eliminate the extra concurrency that was gained by receiving the messages out of order. Thus, our approach is more robust and simpler for the programmer.

On the other hand, nondeterministic choreographies can express some programs that our model cannot. For example, choreographic choice can assign different variable names to messages, according to their arrival order. Other choreographic languages include nondeterministic operators [22, 6], but they do not support computation (a requirement for choreographic programming) or recursion.

Choral is arguably the most powerful implementation of choreographic programming to date, but there are also others that target, e.g., Haskell, Java, Jolie, and Rust [8, 9, 29, 32, 21]. We believe that implementing the out-of-order semantics of O_3 in these languages is possible, too. However, it would likely require more work that touches also the implementation of EPP because, differently from Choral, these languages do not support user-defined communication primitives. Since Choral is more expressive than all other current choreographic programming languages, we have targeted the most general case.

In [23], the authors introduce a Choral library for handling protocols that might deliver messages out of order. Unlike Ozone, this library requires explicitly writing which parts of a choreography are independent. Dependencies between actions also need to be managed at a low level via side-effects. In our approach, out-of-order communications can be elegantly combined by using futures. Furthermore, the work in [23] does not deal with CIVs (which might arise if programmers are not careful) and presents no formal model.

A more loosely related line of research is that on multiparty session types (MPSTs) [19], where abstract choreographies without data or computation are used as protocol specifications that are compiled to “local session types”. Similarly to most work on choreographic programming, some works on MPSTs allow for non-blocking send, but not non-blocking receive as in O_3 . Previous work considered reordering actions in local session types [14], but these reorderings are necessarily limited because asynchronous multiparty session subtyping is undecidable in general [5]. Interprocedural MPSTs have been presented [15], but unlike O_3 , the procedure calls require a central coordinator. Similar comments hold for recent investigations that add nondeterminism because of crashes [1, 33]. More generally, it is unclear whether “concurrency up to data dependency” could be expressed with MPSTs in their current form, since the types do not encode data dependencies.

7 Conclusion

We investigated a model for choreographic programming in which processes can execute out of order and messages can be reordered by the network. These features improve the performance of choreographies, without requiring programmers to rewrite their code, by allowing processes to better overlap communication with computation. However, compilers that use these features must have mechanisms in place to prevent communication integrity violations (CIVs). We presented a scheme to prevent CIVs by attaching dynamically-computed integrity keys to each message. Our results enlarge the class of behaviors that can be captured with choreographic programming without renouncing its correctness guarantees.

An important subject for future work is confluence. Statements can read and write to the local state of a process, so executing statements out of order can cause nondeterminism. Sometimes this nondeterminism is desirable (for instance, to implement consensus algorithms) but sometimes the nondeterminism is unexpected and causes bugs. In our formal model, nondeterminism could be controlled manually by allowing programmers to insert synthetic data dependencies. For example, below we use a hypothetical keyword barrier_p to prevent a file from being closed before it has been written-to:

```
val p.file = open("foo.txt"); p.write(p.file, "hello"); barrier_p; p.close(p.file)
```

More generally, future work could develop a static analysis that identifies when two statements are not safe to execute out of order.

Another opportunity for static analysis to improve on our work concerns the size of session tokens. We chose to represent session tokens as lists of integers, which allowed processes to compute new session tokens without coordinating with one another. However, this encoding means the size of a token is proportional to the depth of the call stack – a problem for tail-recursive programs such as *StreamIt* in Figure 7b. Fortunately, it is easy to see that communication integrity in *StreamIt* could be achieved in constant space by representing the token as a single integer, incremented upon each recursive call, assuming that processes do not participate in multiple instances of the choreography concurrently. With static analysis, a compiler could identify such programs and use a more efficient session token representation.

Abstract

Tensor processing infrastructures such as deep learning frameworks and specialized hardware accelerators have revolutionized how computationally intensive code from domains such as deep learning and image processing is executed and optimized. These infrastructures provide powerful and expressive abstractions while ensuring high performance. However, to utilize them, code must be written specifically using the APIs / ISAs of such software frameworks or hardware accelerators. Importantly, given the fast pace of innovation in these domains, code written today quickly becomes legacy as new frameworks and accelerators are developed, and migrating such legacy code manually is a considerable effort.

To enable developers in leveraging such DSLs while preserving their current programming paradigm, we present TENSPILER, a verified-lifting-based compiler that uses program synthesis to translate sequential programs written in general-purpose programming languages (e.g., C++ or Python code that does not leverage any specialized framework or accelerator) into tensor operations. Central to TENSPILER is our carefully crafted yet simple intermediate language, named TENSIR, that expresses tensor operations. TENSIR enables efficient lifting, verification, and code generation. Unlike classical pattern-matching-based compilers, TENSPILER uses program synthesis to translate input code into TENSIR, which is then compiled to the target API / ISA. Currently, TENSPILER already supports **six** DSLs, spanning a broad spectrum of software and hardware environments. Furthermore, we show that new backends can be easily supported by TENSPILER by adding simple pattern-matching rules for TENSIR. Using 10 real-world code benchmark suites, our experimental evaluation shows that by translating code to be executed on 6 different software frameworks and hardware devices, TENSPILER offers on average **105 \times** kernel and **9.65 \times** end-to-end execution time improvement over the fully-optimized sequential implementation of the same benchmarks.

1 Introduction

We have witnessed an explosion of new computational infrastructures for tensor computation in recent years: from software frameworks such as TensorFlow to specialized hardware accelerators like tensor processing units. Such infrastructures arise due to new application domains such as image processing and training deep learning (DL) models, and they often expose their functionality via various domain-specific languages (DSLs) that range from specialized instruction sets such as vectorized instructions to high-level programming interfaces such as Apple’s MLX [27] or TensorFlow’s XLA [37].

To leverage the optimization offered by such infrastructures, applications must be written against the provided programming interfaces: developers must first master each DSL’s programming model to write new code, and existing applications must be rewritten. This problem is recurring as new DSLs keep appearing targeting different application domains. Manually rewriting existing applications is tedious and increases the likelihood of introducing bugs. The classical way of addressing such issues is to build transpilers [15, 5, 6, 19, 25, 26] that translate code from paradigms developers are familiar with (e.g., C++ code using the STL library) to the one provided by the target DSL (e.g., NumPy API). Nonetheless, building such a transpiler is resource-intensive, error-prone, and each one is specialized to a specific target DSL. For instance, existing compilers such as Dexter [6], STNG [19], and C2TACO [25] target specific DSLs like Halide and TACO, and are not easily extensible to support new operators or backends. While recently developed DL models such as GPT have shown promise in code translation, they do not provide any guarantees on the correctness of output. Moreover, GPT fails to generate even syntactically correct code for DSLs it has not seen in training data, limiting its applicability to new or less popular DSLs.

In this paper, we describe a tensor compiler that addresses these challenges. We introduce TENSPILER— a compiler designed to automate the transpilation of code to *multiple* tensor processing frameworks and hardware accelerators. TENSPILER uses verified lifting [12] (VL), a technique using inductive program synthesis to infer provably equivalent program summaries expressed using a user-defined intermediate representation (IR), and generate executable code from the synthesized summary to the target DSL. In contrast to conventional compilers that rely on pattern-matching to compile code, VL uses a search-based technique for the translation process. The two key steps of VL are:

- **Search Phase:** This stage lifts the input code to an equivalent program written using a user-provided IR, where the IR is used to model the functionality of each operator in the target DSL. Lifting is formulated as a syntax-guided synthesis [8] problem.
- **Verification:** Once lifted, a theorem prover is used to validate if the synthesized summary is functionally equivalent to the input. If so, executable code is produced by calling the user-provided code generator from the summary; otherwise, another summary is generated by the search phase.

The key to making lifting efficient lies in the design of the IR (i.e., how the target DSL is modeled). In prior work [5, 6, 7, 34, 21], each function or instruction exposed by the target DSL is modeled explicitly. While doing so makes the search efficient, such explicit modeling makes the compiler hard to extend to other DSLs. With TENSPILER, we introduce, for the first time, a *single unified* IR, TENSIR, that is designed for tensor operations and can easily generate code to *multiple* tensor processing software frameworks and hardware accelerators. Surprisingly, TENSIR is a small language based on tensor algebra that includes commonly used vector and matrix operations. While other unifying IR exists (e.g., MLIR [23]), they are targeted for classical pattern-matching compilers. As we will discuss in Sec. 5 and Sec. 4.2, TENSIR instead is designed for synthesis-based compilers and thus aims to enable both efficient search and verification.

In summary, this paper makes the following contributions:

1. We describe the design of TENSIR for transpiling code to tensor processing DSLs. TENSIR is simple yet expressive enough to model the functionalities provided by different software frameworks and hardware accelerators, and enables efficient code transpilation using verified lifting, as detailed in Sec. 3.
2. Based on TENSIR, we devise various optimization techniques to make synthesis and verification tractable, and scale to real-world programs in Sec. 5.
3. We implement TENSPILER, a verified lifting-driven transpiler built using TENSIR as the modeling language. We demonstrate the effectiveness of TENSPILER by using it to lift real-world code from 10 different suites to **6** different open-source and commercially-available tensor processing software frameworks and hardware accelerators. We illustrate the ease of constructing such transpilers by building one for MLX, a new tensor processing framework that was released only four months ago, using less than **200** lines of code in Sec. 6.

We have released Tenspiler’s code on <https://github.com/tenspiler/tenspiler>.

2 Overview

TENSPILER takes in C/C++ or Python code as input¹ and transpiles it to a functionally equivalent program that leverages different software frameworks and hardware accelerators (details described in Sec. 4.3) for tensor computation. As mentioned, TENSPILER uses verified lifting to first translate the source program into TENSIR. Unlike traditional pattern-matching compilers, TENSPILER formulates code translation as a search for a program expressed in TENSIR that is provably semantic-equivalent to the input. Doing so avoids the need to devise pattern-matching rules and prove their correctness. To make the search scalable, instead of directly searching within the DSL exposed by each target, we designed a high-level IR called TENSIR that abstracts away the low-level implementation details of each DSL operator and captures only their semantics, unifying various DSLs into a common set of tensor operators. TENSPILER uses a program synthesizer (currently Rosette [36], a synthesizer for finite domain theories) to lift the input code to TENSIR during the search phase. The synthesized output is then verified using a theorem prover (currently, an SMT solver, CVC5 [10]) for the unbounded domain. “Unbounded domain” means the verification

¹ TENSPILER currently supports a subset of the C/C++ and Python language (in particular it does not support code that uses pointers or objects, which we have not encountered such use in our benchmarks). It also expects any external libraries used in the input to be functionally modeled, which is how TENSPILER currently supports code that uses the `STL::vector` library.

(d) Generated executable code for different tensor processing DSL.

Figure 1 End-to-End example of using TENSPILER to transpile code.

is performed for all possible program states, not just a bounded set of states (e.g., all states where integers are represented using 8 bits) that Rosette considers during the synthesis phase. Once verified, TENSPILER then translates the TENSIR program to the concrete syntax of the target DSL using simple pattern-matching rules.

We illustrate TENSPILER using the example in Fig. 1a as our **S** (source), where **S** implements blending, a common image processing operation. It lightens the base color by iterating over each pixel, implemented as a nested loop over all the **rows** and **cols** in the image. Our goal is to transpile this code to the target DSLs supported by TENSPILER as shown in Fig. 1d.

TENSPILER first translates the input code to TENSIR. To be discussed in Sec. 4, TENSIR consists of several operators that model common tensor algebra operations, two of which are shown in Fig. 1b. The **t_t** function performs element-wise operations (one of **+**, **-**, *****, **/**, **%**) on tensors **x** and **y** and is defined recursively on each element. Meanwhile, **t_s** performs element-wise scalar operations on tensor **x** using the scalar value **a** and is similarly defined. Importantly, both operators are purely functional models of the tensor operations that lack implementation details that a specific target might leverage (e.g., tiling, vectorization, etc). The idea is that if **S** can be expressed using only these operators via lifting, then the lifted program can be easily translated to the targeted backends.

In TENSPILER, lifting is formulated as a Syntax-Guided Synthesis (SyGuS) [8] problem, where the goal is to synthesize a semantically equivalent program summary (PS), represented as a sequence of operators from our TENSIR, with the input code as the specification. A search space (specified using grammar) describes the set of potential candidate programs for the given specification. An input program S is semantically equivalent to the synthesized expression S' if for all possible program inputs i , $S(i) = S'(i)$.

TENSPILER uses symbolic search to solve the synthesis problem. Symbolic search is typically implemented through enumerative or deductive search, and using constraint-solving approaches which often rely on domain-specific heuristics to scale. As a SyGuS problem, symbolic search is implemented as enumerating different expressions over a user-provided grammar, where the grammar encodes all possible combinations of operators in the target DSL up to a specified depth. However, as the depth increases, the number of choices grows exponentially, making the search intractable. As we will discuss in Sec. 5, TENSIR is designed to make synthesis scalable. For S , the synthesis phase returns the following solution:

```
def lifted_program(b, a): return t_t(t_t(b, a, +), t_s(t_t(b, a, *), 255, /), -)
```

As TENSPILER’s synthesizer currently can only reason about finite domains, all synthesized solutions are checked for full functional equivalence using an automated theorem prover. Since S has loops, checking equivalence with the generated program on all inputs requires loop invariants. Such invariants are synthesized during the synthesis phase by constructing a grammar similar to the PS grammar. For instance, for S , the synthesis phase yields two loop invariants (one for each loop) alongside a PS . As shown in Fig. 1c, these loop invariants are not arbitrary; within the loop invariants, the output variable, `out`, is expressed as a combination of operators from the TENSIR that help prove the synthesized PS . We will leverage this to improve synthesis efficiency, to be explained in Sec. 5.

With the synthesized solution expressed in TENSIR, the final step is to translate it into the concrete syntax of the target DSL(s). In TENSPILER, this is done via simple pattern-matching rules. In Fig. 1d, we present the translated code for different supported DSLs. As we will discuss in Sec. 4.3, TENSIR is designed such that generating executable code is straightforward. In fact, the code generators for the different tensor processing infrastructures supported by TENSPILER are highly similar to each other, as we will discuss in Sec. 6.

3 The TENSIR Intermediate Representation

We now discuss our intermediate representation, TENSIR, which plays a pivotal role in TENSPILER. While prior lifting-based compilers all use search to compile programs, their IRs are specialized for their use cases. Those IRs consist of operators from the target languages, describing their high-level semantics while avoiding low-level implementation details. For example, Casper [5] was built to translate sequential Java to MapReduce programs. The MapReduce framework consists of several versions of `map` that differ by their input types. However, Casper only defines one operator in its IR that models `map`’s functionality, and decides on the implementation to use during code generation. While doing so makes synthesis tractable, it also makes the compiler inflexible as adding another target (e.g., a hardware accelerator that supports `map` over tensors) will require modeling its functionality, which may be incompatible with the existing `map` from Casper’s IR.

To address this challenge, we designed a novel IR, TENSIR, by studying the DSLs provided by various software frameworks and hardware accelerators for tensor computation. TENSIR is rooted in tensor algebra and is designed for flexibility, allowing translation to both software (deep learning frameworks, vector processing libraries) and hardware environments (machine

learning accelerators) as to be discussed in Sec. 4.3. This flexibility enables developers to select which target to execute the translated code based on availability and specific performance requirements. Given the dynamic nature of tensor processing infrastructures, TENSIR can be modified easily in terms of both adding support for new tensor operators and new target backends. This is illustrated in Sec. 6, where it only took **200** lines of code for TENSPILER to support Apple’s recently introduced MLX framework [27].

Comparison with MLIR. MLIR [23] is a compiler infrastructure that enables the representation and transformation of code at various levels of abstraction. The core idea behind MLIR is to provide a unified IR that can capture the semantics of the program at different levels of detail (dialects), from high-level abstractions down to low-level, target-specific instructions. Developers can use MLIR by progressively lowering the code through different dialects until it reaches a level suitable for the target hardware. While MLIR and its dialects offer a powerful infrastructure for progressively targeting multiple hardware backends, we found that the existing dialects do not fully support all the operators required for our use case. Independently, both the `linalg` and `tensor` dialects do not support all the operators TENSIR supports. For example, the `select` operator, which is crucial for image processing kernels that apply operations conditioned on pixel values, is not supported by any MLIR dialects. Additionally, unifying these dialects can be challenging for developers. Instead of unifying, recent work such as mlirSynth [14] has explored using program synthesis to translate between different MLIR dialects. In contrast, TENSIR is designed to be flexible and easily extensible. Developers can add new operators to TENSIR by simply describing their high-level semantics, and new backend support can be incorporated by defining simple pattern-matching rules. This approach allows developers to extend TENSIR without going into the intricacies of MLIR. Moreover, TENSIR can practically be compiled into different MLIR dialects, providing developers the flexibility to leverage the MLIR infrastructure if desired.

3.1 Language Definition

The operators and grammar of TENSIR are shown in Fig. 2. TENSIR operates on tensors² and includes various operations. The core strength of TENSIR lies in `tensorOp`, which forms the backbone of tensor operations, including a diverse range of manipulations on tensors, such as element-wise operations, tensor vector multiplication, and reductions. These are grouped into different categories:

- `tensor_scalar` operations describe element-wise operations involving tensors and scalars, such as scalar multiplication of each element in a matrix.
- `tensor_tensor` operations perform element-wise operations between two tensors, such as element-wise multiplication of two tensors.
- Tensor reshaping such as `transpose`.
- `tensor_vec_prod` operation denotes tensor-vector products, enabling operations like matrix-vector multiplication.³
- Tensor reductions such as `reduce_max` and `reduce_sum`, which focus on aggregating tensor values, with the former determining the maximum element and the latter computing the sum across specified dimensions.

² In the grammar, the *Tensor Literal* refers to 1D or 2D tensors as we did not encounter higher dimensional tensors in our benchmarks.

³ While we can also define a tensor-tensor product operator, we did not encounter such benchmarks in our evaluation and hence omitted it from TENSIR’s grammar.

```

 $p \in Op := s_{comp} \mid t_{comp} \mid c_{control}$ 
 $t_{comp} \in tensorOp := tensor\_scalar(t, l, o) \mid tensor\_tensor(t, t, o) \mid$ 
 $\quad transpose(t) \mid tensor\_vec\_prod(t, t) \mid a$ 
 $s_{comp} \in scalarOp := reduce\_max(t) \mid reduce\_sum(t)$ 
 $o \in op := + \mid - \mid / \mid * \mid \%$ 
 $c_{control} \in controlflowOp := ite(cond, i, i)$ 
 $cond \in boolExpr := i \ rop \ i$ 
 $i \in inp := l \mid t$ 
 $rop \in relOp := > \mid < \mid == \mid \neg$ 
 $a \in accessOp := take(t, l) \mid tail(t, l) \mid slice(t, l, l_1, l_2)$ 
 $l := Integer\ Literal \mid size(t, l) \mid s_{comp}$ 
 $t := Tensor\ Literal \mid t_{comp}$ 

```

■ **Figure 2** TENSIR grammar.

The recursive nature of TENSIR’s grammar allows tensor operations to be composed, facilitating the expression of complex algorithms encountered in source code. TENSIR extends its expressiveness beyond tensor operations by also including a control flow operator (`controlflowOp`). It integrates control flow through the `ite` operator, enabling conditional logic into tensor computation. This operator is crucial for translating real-world loopy programs that contain branches.

TENSIR is notable not only for its diversity of operations but also for the granularity of each operator, which significantly enhances its utility in translating code. The fine-grained nature of operations, from basic element-wise computations to advanced tensor reductions and control flow constructs, allows the grammar to capture the diverse tensor computation present in the input. Moreover, the selected set of operations aligns with the core functionalities supported by most tensor processing infrastructures. This ensures that TENSIR can seamlessly integrate with various frameworks and accelerators, offering flexibility in supporting multiple target DSLs. This comprehensive yet concise grammar serves as a bridge between traditional loop-based programming paradigms and the highly parallelizable world of tensor computation, providing a clear and expressive language for describing mathematical operations on tensors.

Besides tensor operations, TENSIR also supports tensor accessing and manipulation:

- `take(t, n)` extracts `n` elements from the beginning.
- `tail(t, n)` returns all the elements in tensor `t` after the first `n` elements.
- `slice(t, l, s, e)` extracts a contiguous sub-tensor from `t` from indices `s` (inclusive) to `e` (exclusive) along dimension `l`.
- `size(t, l)` returns the size of tensor `t` in dimension `l`.

Such functions are used to express the loop invariants and program summaries in the synthesis phase, as we describe next.

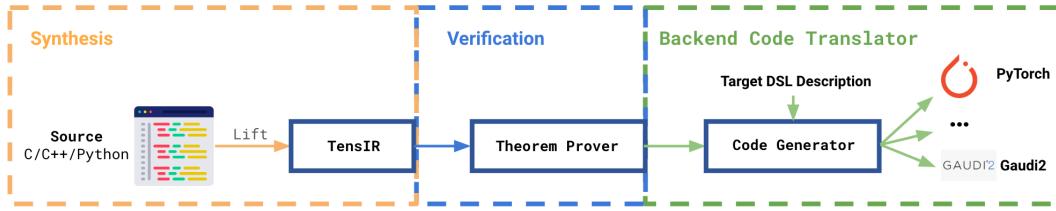

Figure 3 An overview of the TENSPILER Framework.

4 Transpiling Code Using Tenspiler

As shown in Fig. 3, TENSPILER is designed to translate a program in high-level languages, source (S), into another program that leverages different tensor processing infrastructures. TENSPILER currently support a vector processing library (NumPy) for CPU execution, DL frameworks (PyTorch, TensorFlow, MLX) for GPU execution, and ISAs for specialized hardware accelerators (Gaudi, Gemmini). TENSPILER is a verified-lifting-based compiler, leveraging search to find a program within the target domain. Instead of relying on traditional pattern-matching rules, TENSPILER translates source programs with a 3-phase workflow:

1. synthesis,
2. verification, and
3. backend code generation.

TENSPILER uses a single IR, TENSIR, to facilitate all 3 phases of its workflow. TENSIR is designed to include tensor processing operators common to all target backends. As shown in the figure, the synthesis phase takes in S and generates a program summary expressed using TENSIR. Then, in the verification phase, TENSPILER verifies the generated summaries to ensure their semantic equivalence with S . Finally, in the code generation phase, the TENSIR program is translated to the concrete syntax of the target DSL(s).

4.1 Synthesis

The objective of this phase is to search for a program expressed using the operators in TENSIR, and to ensure that the generated program is semantically equivalent to S . We formulate the search as a SyGuS problem [8] characterized by three parameters:

1. the **specification** describing the property the synthesized TENSIR expression should satisfy,
2. the **search space** that describes the space of possible solutions,
3. the **search algorithm** which searches for the candidate programs.

For TENSPILER, the specification is to find a functionally equivalent program to S . Various methods exist to express this specification, such as using input-output examples, bounded-model checking, and verification conditions (VC) [18].

In TENSPILER, we use VCs as the specification for the synthesis phase as it provides full guarantees (i.e., for all program states up to a bound, e.g., states where all integers are encoded using 8 bits) on the equivalence of S and the translated program. VCs are logical expressions encoding the correctness properties of S .

Specifically, given a program P with $vars$ representing all the variables appearing in P , and pre , $post$, inv representing the pre-conditions, the post-condition, and the invariant(s), respectively, the VCs for a program with loops consist of the following clauses:

1. **Initial Condition:** $\forall vars. pre(vars) \rightarrow inv(vars)$: loop invariants must hold before the loop begins its execution.
2. **Loop Preservation:** $\forall vars, vars'. inv(vars) \wedge P(vars, vars') \rightarrow inv(vars')$: if the invariant holds before a loop iteration, they should continue to hold after that iteration.
3. **Post-Condition:** $\forall vars. inv(vars) \rightarrow post(vars)$: invariants should hold once the loop has completed its execution.

There exist standard techniques for generating VCs from a given source program [11]. In TENSPILER, the *PS* and invariants in the VCs are generated as placeholders as **S** is analyzed, with their bodies to be synthesized during the synthesis phase.

Next, we define the search space for synthesis. This space outlines the potential solutions for both the *PS* and invariant(s), describing the solutions that could potentially satisfy the VC. Expressed as a context-free grammar (CFG), the search space imposes syntactic constraints on the structure of the outputs. In TENSPILER, the goal is not to find any *PS* or invariants but ones that represent the output variables in **S** as some sequence of operators from TENSIR, expressed mathematically as:

$$\forall o \in outputVars. o = p, \text{ where } p \in Op \text{ as defined in Fig. 2.} \quad (1)$$

This states that all return variables in **S** should be expressed as a program from TENSIR. With the specification in the form of VCs, *p* expressed using TENSIR, and the search space for the *PS* and invariants, the synthesis problem can be formally defined as:

$$\exists inv_0, inv_1, \dots, PS \in G. \forall \sigma. VC(S, inv_0, inv_1, \dots, PS, \sigma) \quad (2)$$

The goal of synthesis is then to find expressions from the search space *G* for *PS* and *invs* such that, for all program states σ , they satisfy the VC.

For TENSPILER, we use an off-the-shelf symbolic search engine, Rosette [36], which uses constraint solving to address the synthesis problem. In a constraint-solving-based approach, the specification ϕ (i.e., VC) and the search space *G* are encoded as a single formula, and an SMT solver is then utilized to find a model that satisfies the formula. As a constraint-based solver, increasing the number of constraints makes the problem more challenging. Given that ϕ is fixed for a particular benchmark, the design of the *G* becomes crucial. In Sec. 5, we discuss how the design of TENSIR helps keep the grammar size reasonable and scales the synthesis process.

4.2 Verification

During the synthesis phase, as the *PS* and loop invariant(s) are validated against the VC only for a bounded set of program states,⁴ it is essential to check their validity for all program states. TENSPILER uses an SMT solver to do so by negating the VC in program verification i.e., checking if $\neg VC(S, inv_1, inv_2, \dots, PS, \sigma)$ is satisfiable for some σ . The placeholders in the VC are substituted with the synthesized bodies of *PS* and *invs*. If the solver cannot find any such σ , then the generated *PS* and *invs* are correct for all possible program states, thus proving *PS* and *invs* hold for all program states. If a σ is found, then TENSPILER will iterate back to the synthesis phase in search of another candidate expression.

Besides using SMT solvers for Eq. (2), TENSPILER also leverages SMT solvers' support of algebraic data types (ADT) to allow users to define common data structures such as lists and tuples. Internally, TENSPILER models tensors using the list data structure defined using

⁴ We are unaware of any SyGuS solvers that can validate against an unbounded set of program states efficiently, including state of the art solvers such as Z3 and CVC5.

```

1  (assert (forall ((data (Tensor Int)) (a Int) (idx Int))
2  (=> (>= index 0) ∧ (≤= index len(data))
3  (= t_s(data[:idx], a, *) (+ [data[0]*a] t_s(data[1:idx], a, *))))))

```

 **Figure 4** Example of an inductive axiom for the `tensor_scalar` operator in TENSIR described using SMT-LIB. “+” corresponds to the concat operator.

ADTs. We use ADT’s accessor and constructor functions to retrieve and create new tensors. All the tensor accessing functions like `slice`, `take` are modeled as recursive functions over the list data structure. Currently, while image processing kernels use integers and deep learning kernels operate over floats, we verify all the benchmarks using the theory of integers and reals, due to poor solver support for reasoning about floats.

Since the verification of loop invariants is undecidable in general, we define additional *axioms* for the operators in TENSIR to aid verification. These axioms describe the behavior of functions that cannot be automatically deduced by the solver. Identifying the axioms requires an understanding of the program’s semantics and the properties that need verification. Such axioms describe simple attributes such as distributivity, associativity, and commutativity of the tensor operators. In Fig. 4, we show an inductive axiom for the `tensor_scalar` operator which states that the result for a given index is determined by the product of the first element of the tensor and an integer, plus the result for the remaining sub-tensor up to that index. As shown, having tensors as first-class objects in TENSIR greatly simplifies the task of defining these properties. Instead of defining these properties using low-level SMT-LIB list data structures, TENSIR enables users to define them at the tensor level, abstracting away the low-level solver-related details. This high-level representation greatly simplifies the task of defining these properties and makes the axioms more readable and maintainable.

4.3 Code Generation

After successfully verifying the synthesized TENSIR program, the final stage in TENSPILER’s workflow is to translate the TENSIR program into the concrete syntax of a target DSL. TENSIR makes this easy as it inherently represents tensor operations supported by all the target DSLs, and code can be generated using simple syntax-driven rules that map TENSIR operators to their DSL-specific counterparts.

To translate the TENSIR expression into an executable DSL program, our code generation step recursively processes each part of the TENSIR expression. Fig. 5 illustrates a portion of the code generation function for PyTorch. The function maps TENSIR variables to their names (line 3), literals to their values (line 5), and function calls to their PyTorch equivalents based on function signatures (lines 6-15).

Consider the running example in Fig. 1a, where the synthesized TENSIR solution is `t_t(t_t(b, a, +), t_s(t_t(b, a, *), 255, /), -)`. This expression represents a `t_t` function call with the `-` operator, which maps to `torch.subtract` as shown in line 13. Next, the `codegen` function is called recursively on the two arguments, `t_t(b, a, +)` and `t_s(t_t(b, a, *), 255, /)`. This results in the final translated PyTorch expression as `torch.subtract(torch.add(b, a), torch.divide(torch.add(b, a), 255))`.

To extend support for a new backend, one simply needs to replace the DSL operator names in lines 11, 15, 17, and 19. For example, in MLX’s codegen, `torch.add` on line 11 would be replaced by `mlx.core.add`.

This direct and syntactic translation simplifies the integration of new tensor-based target DSL into TENSPILER, as one would only need to add simple translation rules in the code generation process. For instance, we add support for MLX by changing only 65 lines of code to an existing 200-line template, as its API closely follows that of NumPy.

```

1 def codegen(expr: Expr):
2     if isinstance(expr, Var):
3         return expr.name()
4     elif isinstance(expr, Lit):
5         return expr.val()
6     elif isinstance(expr, Call):
7         f_name, args = expr.name(), expr.arguments()
8         if f_name in {"t_t", "t_s"}:
9             op = args[-1]
10            if op == "+":
11                return f"torch.add({codegen(args[0])},{codegen(args[1])})"
12                #corresponding MLX return statement
13                #return f"mlx.core.add({codegen(args[0])},{codegen(args[1])})"
14            elif op == "-":
15                return f"torch.subtract({codegen(args[0])},{codegen(args[1])})"
16            elif op == "*":
17                return f"torch.multiply({codegen(args[0])},{codegen(args[1])})"
18            elif op == "/":
19                return f"torch.divide({codegen(args[0])},{codegen(args[1])})"
20            ...

```

Figure 5 Code generation for the element-wise add operator to different targets.

As a part of this work, we have implemented support for **six** different target DSLs in our code generator: **NumPy**, **TensorFlow**, **PyTorch**, **MLX** (an ML framework for Apple silicon), **TPC-C** (C-based programming language for Intel’s Gaudi processor), and **Gemmini** (an open-source neural network accelerator generator).⁵

5 Synthesis Optimizations

A naive approach to constructing the grammar for search space is to enumerate all possible combinations of TENSIR expressions up to a fixed depth. For TENSIR as defined in Fig. 2, if we focus solely on the compute operators, a depth-4 grammar (i.e., sequence of 4 operators) results in a search space of $\sim 200k$ expressions, since it grows exponentially with the depth and the number of operations. In Fig. 6, we show a small part of the depth-4 grammar. We have devised several optimizations to reduce the search space and make the search tractable.

5.1 Restricting Operators

First, we generate the grammar based on types, i.e., we only include the operators whose output types match with the expected return type. In the case of **S** in Fig. 1a, since the return type is `vector<vector<int>>`, all reduction operations are excluded. In Fig. 6, the operators in v_4 and l_4 will be removed (shown in red). These correspond to operators returning 1-D vectors and integers respectively.

5.2 Restricting Program States

We further optimize the search space by restricting the set of program states in Eq. (2). Instead of satisfying the VC for all σ , we find PS and $invs$ that satisfy a bounded set. Bounded synthesis is crucial because most SyGuS solvers have limited support for recursive function definitions and require SMT solvers for validation. However, SMT solvers lack inherent support for reasoning about TENSIR operators that are not covered by the standard theories defined in SMT-LIB [9] and require additional axioms to be defined. We instead

⁵ We provide further details of these DSLs in Appendix A in the extended version of this paper[29].

```

out   := m4 | v4 | l4
m4  := tensor_scalar(m3, l4, o) | tensor_tensor(m3, m3, o) |
          transpose(m3) | ite(cond4, m3, m3) | m3
v4  := tensor_scalar(v3, l4, o) | tensor_tensor(v3, v3, o) |
          tensor_vec_prod(m3, v3) | ite(cond4, v3, v3) | v3
l4  := reduce_max(l3) | reduce_sum(l3) | l3
cond4 := l3 rop l3
...
l1  := 255 | size(t1)
t1  := a⟨a1, a2 ... an⟩ | b⟨b1, b2 ... bn⟩ a⟨a1, a2⟩ | b⟨b1, b2⟩
rop  := > | < | == | ∼
o    := + | - | / | *

```

 **Figure 6** A depth 4 general synthesis grammar for the source in Fig. 1a.

integrate bounded synthesis by restricting the maximum unrollings of recursive operators, thereby eliminating the need for additional axioms. Specifically, we restrict the program states by limiting the lengths of the data structures and the sizes of the data types. For instance, in TENSPILER, we constrain all 1D tensors to length 2 and the integers to 6 bits or less for the first rounds of synthesis. In Fig. 6, all the tensor literals in t_1 are changed from an unbounded length “n” (shown in orange) to length 2 (shown in blue). If the synthesized choices fail to verify, we then increase the bounds in subsequent rounds. Note that since the synthesized solutions only work for a restricted set of program states, we invoke the theorem prover for subsequent verification to check if PS and $invs$ are valid for all states.

5.3 Leveraging Expression Trees

Despite the above two optimizations, the synthesis search space remains large. For example, in the context of S in Fig. 1a for which we need to synthesize two $invs$ and one PS , a depth-4 grammar, after removing the reduction operations, still presents around 100k potential solutions just for PS . TENSIR plays a significant role in the further pruning of this search space. The design of TENSIR operators effectively bridges the gap between high-level tensor operations and the loop-based paradigm commonly used for computing on tensors. This property of TENSIR allows us to leverage the expression-tree-based filtering approach, which we describe next, to efficiently prune the synthesis search space.

Our approach starts with the static analysis of S to identify the computations performed; the static analysis pass emits an expression tree that represents the computation. For example, the pre-order traversal of the expression tree for S from Fig. 1a is: (- (+ b a) (/ (* b a) 255)). In Fig. 6, this results in the pruning of `tensor_scalar` and `ite(cond5, m4, m4)` at the top-level (shown in teal) and similarly operators at other depths (m_4, m_3) are filtered. The generated expression tree is then transformed into an abstract expression tree, where variables and constants are replaced with placeholders, resulting in a synthesis template.

The abstract expression tree for S is then: $(- (+ \text{var} \text{ var}) (/ (* \text{var} \text{ var}) \text{lit}))$. This abstract expression tree guides TENSPLIER in identifying the sequence of TENSIR operators. In this example, TENSPLIER deduces the sequence of operators from the tree as: $t_t(t_t(\text{var}, \text{var}, +), t_s(t_t(\text{var}, \text{var}, *), \text{lit}, /), -)$, where var and lit are variables and literals to be synthesized, respectively.

Our expression trees are amenable to vectorized operations, which simultaneously perform the same computation on multiple data elements. Specifically, each level of the tree corresponds to an operation with the branches indicating data flow. In the example expression shown above, we see element-wise subtraction, addition, scalar division, and element-wise multiplication orchestrated such that it aligns with the vectorized execution of the original computation.

This approach is not confined to specific operators but is adaptable to a range of operations in TENSIR. It can identify constructs like if-else blocks, where *ite* arguments are determined using the same expression tree strategy, allowing the synthesis process to determine the optimal sequence of operators within the constructs. This flexibility extends to reduction operators and other complex operations, aiding in the synthesis of efficient operational sequences.

5.4 Constraining Variables

The final optimization is to pinpoint specific variables (*vars* such as a, b in Fig. 1a) and literals (*lits* such as 255 in Fig. 1a) to be used in the grammar. Specifically, we constrain the variables to the set of live variables and also constrain constants to the set of constants that have appeared in the program. This strategy simplifies the computational task, avoiding the complexity of synthesizing a complete depth-4 operator sequence. By leveraging our expression tree-based approach, the search space reduces to 64 expressions, and the synthesizer promptly yields the correct solution within 76 secs: $t_t(t_t(b, a, +), t_s(t_t(b, a, *), 255, /), -)$.

5.5 Overall Synthesis Algorithm

The algorithm described in Fig. 7 summarizes the synthesis phase in TENSPLIER. This phase is used to search for the bodies of PS and invariants which satisfy the VC. The synthesis is an iterative process conducted over multiple rounds, assuming a filtered search space leveraging type-based and expression tree optimizations described earlier. We start with the tensor bound size set to 2 which corresponds to restricting the program states optimization. In each round, we invoke Rosette’s search algorithm (line 5) to generate candidates for PS and $invs$. Upon obtaining a solution, the candidate undergoes validation against the VC for all program states, as the synthesis phase only checks within a constrained set of program states. We invoke a verifier (CVC5) (line 8) to perform this check. If the verifier yields “UNSAT,” the generated candidates are correct. Conversely, if “SAT” is returned, indicating incorrect candidates (line 11), the VC is augmented with blocking constraints. These constraints state that the generated PS or $invs$ in next round should differ from those in the previous rounds. This iterative process continues for a specified number of rounds (`max_rounds`) before incrementing the tensor bound sizes. In cases where Rosette’s search algorithm does not produce a solution initially (line 13), indicating an overly restrictive grammar, the initial grammar is expanded to include additional options for both PS and invariants, such as choices for loop bounds, indexing, and operator sequences. We keep a separate timer (not shown in Fig. 7) that maintains a maximum time bound for the entire synthesis process.

```

1  def synthesis_algorithm(spec, tensor_size_bound, holing_grammar, search_algorithm,
2      verifier, max_rounds, timeout):
3      r = 0 # rounds within one list bound
4      #bounded synthesis optimization
5      while r < max_rounds:
6          ps_inv = search_algorithm(spec, holing_grammar) #rosette
7          if ps_inv is not None:
8              ps_r, inv_r = ps_inv
9              if verifier(specification, ps_r, inv_r) == "UNSAT": return ps_r, inv_r
10             else:
11                 spec = spec and (ps != ps_r) and (inv != inv_r) #add blocking constraint
12                 r += 1
13             else:
14                 expand_holing_grammar(holing_grammar)
15             # Increment tensor size bound
16         return synthesis_algorithm(spec, tensor_size_bound + 1, holing_grammar,
17             search_algorithm, verifier, max_rounds, timeout)

```

6 Experiments

We evaluate TENSPILER’s effectiveness in converting code into various tensor processing infrastructures using 10 loop-based real-world benchmark sets: **blend**, **Llama** [24], **blas**, **darknet**, **dsp**, **dspstone**, **makespeare**, **mathfu**, **simpl_array**, and **utdsp**. The **blend** benchmarks focus on image processing kernels, the **Llama** benchmarks contain traditional deep learning applications, and the rest 8 are all sourced from various existing software libraries, such as the BLAS linear algebra library and the TI signal processing library, and are used recently to evaluate C to TACO translations [25]. This combination of benchmarks allows for a comprehensive assessment of TENSPILER’s effectiveness and adaptability across diverse domains and programming paradigms.

1. Used in prior work [6], the **blend** benchmarks consist of 12 functions dedicated to point-wise image blending operations – a fundamental aspect of image processing known for diverse visual effects. These functions span 180 lines of C++ code, and 10 are characterized by doubly-nested loops, which are common in image processing algorithms.
2. **Llama** benchmarks are derived from the C++ based inference code of Llama2 [24], an open-source LLM from Meta. We labeled the portion of code to be lifted from the source code without doing any extensive syntax or code logic edits. These benchmarks include 11 functions capturing essential operations like computing activations, attention mechanisms, and layer norms. They total around 106 lines of code, with 2 functions incorporating doubly-nested loops.
3. **blas**: 2 benchmarks from the BLAS [13] linear algebra library.
4. **darknet**: 10 neural network functions sourced from the Darknet [2] deep learning framework.
5. **dsp**: 12 signal processing functions from the TI library [4].
6. **dspstone**: Kernels from the DSPStone suites [38] that target digital signal architectures.
7. **makespeare**: Programs originally from Rosin [31] that manipulate integer arrays.
8. **mathfu**: 11 mathematical functions extracted from the Mathfu library [3].
9. **simpl_array**: 5 functions for computations on integer arrays originally from prior work [35].
10. **utdsp**: Kernels from the UTDSP suite [33] that targets digital signal architectures.

6.1 Evaluation Setup

The synthesis and verification phases for all benchmarks are executed on a MacBook Pro 2 GHz Quad-Core Intel Core i5 Processor with a timeout of 1 hour. After lifting the code to TENSIR, the code generator, as explained in Sec. 4.3, generates executable code for each target backend. In the next section, we first describe the datasets used for evaluating the performance of lifted benchmarks. Then, we describe each target backend used for executing these benchmarks.

6.1.1 Datasets for Evaluation

To mimic real-world settings, we evaluate the translated code on actual datasets instead of generating random inputs.

For the **blend** image processing benchmarks, **blas**, **darknet**, **dsp**, **dspstone**, **makespeare**, **mathfu**, **simpl_array**, and **utdsp**, we source images from ImageNet [17], a large-scale image dataset. We process these images as grayscale to ensure pixel values fall within the appropriate range. For benchmarks with 1-D tensor inputs, we flatten the images before feeding them as inputs and pass them in as they are for 2-D tensor inputs. For the blending layers in the blend benchmarks, we generate random pixel values from 0 to 255. We randomly select a set of 10,000 images from the dataset for evaluation.

For the **Llama** benchmarks, we evaluate the synthesized code using weights from Vicuna [16], an open-source LLM with similar model size as Llama2.⁶ Some kernels operate over model weights, for which we directly use the weight matrices from Vicuna. For kernels operating over inputs, we simulate embeddings by creating random 32-bit float vectors within the range [0, 1). The evaluation primarily uses the 33B-parameter Vicuna model; however, for evaluating the MLX framework, the 7B-parameter version is used due to memory limitations.

6.1.2 Target Software Frameworks and Hardware Accelerators

The core objective of TENSPILER is to translate sequential programs to a spectrum of diverse target DSLs, which can then be executed on conventional CPUs, GPUs, or specialized hardware accelerators. Although finding the optimal target DSL for the given input program would be an interesting feature in TENSPILER, currently TENSPILER is designed to provide users with the flexibility of choosing their preferred environment.

For our experimental evaluation, we choose 6 different target DSLs as we mentioned in Sec. 4.3: **NumPy**, **TensorFlow**, **PyTorch**, **MLX**, **TPC-C**, and **Gemmini**. We believe that our comprehensive selection of DSLs is necessary to test the robustness of TENSPILER.

The TENSIR design greatly simplified this process as NumPy, TensorFlow, PyTorch, and MLX have similar APIs, and each of these DSLs uses only 200 lines of code for generating executable code.

To establish a baseline for execution performance, we compile C++ code for all the benchmarks using `gcc-8.3.0` with `-O3` flag and then run them on an Intel Xeon 8380 CPU. Given that each DSL is tailored to enhance performance on specific hardware, we conduct evaluation across five distinct platforms: the Intel Xeon 8380 CPU, Nvidia V100 GPU, Apple M1 Pro, Intel Gaudi 2 processor, and the Gemmini accelerator.⁷ In all, we utilized 7 different

⁶ We did not use Llama2 model weights as they are not publicly available.

⁷ Due to lack of physical device, Gemmini evaluations are done on a simulator with limited computing power and no file system support. Thus, it is compared with smaller random inputs.

DSL-hardware device combinations for our experiments: (1) NumPy-CPU, (2) TensorFlow-V100, (3) PyTorch-V100, (4) MLX-Apple M1 (5) TPC-C-Gaudi, (6) PyTorch-Gaudi, and (7) Gemmini. This comprehensive mapping of each backend to its corresponding device enables us to accurately assess the benefits TENSPILER provided through lifting.⁸

6.2 Synthesis Timings

In this section, we present the time TENSPILER takes to synthesize and verify solutions for each of our benchmarks. During the synthesis phase, we apply all the optimizations mentioned in Sec. 5 with a 1 hour timeout. TENSPILER synthesizes the correct translations for all the benchmarks under **15 mins**.

Fig. 8 illustrates the synthesis performance for our 10 benchmark suites. Fig. 8a illustrates the synthesis performance for the **blend** benchmarks. All but three benchmarks are synthesized in one synthesis (and verification) iteration, with an average synthesis time of 40.7 seconds and a median synthesis time of 2.357 seconds. Single-loop benchmarks synthesize with an average of 2.17 seconds and a median of 1.92 seconds. Double-loop benchmarks, on the other hand, have an average of 128.91 seconds and a median of 22.74 seconds for synthesis.

The three benchmarks that take more than one round of synthesis are **softmax1**, **transformer1**, and **transformer2** from the **LLama** suite. **softmax1** fails to synthesize within one round because the initial grammar is overly restrictive for its loop invariant. **transformer1** and **transformer2** involve complex indexing constraints for their invariants, initially leading to spurious solutions with tensor size limit of 2. **transformer2** finds the correct solution after 6 tries, while **transformer1** exhausts the maximum number of tries (10) with tensor size 2. We then increase the tensor size limit to 3 for **transformer1** and a correct solution is generated within 3 rounds.

6.2.1 Analysis

We observe that synthesis difficulty is correlated to both the number of loops and the complexity of the TENSIR solution. For example, the **dot** benchmark in the blas benchmark set has a single loop. Its TENSIR solution is `reduce_sum(t_t(a, b, *))`, which has two operators and only two arguments, **a** and **b**, to be synthesized. This benchmark synthesizes in around two seconds. On the other hand, the **transformer_part1** benchmark from the **LLama** benchmark set has a doubly-nested loop and a complex solution with six operators. All arguments to these operators must be synthesized, with some requiring 3 expressions such as `head * head_size + head_size` and `sqrt(head_size * 1)`. This benchmark takes around 1300 seconds to synthesize.

In addition to synthesis challenges, we recognize that the tree approach may restrict the ability of TENSPILER to synthesize different solutions. However, through manual verification, we confirm that TENSPILER consistently generates optimal solutions across our benchmarks. We evaluate the solutions using expression length as the cost function. Generally, shorter expressions mean fewer function calls and thus lower execution cost. To illustrate, we use the **linear_dodge** example from the **blend** benchmarks for which the synthesized solution is as follows:

```
def linear_dodge(a, b): t_t(a, b, +)
```

⁸ The exact configurations of all the hardware devices and their software environments are described in Appendix C in the extended version of this paper[29]

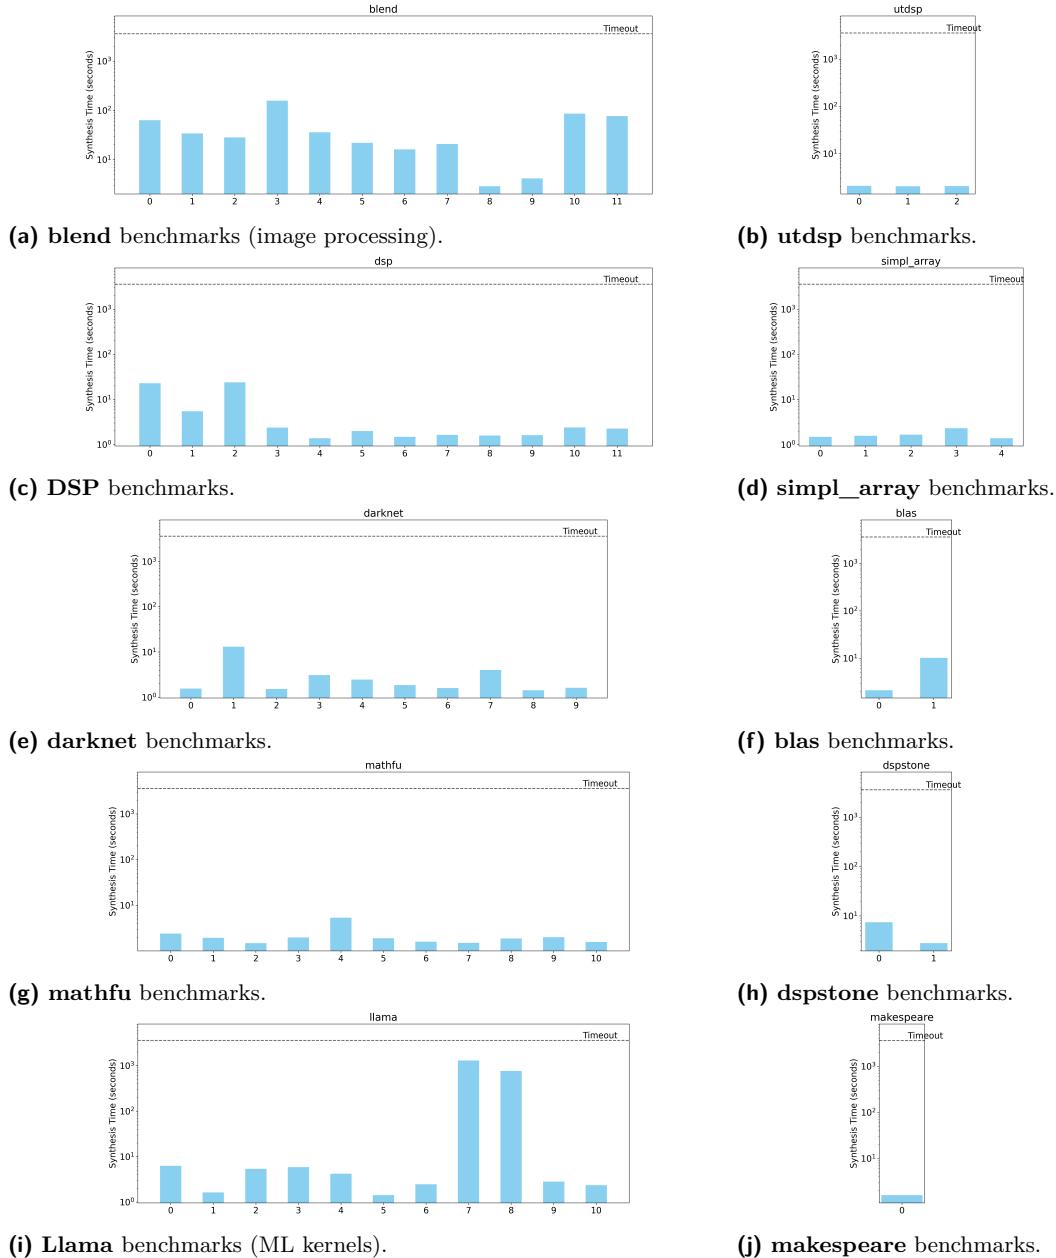

Figure 8 Synthesis timings for all the benchmark suites. Benchmark name legend in Appendix B in the extended version of this paper[29].

After relaxing the constraint on the tree structure, we were able to synthesize a different solution as shown below:

```
def linear_dodge(a, b): t_t(a, t_s(b, -1, *), -)
```

The latter solution is longer in length, and involves **2** tensor operations – a **tensor_tensor** operation and a **tensor_scalar** operation – as opposed to **1** **tensor_tensor** operation synthesized using the tree approach. Therefore, it is less optimized. In addition, the tree approach also speeds up the synthesis process as shorter expressions are easier to synthesize.

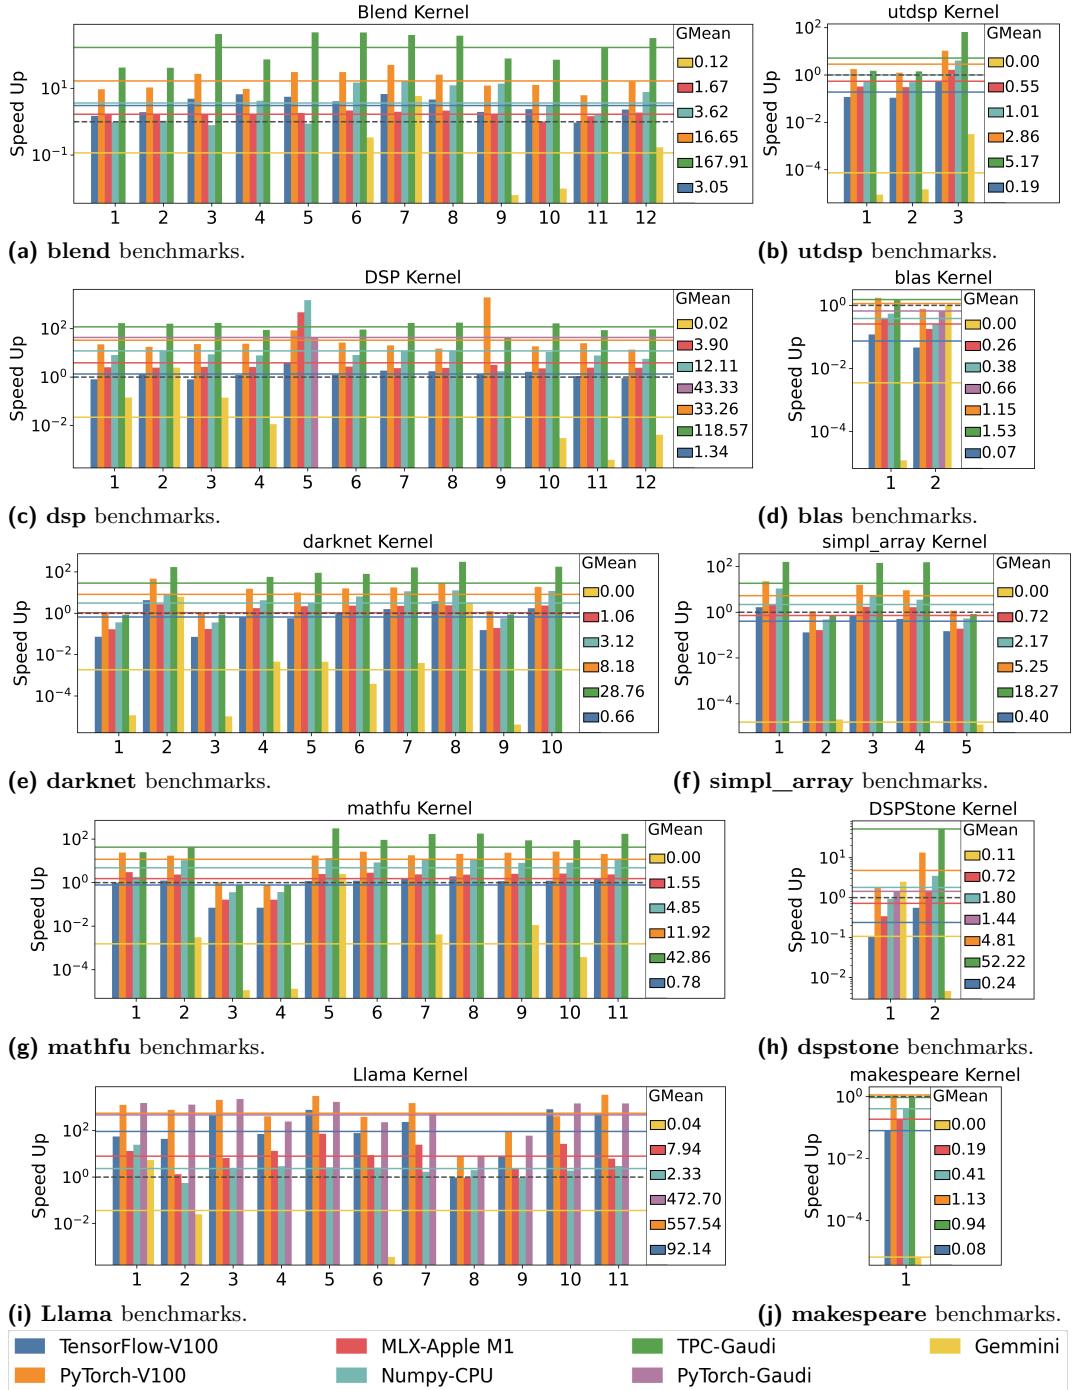

Figure 9 Kernel speedup over baseline. Benchmark name legend in Appendix B in the extended version of this paper[29].

6.3 Performance Timings

In this section, we evaluate the performance of the original input code – sequential C++ programs compiled with `gcc -O3` – by comparing them with their translated versions executed across different target backends as detailed in Sections 6.1.2 and 6.1.1.

Kernel Performance. Kernel performance focuses on computation time excluding data transfer overhead. We see significant improvements as illustrated in Figures 9, with an average speedup of **105.1 \times** across all benchmarks. Notably, the Gaudi 2 processor demonstrates an exceptional speedup of **241 \times** , highlighting the advantages of migrating legacy code to newer hardware platforms. For other backends such TensorFlow, PyTorch, MLX and NumPy we see speedups of **46 \times** , **244 \times** , **10.5 \times** and **26.12 \times** respectively.

However, compatibility issues can emerge with certain backends. For example, the Gemmini accelerator does not support certain operations in our TENSIR like `tensor_tensor` element-wise multiplication, `slice`, and `tail`. To address this, we only translate supported TENSIR operations from the synthesized *PS*, and default to running the unsupported operations using sequential C on CPUs. Out of 69 benchmarks, 41 are translatable to Gemmini’s instruction set architecture (ISA), yet only 10 can be fully expressed using Gemmini instructions alone. Challenges are notable in benchmarks like `screen_blend` (Fig. 9a), where element-wise vector multiplication must fallback to execution on a less powerful CPU. Furthermore, most Gemmini’s instructions require square matrices inputs. This means that we need to pad vector inputs to square matrices before being able to utilize Gemmini’s instructions, effectively squaring the data volume to be processed. This results in varied performance as shown in Fig. 9i and Fig. 9e.

End-to-end Performance. While frameworks and accelerators deliver substantial kernel performance enhancements, a comprehensive assessment must account for end-to-end benchmark times, encompassing initial setup and data movement between the host (CPU) and the accelerator device. Our focus here is on data transfer (TensorFlow, PyTorch, and Gaudi processor) and memory management (C++). As illustrated in Fig. 10, we again observe an overall speedup, averaging **9.7 \times** . In particular, CPU libraries like NumPy and MLX show more improvements with the notable advantage of avoiding transferring data to specialized hardware. These benchmarks, involving the processing of 1D or 2D character vectors, benefit largely from C++’s efficient handling of contiguous data structures. Meanwhile, Gaudi 2 drivers encounter performance bottlenecks due to the overheads associated with hardware initialization and frequent small data transfers. This significant upfront cost, especially pronounced in small-scale data operations, leads to a much less announced speedup. We believe such a phenomenon is uncommon in real-world use cases such as training deep learning models, due to techniques like batch processing or pipelining to minimize data transfers or to overlap computations with communications, thereby reducing or hiding transfer overhead and enhancing overall efficiency.

Compare Against Pattern Matching-Based Compilers. As outlined in Sec. 1, TENSPILER is designed to address the limitations inherent in traditional compilers that rely on pattern matching to compile. Such compilers are resource-intensive to develop and prone to errors. To the best of our knowledge, no existing compiler matches the breadth of DSL support offered by TENSPILER. However, specialized compilers, such as Numba [28], have been introduced for accelerators like GPUs. Numba leverages LLVM IR to generate GPU-accelerated code from Python code, making it a suitable candidate for comparison.

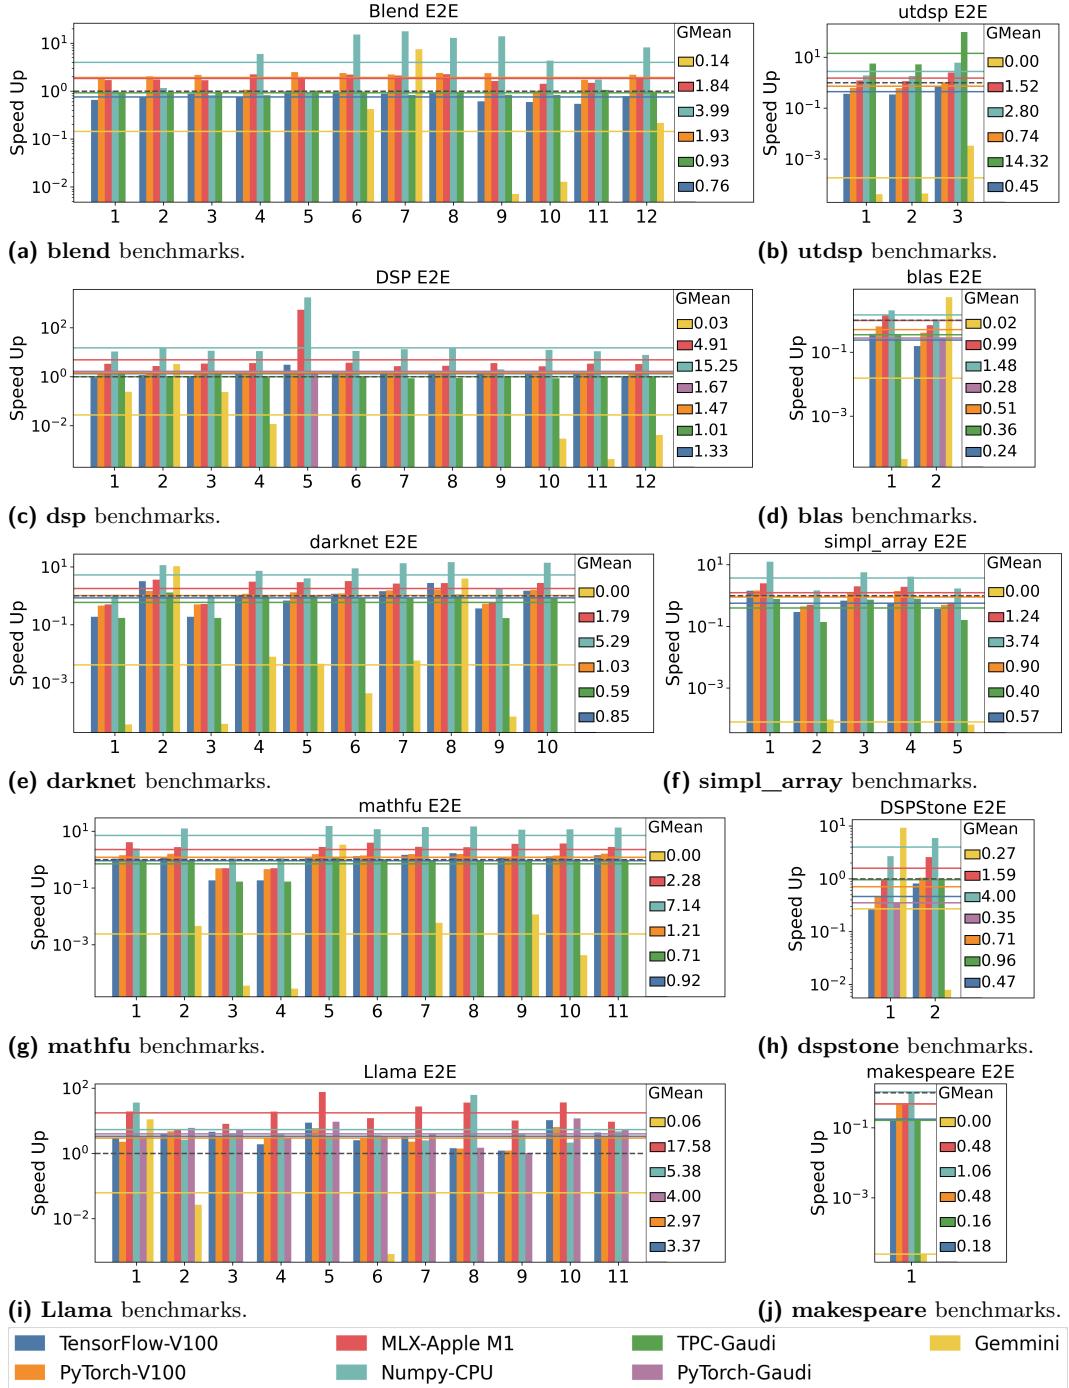

Figure 10 E2E speedup over baseline. Benchmark name legend in Appendix B in the extended version of this paper[29].

```

1  vector<float> matmul(vector<vector<float>> weight, vector<float> input) {
2      vector<float> output;
3      int m = weight.size();
4      int n = input.size();
5      for (int row = 0; row < m; row++) {
6          float curr = 0;
7          for (int col = 0; col < n; col++) {
8              curr += weight[row][col] * input[col];
9          }
10         output.push_back(curr);
11     }
12     return output;
13 }
```

(a) Original `matmul` function in C++.

```

1  @cuda.jit()
2  def matmul (weight, input, res):
3      m = len(weight)
4      n = len(input)
5      for i in range(m):
6          curr = 0
7          for j in range(n):
8              curr += weight[i][j] * input[j]
9          res[i] = curr
10 
```

(b) Numba kernel annotated version of `matmul`.**Figure 11** Manually rewritten Numba example.

For benchmarking purposes, we utilize the same datasets, test cases, and setup described previously in Sec. 6. Benchmarks are rewritten in Python and adapted to conform to CUDA kernel requirements by removing return statements, as shown in Fig. 11. Additionally, relevant data are cast to NumPy arrays as Numba focuses on optimizing code written against NumPy’s API. These syntactic requirements represent a limitation of Numba’s approach. In contrast, TENSPLIER operates directly on the original benchmark implementations.

Experimental results demonstrate that GPU-based PyTorch and TensorFlow code generated by TENSPLIER performs, on average, 1.87 \times faster than code annotated with Numba. Remarkably, while Numba benefits from years of development by expert engineers, TENSPLIER achieves superior performance with only 200 additional lines of code dedicated to code generation. A closer examination of the compiled PTX assembly code for the `matmul` benchmark, which shows a 2.6 \times speedup, reveals that the Numba-generated code lacks the use of advanced instructions and techniques such as fused multiply-add (FMA), tiled-based computation models, or shared memory,⁹ which are crucial for peak performance. These techniques are standards in PyTorch and TensorFlow with optimized kernels. In contrast, Numba requires extensive manual tuning to implement, evident in the more complex and faster `matmul` example in its documentation.¹⁰ TENSPLIER, by automatically recognizing and translating matrix multiplication operations to leverage the pre-optimized kernels, avoids the complexities of manual code optimization while achieving high performance.

6.4 Ablation Study

In our ablation study, we evaluate using our benchmark suites the effectiveness of the optimizations (described in Sec. 5) in making synthesis scale.

⁹ See Appendix D in the extended version of this paper[29] for the PTX code.

¹⁰ For the detailed example of an optimized `matmul` function with shared memory for Numba, see <https://numba.readthedocs.io/en/stable/cuda/examples.html#id30>

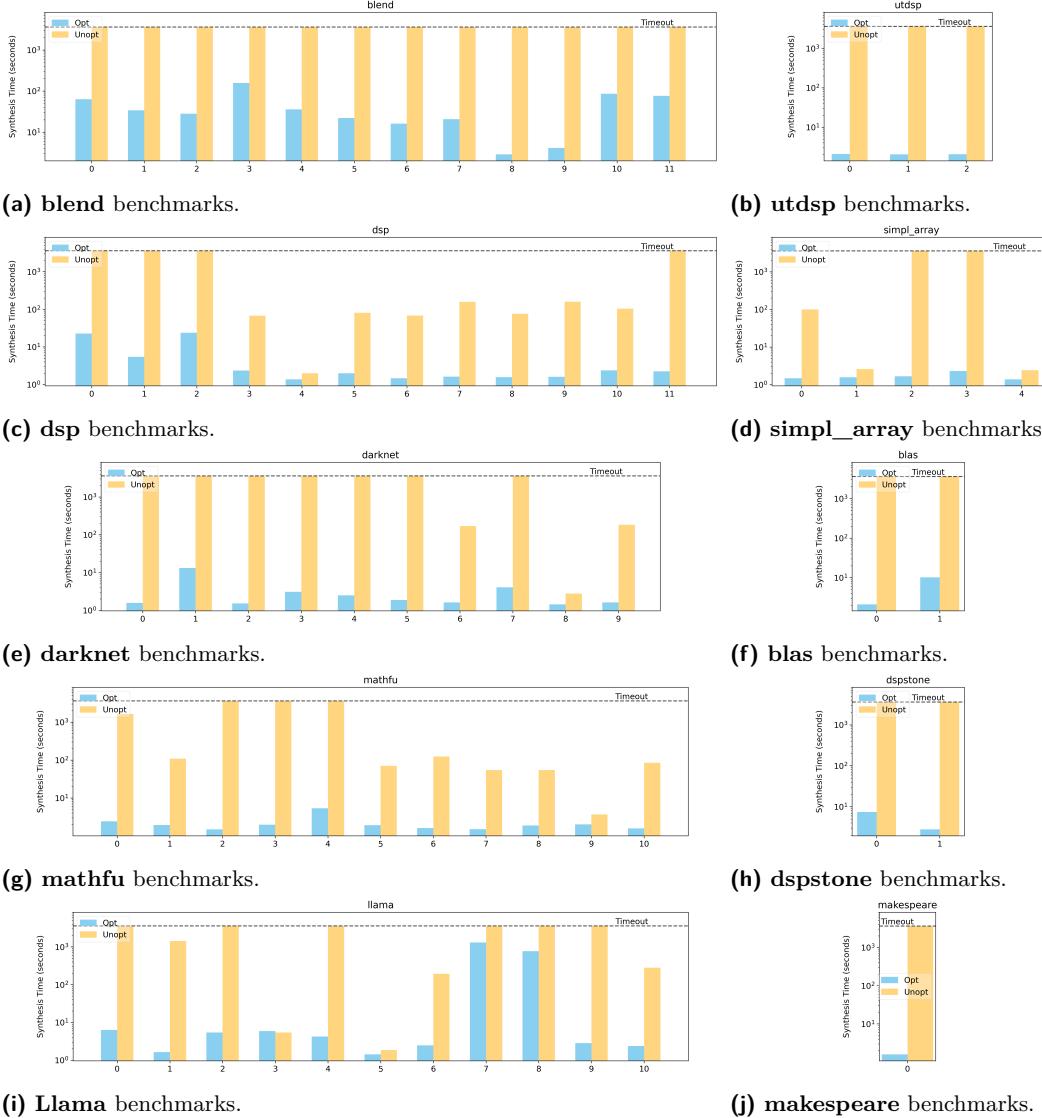

Figure 12 Synthesis timings for all the benchmarks with and without TENSPILER’s tree-based optimization. Benchmark name legend in Appendix B in the extended version of this paper[29].

Bounded Synthesis. In this experiment, we keep the type-based filtering and tree approach while removing the incremental bounded synthesis optimizations. We start with a static tensor bound of 4 instead of the incremental approach. With this, **6** of the **12** **blend** benchmarks time out. In addition, benchmarks involving 2D tensors that do not time out see an average of **36.75 \times** slowdown.

Tree Approach. For this experiment, we include type-based filtering and remove the expression tree approach for grammar filtering. We assume a fixed depth for the grammar, i.e., including all operators up to the specified depth, and increase it upon synthesis failure (starting at depth 1). Without static analysis, no assumptions are made about the operators, slice indices, variables, or constants, necessitating their synthesis. Unlike the tree approach with a fixed number of placeholders, this approach exhibits scalability issues as the number of grammar choices increases exponentially with depth. Therefore, only benchmarks with depth 1 and 2 expressions could be successfully synthesized.

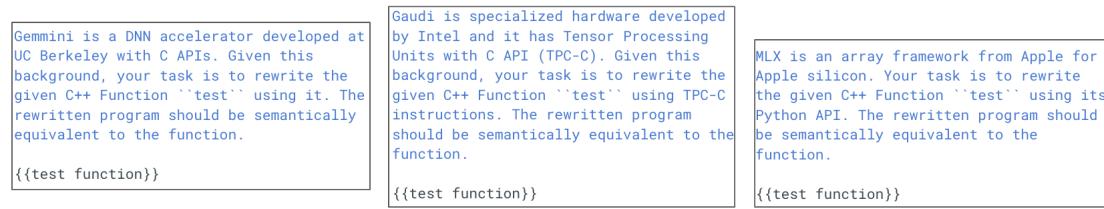

Figure 13 Prompts for LLM.

As illustrated in Fig. 12, without the tree based optimization, **42** out of the total **69** benchmarks timed out. In particular, all benchmarks of the **blend**, **blas**, **dspstone**, **makespeare**, and **utdsp** suites timed out. For the benchmarks that succeed, the synthesis phase slows down by an average **101.55 \times** compared to the tree-based grammar filtering approach due to the need to synthesize additional expressions in both *PS* and *invs*.

6.5 Comparison with LLMs

LLMs have shown promising results in various programming-related tasks, such as code generation, translation, and testing. However, these models suffer from a lack of formal verification of the translated code and face challenges in adapting to new DSLs or backends that are not well-represented in their training corpus.

To test the capabilities of LLMs in generating code for new or low-resource DSLs, we prompt a state-of-the-art proprietary LLM Claude Opus [1] (our evaluation using other LLMs such as GPT4 shows similar results). We selected three backends for this experiment: MLX, a completely new DSL, Gaudi, and Gemmini, which are not well represented in the training corpus of these models. We prompted Claude Opus to generate code for these DSLs for the `linear_dodge` benchmark from the **blend** suite. The prompt instructions are shown in Fig. 13. In Fig. 14 we show the code generated by the LLM for the three prompts.

Upon analysis, we found that all three generated programs were incorrect. The Gemmini-generated code in Fig. 14a partially uses the correct APIs (`mvin`, `mvouts`), but the computation with `config_ex` is incorrect. For the Gaudi-generated code in Fig. 14b, the model hallucinates the TPC-C library, which does not exist in the actual Gaudi programming model. The MLX-generated code in Fig. 14c has the correct call to the library function `add`, but the imports are incorrect, making the code non-functional. In addition to the generated code being incorrect, it is challenging to verify these outputs formally as syntactically translating the generated code to SMT-LIB is not trivial. The experiment highlights two significant challenges in generating verified code using LLMs mentioned earlier. In contrast, TENSPILER, which uses a verified lifting-based approach, can easily handle these challenges. LLMs cannot be directly prompted to generate code in new DSLs. LLMs could potentially be fine-tuned or prompted with few-shot learning to generate code in an IR, which can then be utilized within the TENSPILER's framework for verification; however, we leave this as future work.

6.6 Extension to Higher-Dimensional Tensors

Our benchmarks only involve 1D and 2D tensors, as most operations are performed on images (the **blend** benchmarks) and weight matrices (the **LLama** benchmarks). In this section, we demonstrate that TENSPILER can be extended to support higher-dimensional tensors with the generalizability of TENSIR and the synthesis optimizations discussed in Sec. 5. Specifically, we extend TENSIR to accommodate 3D tensors and all corresponding element-wise operations.

```
#include <gemmini.h>

void linearDodge8_gemmini(uint8_t* base, uint8_t* active, uint8_t* out, int height, int width) {
    gemmini_config_ex(BANK_SIZE, BANK_NUM, ACCEL_NUM);
    gemmini_flush(0);
    elem_t A[height * width];
    elem_t B[height * width];
    elem_t C[height * width];
    for (int i = 0; i < height * width; i++) {
        A[i] = base[i];
        B[i] = active[i];
    }
    gemmini_config_st(A, height * width);
    gemmini_config_st(B, height * width);
    gemmini_config_ld(C, height * width);

    gemmini_mvin(A, 0);
    gemmini_mvin(B, 1);
    gemmini_config_ex(ELEM_ADD, 0, 0, 0);
    gemmini_mvout(C, 0);

    for (int i = 0; i < height * width; i++) {
        out[i] = (uint8_t)C[i];
    }
    gemmini_fence();
}

#include <tpc.h>

void linearDodge8_tpc(Buffer<uint8_t,2> base, Buffer<uint8_t,2>
active, Buffer<uint8_t,2> out) {
    int height = out.height();
    int width = out.width();
    tpc::nd_range<2> nd_range({height, width}, {1, 1});
    tpc::parallel_for(nd_range, [&](tpc::nd_item<2> item) {
        int row = item.get_global_id(0);
        int col = item.get_global_id(1);
        tpc::vector<uint8_t, 16> base_vec = tpc::load<uint8_t,
16>(base.data() + (row * width + col));
        tpc::vector<uint8_t, 16> active_vec = tpc::load<uint8_t,
16>(active.data() + (row * width + col));
        tpc::vector<uint8_t, 16> result_vec = base_vec + active_vec;
        tpc::store<uint8_t, 16>(out.data() + (row * width + col),
result_vec);
    });
}
```

(a) LLM generated Gemmini Code.

```

def linear_dodge_8(base, active):
    out = mlx.add(base, active)
    return out.astype(mlx.uint8)
```

(c) LLM generated MLX Code.

(b) LLM generated Gaudi Code.

Figure 14 LLM generated code for the prompt.

Additionally, we adapt the operator restriction optimization (introduced in Sec. 5.1) to apply to 3D tensors. When the source program returns a 3D tensor, our grammar is restricted to include only element-wise 3D tensor operations. We also retain the program state restriction optimization technique from Sec. 5.2. Furthermore, we extend our support to leverage expression trees performed on individual elements in tensors, as detailed in Sec. 5.3, to guide the search for vectorized operations within 3D tensor spaces.

We evaluate TENSPILER’s synthesis optimizations on artificial benchmarks involving 3D tensors. We create these benchmarks by combining random element-wise operations. The maximum depth of these benchmarks is chosen to be 5 to match that of all our existing real-world benchmarks, as described in Sec. 6. Results in Fig. 15 show that the synthesis time grows linearly with the depths of the benchmarks. The depth-1 benchmark synthesizes the fastest in 6 seconds, while the depth-5 benchmark takes the longest, in 184 seconds.

The sharp increase in timing for depth 5 expressions in Fig. 15 is due to the number of expressions we are synthesizing and their complexity. A benchmark with 3 loops involves synthesizing 3 invariants and 1 post-condition, each with expression sizes up to depth 5. Despite these challenges, we easily extend TENSPILER’s optimizations and synthesize these benchmarks well within the 1 hour timeout. As future work, to further scale TENSPILER’s synthesis algorithm for handling more complex benchmarks, we could explore strategies such as guiding the search process using machine learning techniques, implementing bottom-up synthesis starting with inner loops first, performing bounded synthesis with unrolled loops, and combining these approaches with TENSPILER’s current synthesis optimizations.

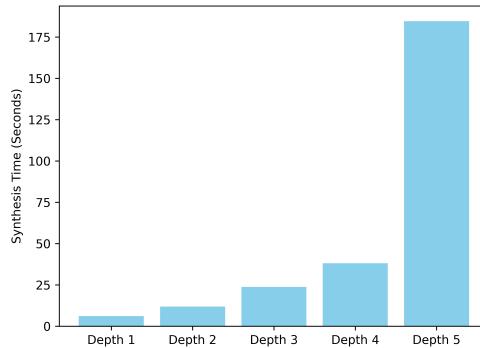

Figure 15 Synthesis timings for artificial 3D tensor benchmarks.

7 Related Work

Verified Lifting. Verified lifting uses program synthesis to translate code instead of designing traditional pattern-matching compilers, and has been used across application domains [15, 5, 6, 19, 21]. Adapting these prior compilers for translation to tensor operations is nontrivial. TENSPILER introduces a novel tensor algebra-based to make synthesis efficient, and supports a diverse set of backends.

Code Translators. TENSPILER differs from other code translation approaches. While symbolic methods like pattern-matching compilers [30] face challenges with the error-prone nature of their rules, TENSPILER uses a search-based approach to avoid these complexities. Neural techniques [32, 26], treat translation as a machine translation task but struggle to ensure correctness. In contrast, TENSPILER uses a theorem prover to guarantee semantic equivalence between the translated and source code. More recently, despite the success of LLMs in programming tasks, they are unable to translate code to unfamiliar frameworks or custom hardware ISAs. TENSPILER’s approach of searching in an TENSIR and using simple rules for translation makes it easy to support new backends.

Intermediate Representations. LLVM [22], MLIR [23] and TACO’s IR [20] are examples of IRs that generate code to multiple backends. LLVM in addition can generate optimized code for various hardware targets. MLIR introduces “dialects,” allowing specific optimizations for different domains or hardware targets. Despite their versatility, LLVM and MLIR were originally designed for traditional pattern-matching compilers, posing challenges for search-based compilers due to their extensive set of operators. In contrast, TENSIR is designed for expressing tensor operations to be used in search-based compilers. As discussed, TENSIR enables efficient lifting, verification, and code generation.

8 Conclusions

We presented our experience in building TENSPILER, a compiler that leverages verified lifting to transpile code to leverage tensor processing infrastructures. At the core of TENSPILER is TENSIR which concisely captures various tensor computations. TENSPILER efficiently translates all 69 real-world benchmarks and can generate code to be executed on 6 different software and hardware backends. The generated code achieves an average speedup of **105 \times** for kernel and **9.65 \times** for end-to-end execution compared to the input.

Abstract

Linear algebra computations are foundational for neural networks and machine learning, often handled through arrays. While many functional programming languages feature lists and recursion, arrays in linear algebra demand constant-time access and bulk operations. To bridge this gap, some languages represent arrays as (eager) functions instead of lists. In this paper, we connect this idea to a formal logical foundation by interpreting functions as the usual negative types from polarized type theory, and arrays as the corresponding dual positive version of the function type. Positive types are defined to have a single elimination form whose computational interpretation is pattern matching. Just like (positive) product types bind two variables during pattern matching, (positive) array types bind variables with *multiplicity* during pattern matching. We follow a similar approach for Booleans by introducing conditionally-defined variables.

The positive formulation for the array type enables us to combine typed partial evaluation and common subexpression elimination into an elegant algorithm whose result enjoys a property we call maximal fission, which we argue can be beneficial for further optimizations. For this purpose, we present the novel intermediate representation *indexed administrative normal form* (A_iNF), which relies on the formal logical foundation of the positive formulation for the array type to facilitate maximal loop fission and subsequent optimizations. A_iNF is normal with regard to commuting conversion for both let-bindings and for-loops, leading to flat and maximally fissioned terms. We mechanize the translation and normalization from a simple surface language to A_iNF , establishing that the process terminates, preserves types, and produces maximally fissioned terms.

1 Introduction

Linear algebra computations are of rising importance due to their foundational role in neural networks and other machine learning systems. The fundamental unit of computation in linear algebra is the multidimensional array (or just *array* from now on). Linear algebra programs are full of computations that construct arrays from other arrays, such as element-wise sum, matrix multiplication, convolution, (transformer) attention, and more.

In functional programming we usually work with lists not arrays. Lists are inductively defined data types, and processed using recursion. Even element access on lists is implemented by recursion, so it has to traverse the list until the element is found, giving it running time¹ linear in the size of the list. Arrays, on the other hand, should have constant-time access and be processed using bulk operations. As such arrays do not fit into the usual pattern of inductive data types. A number of functional programming languages that aim to facilitate programming of array computations have been proposed [12, 37, 31]. Aiming for high expressivity with few language constructs, they leverage the idea that arrays can be represented as functions [12, 37, 31], or that arrays are eager functions [28].

Functions are lazy in the sense that a function definition does not perform any computation and the function body is only executed when a function is applied. Arrays are eager in the sense that all contents of an array are evaluated during construction, and array access does not perform further computation. Prior work had this intuition on the duality between arrays and functions, and here we ground that correspondence on proof-theoretic concepts, which explain why arrays are eager and functions are lazy and yield further convenient consequences.

A key insight of our work is that arrays can be interpreted as a positively polarized version of the function type. The connection between the positive and negative formulation of data types and the computational interpretation of elimination forms as pattern matching has been developed in the context of polarized type theory and focused logic [39, 1, 9, 10, 8, 19, 40]. Thus, similarly to how pattern matching on a binary tuple introduces two variables, the computational content of pattern matching on an array of size N is the introduction of N -many variables. Further, we explore pattern matching on Booleans by introducing *conditional variables*. This insight provides the foundation for the design of the *indexed administrative normal form* ($A_i\text{NF}$), an intermediate representation for array computations. We also present a simple surface array language, called POLARA, and show how these changes together (the positive formulation for the array type and a negative presentation of Booleans) enables us to combine *typed partial evaluation* (a.k.a *normalization by evaluation*) and *common subexpression elimination* into an elegant optimization algorithm overcoming some challenges usually associated to partial evaluation.

In particular, partial evaluation of let-binding is not *safe* in the sense of always resulting in a better, or at least equal, performance than the original. This is because a variable may appear multiple times, hence substituting it multiple times would duplicate code. Ideally, common subexpression elimination (CSE) would remove redundancies introduced by partial evaluation. But the presence of scopes, as e.g., introduced by functions, loops, and branches – all constructs that prevail in array computations – can complicate CSE. While compilers can rectify these issues by using additional rules often summarized under the general term of *code motion*, this comes at the cost of having to decide in what order and how often to apply these additional rules, i.e., it implies creating an optimization schedule, which complicates the algorithm.

¹ We distinguish run-time (as in run-time library) from running time as the time it takes to run something.

<code>let z = let y1 = x + 1 2 * y1 let y2 = x + 1 ...</code>	<code>let y1 = x + 1 let z = 2 * y1 let y2 = x + 1 ...</code>	<code>let f = fun i:nat. let y1 = x + 1 2 * y1 let y2 = x + 1 ...</code>	<code>let z = if c then let y1 = x + 1 2 * y1 else 2 * x let y2 = x + 1 ...</code>
--	--	---	--

(a) Nested lets.

(b) Flat let-bindings.

(c) Functions.

(d) Branches.

Figure 1 Sample programs.

Instead of these complications, with $A_i\text{NF}$, we propose a novel intermediate representation for array programs based on logical foundations that avoids the complexity of optimization schedules. Like ANF, which is normal with regard to commuting conversion of let-bindings implying maximal flatness, $A_i\text{NF}$ is normal with regard to commuting conversions of for-loops, thus enabling what we call maximal loop fission. Maximal loop fission is a fundamental property to enable further optimizations such as dead code elimination or common subexpression elimination. We provide a translation of POLARA into $A_i\text{NF}$, which performs maximal loop fission and loop invariant code motion.

Contributions. In summary, this paper makes the following contributions:

- We present $A_i\text{NF}$, an intermediate representation that makes use of the unconventional idea of treating arrays as positive types from polarized type theory. $A_i\text{NF}$ is normal with regard to commuting conversion for both let-bindings and for-loops, leading to flat and maximally fissioned terms.
- We present POLARA, a simple surface array language, along with a translation of POLARA to $A_i\text{NF}$, for which we prove termination, type preservation, and maximal fission.
- We present an optimization algorithm for $A_i\text{NF}$ based on normalization by evaluation and common subexpression elimination, for which we prove termination and type preservation.

2 Problem Statement

Typed partial evaluation is a powerful optimization technique [17], which can reduce excessive terms by applying computation laws. For example, it can reduce a projection on a pair $(a, b).1 \equiv a$ by applying β -reduction. Or, it can eliminate superfluous branches like in $\text{if } x \text{ then } (\text{if } x \text{ then } a \text{ else } b) \text{ else } c \equiv \text{if } x \text{ then } a \text{ else } c$ by applying uniqueness laws (e.g., η -expansion).

But, while shining on its logical foundation, partial evaluation is not a *safe* optimization. A *safe* optimization has to either reduce the running time of a program or at least preserve it. Partial evaluation of let-bindings is not *safe* because a variable may appear multiple times, hence substituting it multiple times would duplicate code. Ideally, common subexpression elimination (CSE) would remove all redundancies introduced by partial evaluation. But scopes introduced by nested let-bindings, functions, and branches complicate CSE. For illustration, below we consider a few examples of redundancies that can occur in programs and how CSE handles them.

In Figure 1a, a program with nested let-bindings is shown. Here, the variable z is bound to $2 * y_1$, where y_1 is bound to the successor of x ; and then the variable y_2 is bound to the successor of x as well. It is easy to see that y_1 is redundant with y_2 , yet y_1 is not in scope at the definition of y_2 , so we cannot simply replace one by the other. The problem can be

avoided by bringing the program into a form, where no let-binding is nested inside another let-binding, such that all previously bound variables are in scope for the whole remaining expression. Consider the program shown in Figure 1b, which is equivalent to the previous program, but this time no expression has a subexpression. Now, the former definition is in scope at the latter definition, and thus y_2 can be replaced by y_1 , thereby eliminating a duplicate subexpression.

As mentioned, functions and branches introduce scope as well, and therefore complicate CSE. Yet, the solution of flattening the code is not as straightforward to apply. To illustrate the problem with functions, consider the program shown in Figure 1c, which defines a function f . Inside the function the successor of x is bound to y_1 , and outside the function it is bound redundantly to y_2 . To share the expressions, we could consider moving the definition of y_1 out of the functions. But moving an expression out of a function is not *safe*, as long as we do not know whether the function will be called at all.

To illustrate the problem with branches, consider the program shown in Figure 1d. Here, the result of a conditional expression is bound to the variable z , in one branch the successor of x is bound to y_1 , and after the conditional expression the successor of x is bound to the variable y_2 . Similar to the function case, to share the expressions, we could consider moving the definition of y_1 out of the branch, but that is again not a *safe* optimization, as long as we do not know that this branch is taken.

To rectify the issues outlined above compilers use additional rules often summarized under the general term of *code motion*. But this comes at the cost of introducing the problem of having to decide in what order and how often to apply these additional rules (i.e., creating an optimization schedule).

Our work avoids the complexity of optimization schedules. We argue that – instead of complicating the CSE algorithm with optimization schedules – a better approach is to design an intermediate representation for array programs, which like ANF bans nested expressions. This simplifies the optimization of array programs, which now can safely rely on algorithms based on logical foundations such as partial evaluation and CSE. The novel intermediate representation, called A_iNF , is informally presented in the following along with a simple surface arrays language and the optimized translation of the latter to the former.

3 A_iNF , Polara, and Simplified Optimizations

We describe the two key insights on which our approach is based (Sections 3.1 and 3.2), introduce POLARA and A_iNF by example (Section 3.3), and explain how A_iNF simplifies optimizations (Section 3.4).

3.1 The Duality of Functions and Arrays

The list type is an inductive datatype defined by its constructors `nil` for the empty list and `cons` for constructing a list from another list with an additional element. Accordingly, algorithms over lists work by recursion, expressed with functions and branches. As element access on lists is implemented by recursion, it has to traverse the list until the element is found, giving it running time linear in the size of the list. Arrays, on the other hand, enjoy constant-time access and feature bulk operations. The consequence is that arrays do not fit into the usual pattern of inductive data types. Nevertheless, because custom semantics would require further proofs to ensure soundness, arrays are occasionally modelled as lists, with the hint that the actual running time can differ (in Lean for example²).

² <https://lean-lang.org/lean4/doc/array.html>

In functional array languages, we exploit the equivalence of an array of type X and length n with a function from a natural number below n to a value of type X . Forward, this equivalence allow us to access (`get`) elements of an array by its index. Backward, we create (`tabulate`) an array from a function describing each individual element based on their index. The forward direction is indeed already very much ingrained in everyday programming, as array access `a[i]` and function application `a(i)` look very much alike in many languages, and even share identical syntax in some.

$$\text{Array}_n X \leftrightarrow (\text{Fin}_n \rightarrow X)$$

$$\begin{aligned} \text{get} : \text{Array}_n X &\rightarrow (\text{Fin}_n \rightarrow X) \\ \text{tabulate} : (\text{Fin}_n \rightarrow X) &\rightarrow \text{Array}_n X \end{aligned}$$

But something important changes in the conversion from a function to an array, and vice versa. Functions are *lazy*, in the sense that the evaluation of a function is delayed until it is applied, while arrays are *eager*, in the sense that all elements of an array have already been evaluated and on array access only need to be looked up. Also, in a language with (side) effects, the two types can be distinguished in that a function application can trigger effects, while an array access cannot trigger effects. Dually, constructing a function cannot trigger effects, while constructing an array can trigger effects.

We can put the relationship between functions and arrays on a logical foundation by considering the difference between positive and negative types [39]. A positive type is defined by a set of constructors (introduction forms), and we get a single corresponding destructor (elimination form) for it with one continuation for the content of each possible constructor (pattern matching). A negative type is defined by a set of destructors, and we get a single corresponding constructor for it that has to provide one value for each destructor to extract (copattern matching). Positive types are usually associated with eager (call-by-value) evaluation, and negative types with lazy (call-by-name) evaluation. Many types can be defined either as a positive or as a negative type. For illustration, we consider the positive and the negative formulations of the product type below.

Products as Positive and as Negative Types. The product type as a positive type \times has a single constructor (a, b) (INTRO). A corresponding destructor (ELIM) can be systematically derived as pattern matching on the constructor. Reduction (BETA) occurs when a destructor is applied to a constructor, and they eliminate each other.

$$\begin{array}{c} \text{INTRO} \\ \Gamma \vdash a : A \quad \Gamma \vdash b : B \\ \hline \Gamma \vdash (a, b) : A \times B \end{array} \qquad \begin{array}{c} \text{ELIM} \\ \Gamma \vdash p : A \times B \quad \Gamma, a : A, b : B \vdash c : C \\ \hline \Gamma \vdash \text{let } (a, b) = p; c : C \end{array}$$

$$\begin{array}{c} \text{BETA} \\ \Gamma \vdash a : A \quad \Gamma \vdash b : B \quad \Gamma, x : A, y : B \vdash c : C \\ \hline \Gamma \vdash (\text{let } (x, y) = (a, b); c) \equiv c[x := a, y := b] \end{array}$$

Alternatively, products can also be defined as negatives types \otimes . In this case, we give primacy to a set of destructors, namely the projections `p.fst` and `p.snd` (ELIM1, ELIM) to access the individual elements of a tuple p , and derive systematically the corresponding constructor (INTRO) providing one value for each destructor to extract. Beta reduction occurs (BETA1, BETA1) when a destructor is applied to a constructor by extracting the corresponding value.

$$\begin{array}{c}
 \text{ELIM1} \quad \frac{\Gamma \vdash p : A \otimes B}{\Gamma \vdash p.\text{fst} : A} \quad \text{ELIM2} \quad \frac{\Gamma \vdash p : A \otimes B}{\Gamma \vdash p.\text{snd} : B} \quad \text{INTRO} \quad \frac{\Gamma \vdash a : A \quad \Gamma \vdash b : B}{\Gamma \vdash (\text{fst} = a; \text{snd} = b) : A \otimes B} \\
 \\
 \text{BETA1} \quad \frac{\Gamma \vdash a : A \quad \Gamma \vdash b : B}{\Gamma \vdash (\text{fst} = a, \text{snd} = b).\text{fst} = a} \quad \text{BETA2} \quad \frac{\Gamma \vdash a : A \quad \Gamma \vdash b : B}{\Gamma \vdash (\text{fst} = a, \text{snd} = b).\text{snd} = b}
 \end{array}$$

Functions as Negative and Positive Types. Usually, the function type is considered a negative type. It has a single destructor – function application $f a$ (ELIM) – and the corresponding constructor is systematically derived by copattern matching on the possible destructors (INTRO). When a destructor is applied to the constructor, we extract the value provided as the body of the function, and substitute the variable with the argument (BETA).

$$\frac{\text{ELIM} \quad \Gamma \vdash f : A \rightarrow B \quad \Gamma \vdash a : A}{\Gamma \vdash f a : B} \quad \frac{\text{INTRO} \quad \Gamma, a : A \vdash b : B}{\Gamma \vdash \text{fun } a. b : A \rightarrow B} \quad \frac{\text{BETA} \quad \Gamma, x : A \vdash b : B \quad \Gamma \vdash a : A}{\Gamma \vdash (\text{fun } x. b) a \equiv b[x := a]}$$

The function type can also be represented as a positive type. In this case, the function is primarily defined through its constructor, and the destructor is systematically derived from pattern matching on the constructor. But the interpretation of positive function types comes with some challenges for the metatheory. The introduction form of a function turns a term-in-the-context-of-a-variable $a : A \vdash b : B$ into a function $(\text{fun } a. b) : A \rightarrow B$. Thus, the corresponding elimination form of a function $(\text{fun } a. b) : A \rightarrow B$ should introduce a variable of type term-in-the-context-of-a-variable $a : A \vdash b : B$ into the context. But to properly model that, we need a judgment where we have a context in the context, in other words a “higher-order judgment” [26, 25]. A judgment is higher-order when an entailment \vdash occurs inside the context of another entailment. An implementation of higher-order judgments needs to ensure that a variable which has such a judgment as a type is only used in larger contexts, where all required variables are available. For example, $b : (a : A \vdash B) \vdash b : B$ is invalid, given that b must occur in a context where an $a : A$ is available; while $b : (a : A \vdash B) \vdash (\text{fun } a. b) : A \rightarrow B$ is valid, because a variable $a : A$ has been introduced such that the use of b afterwards is safe.

$$\begin{array}{c}
 \text{INTRO} \quad \frac{\Gamma, a : A \vdash b : B}{\Gamma \vdash (\text{fun } a. b) : A \rightarrow B} \quad \text{ELIM} \quad \frac{\Gamma \vdash f : A \rightarrow B \quad \Gamma, x : (a : A \vdash B) \vdash c : C}{\Gamma \vdash \text{let } (\text{fun } a. x) = f; c : C} \\
 \\
 \text{BETA} \quad \frac{\Gamma, a : A \vdash b : B \quad \Gamma, x : (a : A \vdash B) \vdash c : C}{\Gamma \vdash \text{let } (\text{fun } a. x) = (\text{fun } a. b); c \equiv c[x := b]}
 \end{array}$$

Interpreting positive function types as arrays. We avoid the challenges of interpreting functions as positive types by proposing to interpret positive function types as arrays, re-interpreting the rules of the positive function type as the rules of the array type. We require the argument type to be the type of natural numbers below some number n , which corresponds to the index type of an array. Traditionally, functional programming works with lists and not arrays, therefore the constant-time access of arrays is not accurately represented by the model; in functional array languages [15, 37], arrays tend to live in the shadow of the

function type, as their introduction and elimination forms depend on (higher-order) functions. Interpreting the array as a positive function type makes them independent and puts them on an equal footing to the other types with regard to their logical foundation.

We distinguish positive functions, i.e., arrays, from normal functions by using \Rightarrow for the type, writing $(\text{for } a. b)$ as the introduction form for arrays, while the elimination form is given, as always, by pattern matching on all possible introduction forms:

$$\begin{array}{c} \text{INTRO} \\ \frac{\Gamma, x : A \vdash b : B}{\Gamma \vdash (\text{for } x. b) : A \Rightarrow B} A = \text{Fin}_n \end{array} \quad \begin{array}{c} \text{ELIM} \\ \frac{\Gamma \vdash f : A \Rightarrow B \quad \Gamma, x : (a : A \vdash B) \vdash c : C}{\Gamma \vdash \text{let } (\text{for } a. x) = f; c : C} A = \text{Fin}_n \end{array}$$

$$\begin{array}{c} \text{BETA} \\ \frac{\Gamma, a : A \vdash b : B \quad \Gamma, x : (a : A \vdash B) \vdash c : C}{\Gamma \vdash \text{let } (\text{for } a. x) = (\text{for } a. b); c \equiv c[x := b]} \end{array}$$

Intuitively, analogously to how pattern matching on a product introduces two variables (one for each projection of the product), pattern matching on an array introduces a family of variables, one for each element. For illustration, consider $b[a := 2]$ as b_2 , and $(\text{let } (\text{for } a. b) = f; c)$ as $(\text{let } (b_0, b_1, \dots, b_{n-1}) = f; c)$.

Arrays Enable CSE. Flattening let-bindings usually helps CSE. More precisely the rule that is used to create the ANF representation is the let-let commuting conversion:

$$\begin{array}{l} (\text{let } y = (\text{let } x = e1; e2); e3) \equiv \\ (\text{let } x = e1; \text{let } y = e2; e3) \end{array}$$

Note that the following let-fun commuting conversion is not *safe* because on the left-hand side $e1$ is evaluated at most once, even if it was used multiple times in $e2$; but on the right-hand side it will be evaluated once for each usage in $e2$.

$$\begin{array}{l} (\text{let } y = (\text{fun } i. \text{let } x = e1; e2); e3) \equiv \\ (\text{let } (\text{fun } i. x) = (\text{fun } i. e1); \text{let } y = (\text{fun } i. e2); e3) \end{array}$$

On the other hand, the let-for commuting conversion that we use in $A_i\text{NF}$ below is *safe* and states that the following two lines are equivalent. As array construction is evaluated eagerly, the expression $e1$ is evaluated just once for each iteration, on both sides of the equation.

$$\begin{array}{l} (\text{let } y = (\text{for } i. \text{let } x = e1; e2); e3) \equiv \\ (\text{let } (\text{for } i. x) = (\text{for } i. e1); \text{let } y = (\text{for } i. e2); e3) \end{array}$$

Intuitively, this rule allows us to split a complex loop into multiple simpler loops, hence it is closely connected to loop *fission*. If we use this rule to split every loop as much as possible, then we end up with a normal form in which every loop only contains a single operation. First performing loop fission as much as possible helps with implementing other optimizations, for example allows CSE to remove redundancies that it could not otherwise eliminate.

The use of this rule means that frequently both the left side and the right side of a variable definition are surrounded by the same form (on the left as a pattern form, on the right as a term form), so we will introduce some syntactic sugar and write $\text{let for } i. (x = e1); e2$ to mean $\text{let } (\text{for } i. x) = (\text{for } i. e1); e2$ in the following.

3.2 Lifting Branching into the Context

A different problem arises with values of the Boolean type, Booleans have two constructors, `true` and `false` (INTRO1, INTRO2). They have one destructor, the conditional expression (ELIM), where one continuation is provided for each constructor, the consequent and the alternative. A conditional reduces to the consequent when the condition is true (BETA1), and to the alternative when the condition is false (BETA2).

$$\begin{array}{c}
 \text{INTRO1} \qquad \qquad \text{INTRO2} \qquad \qquad \text{ELIM} \\
 \frac{}{\Gamma \vdash \text{true} : \text{bool}} \qquad \frac{}{\Gamma \vdash \text{false} : \text{bool}} \qquad \frac{\Gamma \vdash p : \text{bool} \quad \Gamma \vdash e : C \quad \Gamma \vdash f : C}{\Gamma \vdash \text{if } p \text{ then } e \text{ else } f} \\
 \\
 \text{BETA1} \qquad \qquad \qquad \text{BETA2} \\
 \frac{\Gamma \vdash e : C \quad \Gamma \vdash f : C}{\Gamma \vdash \text{if true then } e \text{ else } f \equiv e} \qquad \frac{\Gamma \vdash e : C \quad \Gamma \vdash f : C}{\Gamma \vdash \text{if false then } e \text{ else } f \equiv f}
 \end{array}$$

The let-if commuting conversion below is *safe* with regard to running time. But applying the commuting conversion duplicates the expression `e3`. If `e3` is a big expression, then even if duplicating it in different branches may not impact the running time, having nested branches will lead to a blow-up of the code size exponential in the number of branches (which is also bad for the compiling time).

```
(let z = (if e0 then e1 else e2); e3) ≡
(if e0 then (let z=e1; e3) else (let z=e2; e3))
```

Essentially, the above rule bubbles up conditionals to the top of the expression. Instead, we propose to trickle down the conditionals using conditionally defined variables and state a new `let-if` commuting conversion that does not duplicate the branches. To avoid duplicating branches, we introduce a syntactically single-branch `if`. A single-branch `if` produces a conditional value, i.e., a value that can only be accessed if the condition is true, and the single-branch `if!` produces a value that can only be accessed if the condition is false.

Analogously, we have let-bindings for conditional variables `let (if e. x) := ...` (or `let (if! e. x) := ...`), which define a variable `x` that can only be accessed if the condition `e` is true (or false, respectively). Two simple syntactical conditions can be used to check whether a conditional variable is accessible: First, a conditional variable is accessible on the right-hand side of the definition of another conditional variable that has the same condition. In other words, a conditional variable can be used to define the value of another conditional variable with the same condition. Second, a conditional variable is accessible in one of the branches of a standard two-branched `if` condition. In other words, two mutually exclusive conditional variables can be combined with an `if` to define a non-conditional variable.

Using the single-branch `if`, we can now express a `let-if` commuting conversion, that does not duplicate `e3`. Here the double-branched `if` is separated into two single-branch `ifs` and `e3` remains to be executed once afterwards:

```
(let z = (if e0 then e1 else e2);
e3)
≡
(let (if e0. z1) = (if e0. e1);
let (if! e0. z2) = (if! e0. e2);
let z = (if e0 then z1 else z2);
e3)
```

Table 1 Common linear algebra operations in POLARA; NumPy for reference.

Name	NumPy	POLARA
Vector addition	<code>v + w</code>	<code>for i. v[i] + w[i]</code>
Matrix addition	<code>A + B</code>	<code>for i j. A[i,j] + B[i,j]</code>
Element-wise product (vector)	<code>v * w</code>	<code>for i. v[i] * w[i]</code>
Element-wise product (matrix)	<code>A * B</code>	<code>for i j. A[i,j] * B[i,j]</code>
Outer product	<code>np.multiply.outer(A, B)</code>	<code>for i j k l. A[i,j] * B[k,l]</code>
Trace	<code>A.trace()</code>	<code>sum i. A[i, i]</code>
Transpose	<code>A.transpose()</code>	<code>for i j. A[j, i]</code>
Matrix multiplication	<code>A @ B</code>	<code>for i k. sum j. A[i,j] * A[j,k]</code>
Matrix-vector multiplication	<code>A @ v</code>	<code>for i. sum j. A[i,j] * v[j]</code>

Correct use of conditional values will thus frequently lead to the use of the same condition on the variable bound by a `let` and in a single-branched if in the bound expression. We will thus make use of syntactic sugar writing `let if e0. (x1 = e1); e2` to mean `let (if e0. x1) = (if e0. e1); e2`.

3.3 Polara and A_iNF by Example

In this section, we informally introduce both POLARA and A_iNF . We do so by giving examples of array operations and programs in POLARA and showing the result of compiling them to A_iNF . Just for reference, we will also provide versions of the POLARA examples written in the widely-adopted array programming library NumPy [14]. Please note that the focus of this paper lies in the exploration of A_iNF , rather than POLARA. The latter serves merely as a vehicle to elucidate how A_iNF effectively facilitates optimizations during the translation process from a surface array language. Hence, compared to NumPy, we have purposely kept it closer to low-level imperative code.

In POLARA, an expression e is either a constant c , or an arithmetic operator $e + e$, function application $e e$, array access $a[i]$, array construction `for i:n. e`, or summation `sum i:n. e`, as well as pairs (e, e) and projection $e.1, e.2$. The array construction `for i:n. e` constructs an array of length n by repeatedly evaluating e , with i bound to the values from 0 to $n-1$. For example, `for i:3. 10*i` evaluates to `[0, 10, 20]`. We will write `for i. e` if the size of the array can be inferred from the context. Summation is syntactic sugar for constructing an array and then summing it, so `sum i.e ≡ sum (for i. e)`.

In Table 1, we list several common linear algebra operations and compare how they can be expressed using the linear algebra library NumPy and POLARA. We assume as given that the vectors v , w and matrices A , B are of appropriate sizes.

Dense Layer. As a slightly more involved example, we show how a dense neural network layer can be implemented in NumPy, POLARA, and A_iNF , respectively. The NumPy example makes use of the built-in matrix multiplication operator \circledast . While such an operation can be implemented as function in POLARA, we show an example that only relies on the few POLARA primitives, using the `for` looping construct and indexing. Likewise, while the NumPy definition uses the built-in `maximum` function and addition, the POLARA version uses an explicit loop that performs element-wise multiplication and additions across the vectors.

Compared to the untyped NumPy program, we also declare the types of the arguments. A type $n \Rightarrow \text{flt}$ describes an array of floating point numbers with size n .

Obviously, the corresponding A_iNF program (Figure 2a) is rather lengthy, as every intermediate result gets assigned to a variable, just like in ANF.

33:10 Compiling with Arrays

<pre>def dense(b, W, x): return np.maximum(0, W @ x + b)</pre>	<pre>dense(b:n⇒flt, W:n⇒m⇒flt, x:m⇒flt): n⇒flt := for i. max(0, (sum j. W[i][j] * x[j]) + b[i])</pre>
NumPy	POLARA

Convolution. We now describe how to express convolution in POLARA. Convolution involves moving a vector, called the kernel, across another vector while repeatedly calculating the dot product. For this example, we need to subtract two indices to indicate that we shift one array while keeping the other as it is. In the A_iNF example (Figure 2b), we create a two-dimensional array $x10$ containing all the possibilities for shifting the array y . For example if $y = [1,2,3]$, then $x10$ is a matrix of size 3×3 so that $\text{tmp1} = [[1,2,3], [2,3,1], [3,1,2]]$. We then form the dot product of each entry with x .

<pre>def conv(x, y): return np.convolve(x, y, 'same')</pre>	<pre>conv(x: n⇒flt, y: (n+m-1)⇒flt): m⇒flt := for i. sum j. x[j] * y[j+i]</pre>
NumPy	POLARA

Black-Scholes. Black-Scholes is a simplified mathematical model for the dynamics of derivative investments in financial markets. The Black-Scholes formula provides an estimate for the price of the call option (buying) and the put option (selling) of a European-style option given the original price S , the strike price K , the expiration time T , the force-of-risk r and the standard deviation σ . The interesting part, from an array programming language's perspective, is that with a naive implementation of the calls and puts as separate functions, common subexpression elimination is not able to identify the redundant computation across these functions over two separate loops.

In particular, note the redundant definition of $d1$ and $d2$ in the `calls` and the `puts` function. This code gets inlined into the `blackScholes` function, but the two function calls land in separate loops. Nevertheless, using loop fission the output can be reduced to just 22 lines of A_iNF (see Figure 2c); without fission and CSE the generated code would have 54 lines.

<pre>calls(S: flt, K: flt, T: flt: r: flt: sigma: flt): flt := let d1 := (log (S / K) + (r + sigma * sigma / 2) * T) / (sigma * sqrt T) let d2 := d1 - sigma * sqrt T S * normCdf d1 - K * exp (0 - var r * var T) * normCdf d2 puts(S: flt, K: flt, T: flt: r: flt: sigma: flt): flt := let d1 := (log (S / K) + (r + sigma * sigma / 2) * T) / (sigma * sqrt T) let d2 := d1 - sigma * sqrt T K * exp (0 - r * T) * normCdf (0 - d2) - S * normCdf (0 - d1) blackScholes(arr: (n ⇒ flt)): n ⇒ (flt × flt) := let S := 1; let K := 1; let r := 1; let sigma := 1 let Calls: (n ⇒ flt) := for i. calls(S, K, arr[i], r, sigma) let Puts: (n ⇒ flt) := for i. puts(S, K, arr[i], r, sigma) for i. (Calls[i], Puts[i])</pre>	POLARA

3.4 Simplifying Optimizations with A_iNF

This section provides an overview showing how some classical optimizations can be applied to A_iNF and illustrates why our novel normal form simplifies their implementation.

To improve readability, we will sometimes present A_iNF code in a way that deviates from the actual representation by putting multiple operations in one line, when this does not affect the optimization.

```

dense(b: n => flt, W: n => m => flt,
      x: m => flt): n => flt :=
let for i:n, (x0 : flt := 0)
let for i:n, j:m, (x1 : m => flt := W[i])
let for i:n, j:m, (x2 : flt := x1[j])
let for i:n, j:m, (x3 : flt := x[j])
let for i:n, j:m, (x4 : flt := x2 * x3)
let for i:n, (x5 : m => flt := for j:m, x4)
let for i:n, (x6 : flt := sum x5)
let for i:n, (x7 : flt := b[i])
let for i:n, (x8 : flt := x6 + x7)
let for i:n, (x9 : flt := max x0 x8)
let (x10 : n => flt := for i:n, x9)
x10

```

A_iNF

(a) A_iNF for a dense layer.

```

conv(x: n => flt, y: p => flt): m => flt :=
let for i:m, j:n, (x0 : flt := x[j])
let for i:m, j:n, (x1 : fin p := j + i)
let for i:m, j:n, (x2 : flt := y[x1])
let for i:m, j:n, (x3 : flt := x0 * x2)
let for i:m, (x4 : n => flt := for j:n, x3)
let for i:m, (x5 : flt := sum x4)
let (x6 : m => flt := for i:m. x5)
x6

```

A_iNF

(b) A_iNF for convolution.

```

blackScholes(arr: n => flt): n => flt * flt :=
let for i1:n, (x0 : flt := 1.500000)
let for i1:n, (x1 : flt := i0[i1])
let for i1:n, (x2 : flt := x0 * x1)
let for i1:n, (x4 : flt := sqrt x1)
let for i1:n, (x5 : flt := x2 / x4)
let for i1:n, (x6 : flt := normCdf x5)
let for i1:n, (x7 : flt := 0.000000)
let for i1:n, (x9 : flt := x7 - x1)
let for i1:n, (x10 : flt := exp x9)
let for i1:n, (x19 : flt := x5 - x4)
let for i1:n, (x20 : flt := normCdf x19)
let for i1:n, (x21 : flt := x10 * x20)
let for i1:n, (x22 : flt := x6 - x21)
let for i1:n, (x37 : flt := x7 - x19)
let for i1:n, (x38 : flt := normCdf x37)
let for i1:n, (x39 : flt := x10 * x38)
let for i1:n, (x47 : flt := x7 - x5)
let for i1:n, (x48 : flt := normCdf x47)
let for i1:n, (x49 : flt := x39 - x48)
let for i1:n, (x50 : (flt * flt) := (x22, x49))
let (x51 : (n => flt * flt) := for i1:1, x50)
x51

```

A_iNF

(c) A_iNF for a Black-Scholes.**Figure 2** Generated A_iNF.

Loop Fission. Loop fission is an optimization pass that prepares code to improve the effectiveness of dead code elimination. Standard dead code elimination can only delete whole loops. Loop fission splits a loop into parts, so that individual parts that are not used can be removed. In A_iNF, the body of each loop is a single operation, which means that any A_iNF program is necessarily as fissioned as possible. A simple partial evaluation pass on A_iNF can then perform dead-code elimination.

Below, the left side shows an array computation in POLARA. On the right, that same computation has been transformed to A_iNF, which implies loop fission. The code follows the principle from ANF that expressions should be atomic, i.e., only have one operation. In terms of array programming, this leads to the first loop being split into three loops. Partial evaluation could then reduce the full program to just `for i. f(xs[i])`.

```

let x = for i.
  let ys = f(xs[i])
  let zs = f(xs[i])
  (ys, zs)
for i.
  fst x[i]

```

POLARA

```

let for i. (ys = f(xs[i]))
let for i. (zs = f(xs[i]))
let for i. (x = (ys, zs))
let for i. (y = fst x)
let z = for i. y
z

```

A_iNF

A further advantage of loop fission is that it improves loop *fusion*: Splitting a program into as many loops as possible, gives more freedom to the algorithm for combining loops again.

33:12 Compiling with Arrays

	$n \in \mathbb{N}$	$f \in \mathbb{F}$	$x \in \text{Var}$	$i \in \text{Idx}$
Types	$t ::= \text{fin } n \mid \text{flt} \mid t \hat{\times} t \mid t \hat{\rightarrow} t \mid n \Rightarrow t$			
Constants	$c ::= n \mid f \mid \hat{+} \mid \hat{:} \mid \hat{-} \mid \hat{/} \mid \text{app} \mid \text{get} \mid \text{pair} \mid \text{fst} \mid \text{snd} \mid \text{sum}$			
POLARA	$e ::= c \bar{e} \mid x \mid \text{fun } x:t. e \mid \text{for } x:n. e \mid \text{ite } e \ e \ e \mid \text{let } e; \ e$			
$A_i\text{NF}$	$a ::= \text{let } C[x = p]; \ a \mid x$			
Primitives	$p ::= c \bar{x} \mid i \mid \text{fun } i:t. x \mid \text{for } i:n. x \mid \text{ite } x \ x \ x$			
Scope Contexts	$C[\cdot] ::= \cdot \mid C[\text{fun } i:t. \cdot] \mid C[\text{for } i:n. \cdot] \mid C[\text{if } x \neq 0. \cdot] \mid C[\text{if } x = 0. \cdot]$			

Figure 3 POLARA and $A_i\text{NF}$.

Common subexpression elimination. We can now see how $A_i\text{NF}$ helps with CSE. On the left, we recapitulate the example from above; on the right, we can see the same program in $A_i\text{NF}$.

<pre> let f = for i. let y = x+1 let y' = 2*y y' let z = x+1 ... </pre>	<hr/> POLARA	<pre> let for i. (y = x + 1) let for i. (y' = 2 * y) let for i. (f = y') let for i. (z = x + 1) ... </pre>	<hr/> $A_i\text{NF}$
---	---	---	--

The loop computing f has been broken down into two loops. As a result, z is clearly redundant, as it performs the same computation in the same scope as y . Therefore, compared to array languages using higher-order functions, $A_i\text{NF}$ allows us to use the simple, standard approach to CSE, and nonetheless remove redundancies between expressions inside and outside of loops.

Loop invariant code motion. Loop invariant code motion (LICM), which moves constants out of a loop, is another optimization that benefits from $A_i\text{NF}$. In $A_i\text{NF}$, this would correspond to dropping an unused index; hence, the implementation of LICM is very simple. On the left, we generate an array ys , in which every element is the constant 1 . We then compute an array zs that makes use of ys . Notice that the index i that is bound in the creation of ys is not used. We can therefore eliminate that loop, adjusting uses of ys accordingly from $\text{ys}[i:=j]$ to ys , as seen on the right.

<pre> let for i. (ys = 1) let zs = for i. f(xs[i], ys) ... </pre>	<hr/> $A_i\text{NF}$	<pre> let ys = 1 let zs = for i. f(xs[i], ys) ... </pre>	<hr/> $A_i\text{NF}$
---	--	--	--

4 Mechanization

We mechanized POLARA, partial evaluation of POLARA, $A_i\text{NF}$, the translation from POLARA to $A_i\text{NF}$, and common subexpression elimination over $A_i\text{NF}$, using the dependently typed programming language Lean 4 [7].

4.1 Polara and Partial Evaluation

Polara. The POLARA grammar uses the set of natural numbers, floating point numbers, variables and indices (Figure 3), but the distinction between variables and indices is only relevant for $A_i\text{NF}$. Types are floating point numbers, products, functions, and arrays, as well as bounded natural numbers, i.e. $\text{fin } n$ is the type of numbers smaller than n . Constants are

$$\begin{array}{c}
\frac{n < m}{\vdash n : \text{fin } m} \quad \vdash f : \text{flt} \quad \vdash \text{app} : (t_1 \hat{\rightarrow} t_2) \rightarrow t_1 \rightarrow t_2 \quad \vdash \text{get} : (n \Rightarrow t_1) \rightarrow \text{fin } n \rightarrow t_1 \\
\vdash \text{pair} : t_1 \rightarrow t_2 \rightarrow (t_1 \hat{\times} t_2) \quad \vdash \text{fst} : (t_1 \hat{\times} t_2) \rightarrow t_1 \quad \vdash \text{snd} : (t_1 \hat{\times} t_2) \rightarrow t_2 \\
\vdash \hat{+} : \text{fin } n \rightarrow \text{fin } m \rightarrow \text{fin } (n + m - 1) \quad \vdash \hat{+} : \text{flt} \rightarrow \text{flt} \rightarrow \text{flt} \quad \vdash \text{sum} : (n \Rightarrow \text{flt}) \rightarrow \text{flt} \\
\begin{array}{c}
\text{VAR} \qquad \text{CONST} \\
\frac{x:t \in \Gamma}{\Gamma \vdash x : t} \quad \frac{\vdash c : \bar{t}_i \rightarrow t' \quad \Gamma \vdash e_i : t_i}{\Gamma \vdash c \bar{e}_i : t'}
\end{array} \\
\begin{array}{c}
\text{FUN} \qquad \text{FOR} \\
\frac{\Gamma, x:t_1 \vdash e : t_2}{\Gamma \vdash \text{fun } x:t_1. e : t_1 \rightarrow t_2} \quad \frac{\Gamma, i:\text{fin } n \vdash e_2 : t}{\Gamma \vdash \text{for } i:n. e_2 : n \Rightarrow t}
\end{array} \\
\begin{array}{c}
\text{LET} \qquad \text{ITE} \\

\end{array}$$

■ **Figure 4** POLARA’s type system.

natural number and floating point literals, arithmetic symbols, function application (`app`), array access (`get`), pair construction (`pair`), first and second projection (`fst`, `snd`), and array summation (`sum`). POLARA terms are variable access, n-ary constant application, function abstraction, array construction, branching (`ite`), and let-binding. We decided to put first-order syntax forms such as function application, array access, pairing, and the product projections into the constants, because they are all handled uniformly by the following algorithms, while the higher-order syntax forms, i.e., the ones that bind variables, such as function abstraction, array construction, branching, and let-binding are kept in the terms because they are all treated differently.

Intrinsic Types. The typing rules for POLARA are given in Figure 4. First, we give the types for constants. Note that we use the \rightarrow symbol for the typing judgement of constants that take arguments. This is not to be confused with the type constructor $\hat{\rightarrow}$. The typing rules for variables (VAR), function abstractions (FUN), and `let`-bindings (LET) are standard. The rule CONST allows one to apply a constant to a number (possibly zero) of arguments. For example, as `app` has type $(t_1 \hat{\rightarrow} t_2) \rightarrow t_1 \rightarrow t_2$, the expression `app` $e_1 e_2$ has type t_2 when $e_1 : t_1 \hat{\rightarrow} t_2$ and $e_2 : t_1$. The FOR rule shows that constructing an array with `for` requires an expression of type `nat` for the size and another expression, which can use the (numerical) index i and whose type gives the element type of the array. The ITE rule states that the condition has to be of type `nat` and the two branches have to be of the same type (the condition is considered true if nonzero).

PHOAS. Our formal development uses parametric higher-order abstract syntax (PHOAS) [29, 5], allowing us to leverage the binders of the host language as binders for the guest language. Terms are parametrized by an abstract denotation of types Γ , and variables contain a value of that type. By using PHOAS, we can avoid certain technicalities relating to variable binding such as capture-avoiding substitution, thereby streamlining the implementation.

Static Size. As mentioned above, our array types have the form $n \Rightarrow a$, where n is the size of the array. The fact that the size of an array is always part of its static type, implies that the sizes of all arrays are known at compile time. This guarantees that indexing can be statically checked for out-of-bounds array accesses, ensuring the absence of run time errors without requiring run time checks.

Because POLARA is not polymorphic, expressions operating on arrays are fixed to specific array sizes. For example, there is no single expression in POLARA that can map a function over an array of *arbitrary* size. This restriction is alleviated because our language is embedded, allowing us to reuse polymorphism from the host language. More concretely, we can define a function in the host language that for each number n returns a POLARA term implementing `map` on an array of size n (here, λ belongs to the host language and `fun` belongs to POLARA):

```
map  :  (n : ℕ) → (Γ ⊢ (t1 ↗ t2) ↗ (n ⇒ t1) ↗ (n ⇒ t2))
map := λn. fun f a. for i. f a[i]
```

Termination. The use of static array sizes ensures that array indexing is total. In fact, every language construct in POLARA is deterministic and terminating, making the language total; hence it is not Turing-complete. Most notably, we eschew general recursion in favor of the more well-behaved looping construct `for`. The lack of non-termination allows us to give a simple denotational semantics and guarantees termination of normalization, as described next.

Normalization by Evaluation (NbE). Normalization is defined in Figure 5 by a denotation for types ($\llbracket t \rrbracket_\Gamma : \text{Type}$), a corresponding denotation for terms and constants (such that when e has type t , then $(\llbracket e \rrbracket_\Gamma : \llbracket t \rrbracket_\Gamma)$), as well as functions `quote` (η), `splice` (η'), and `norm`. Note the additional argument Γ – this is a peculiarity of the PHOAS representation, where Γ determines the denotation of variables. This argument can take different values, depending on which information we want to extract from a term. For example, when pretty-printing a term we want to produce a string, so we associate every variable also with a string ($\Gamma t := \text{String}$). For NbE, every term should be translated to the denotation of their type, so we associate every variable to the denotation $\llbracket \cdot \rrbracket_\Gamma$ of its type using Γ . The function `norm` takes a value of type $(\forall \Gamma. \Gamma \vdash t)$ and returns one of the same type. The quantification means that we can only use variables that were created by the language’s binding constructs, so the type represents closed terms.

The denotation of a bounded natural number is a bounded natural number term, the denotation of a floating point number is a floating point number term, the denotation of a product is a product of the denotations, the denotation of a function is a function of the denotations, the denotation of an array is a function from a bounded natural number term to a denotation of the array’s content. Later, for code generation, we will again distinguish functions and arrays. But for the purpose of normalization by partial evaluation (NbE), we model arrays as functions so as to reduce the need for rules for both of them.

The quote η and splice η' functions perform eta-expansion of terms by recursion over the types. Quote turns denotations into terms, and splice turns terms back into denotations. The denotation of a POLARA term is a corresponding host-language value of that term (i.e., a Lean value in our mechanization). NbE then evaluates terms in the environment of splicing, followed by quoting the denotation back into a term.

Constants denote functions that check for whether their argument is known, and the partial evaluation of their argument; otherwise, they quote/splice the term into a denotation of the type.

$$\begin{array}{lll}

4.2 A_iNF and Common Subexpression Elimination

FOAS. An essential component for implementing common subexpression elimination is the ability to compare to terms for equality. As we cannot decide equality over functions, we have to convert from parametric higher-order abstract syntax (PHOAS) to first-order syntax (FOAS) to get decidable equality for identifiers and terms containing variables.

A_iNF. In A_iNF, we distinguish between variables x and indices i (Figure 3). Variables are introduced by let-binding, while indices are introduced by functions and loops. An A_iNF term is a sequence of pattern-matching let-bindings of primitives, ending in a final variable (Figure 3, A_iNF). An essential property of A_iNF is thus, that it is both maximally fissioned (each for loop just has a single operation as a body) and maximally flat (an A_iNF term is a single list of terms without subterms, executed one after another). Pattern matching contexts C have one hole for the variable, and one form for each higher-order argument to any term former, namely array construction, function abstraction, if-consequence, and if-alternative. Primitives are constant application, indices, variable access, function abstraction, and array construction.

33:16 Compiling with Arrays

$C[\cdot]$	$: (\vdash t_1) \rightarrow (\text{Var } t_1 \rightarrow \text{A}_i\text{NF } t_2) \rightarrow \text{A}_i\text{NF } t_2$
$C[x]$	$= (\lambda x) k$
$C[i]$	$= (\lambda i) k$
$C[c e_1 e_2]$	$= C[e_1] \lambda x_1. C[e_2] \lambda x_2. (\lambda c x_1 x_2) k$
$C[\text{fun } i:t. e]$	$= C[\text{fun } i:t. \cdot] [e] \lambda x. (\lambda \text{fun } i:t. x) k$
$C[\text{for } i:e_1. e_2]$	$= C[e_1] \lambda x_1. C[\text{for } i:x_1. \cdot] [e_2] \lambda x_2. (\lambda \text{for } i:x_1. x_2) k$
$C[\text{ite } e_1 e_2 e_3]$	$= C[e_1] \lambda x_1. C[\text{if } x_1=0. \cdot] [e_2] \lambda x_2. C[\text{if } x_2 \neq 0. \cdot] [e_3] \lambda x_3. (\lambda \text{ite } x_1 x_2 x_3) k$
$C[\text{let } e_1; e_2]$	$= C[e_1] \lambda x_1. C[e_2 x_1] k$

(a) Fission.

$$\begin{aligned} (\cdot) &: \text{Prim } t_1 \rightarrow (\text{Var } t_1 \rightarrow \text{A}_i\text{NF } t_2) \rightarrow \text{A}_i\text{NF } t_2 \\ (\lambda x) k &= k x \\ (\lambda p) k &= \text{let } x = p; k x \quad \text{where } x \text{ unique} \end{aligned}$$

(b) Smart binding.

Figure 6 Fission with smart binding.

Conversion to A_iNF (Figure 6) exploits the fact that continuation-passing-style automatically flattens code. The function $C[e] k$ takes as inputs a POLARA term e , a pattern matching context C , and a continuation k , and returns an A_iNF term. In the mechanization the function uses a reader monad as well to generate unique variable names. The function is initialized with the empty pattern matching context, and the identity continuation; the variable counter is initialized with zero.

Another important helper function is smart binding $(\lambda p) k$, which takes a primitive p and a continuation k . Smart binding ensures that every primitive term passed to it is bound to a variable name, and that variable name is passed to the continuation. If the primitive term is a variable already, this variable name is passed to the continuation; otherwise the term is bound to a unique variable name, incrementing the counter.

Translation to A_iNF by $C[e] k$ recurses structurally over the term e . In the case of a variable or an index, the term is forwarded to smart binding. In the case of a constant application (exemplary shown for binary constant application), first the first subterm is translated, then in the continuation the second subterm is translated, and in the continuation the term is reconstructed as a primitive with variable referencing the name of the translated subterms, which is passed to smart binding to generate a new name for this term, passing the continuation along. In the case of function abstraction, array construction, and conditional expressions, the subterms are translated as well, but in adapted contexts, and the final term is passed as well to smart binding to generate a name for it, and the continuation is passed along. Concretely, in the case of function abstraction, the function body is translated in a context which includes the function argument. In the case of array construction, the array body is translated in a context which includes the iteration variable. In the case of conditional expressions, the consequence is translated in a context which includes the condition, and the alternative is translated in a context which includes the negation of the condition. Finally, in the case of let-binding, first the right-hand side of the binding is translated, and then the body of the binding.

CSE. In addition to deciding equality for terms, a further complication with common subexpression elimination is that we also need to decide equality in the presence of already established equalities. For example consider the term $x=v$, $y=v$, $z=(x+y)$, $q=(y+x)$, $t=z+1$,

$$\begin{aligned}
 \text{Ren} &= [(t_1 : \text{Ty}) \times \text{Var } t_1 \times \text{Var } t_1] \\
 \text{Nam} &= [(t_1 : \text{Ty}) \times \text{Prim } t_1 \times \text{Var } t_1] \\
 \text{CSE} &: \text{Ren} \rightarrow \text{Nam} \rightarrow \text{A}_i\text{NF } t_2 \rightarrow \text{A}_i\text{NF } t_2 \\
 \text{CSE } r \sigma x &= (\sigma, \text{ren}_r x) \\
 \text{CSE } r \sigma (\text{let } C[x = p]; a) &= \begin{cases} \text{CSE } r (\text{let } C'[x = p']; \sigma) a & \text{if } \text{lookup } \sigma C' x p' = \text{none} \\ \text{CSE } ([x := x'] :: r) \sigma' a & \text{if } \text{lookup } \sigma C' x p' = \text{some } (x', \sigma') \\ \text{where } p' = \text{ren}_r p \\ \text{where } C' = \text{ren}_r C \end{cases}
 \end{aligned}$$

■ **Figure 7** Common subexpression elimination.

`r=q+1,` Correct CSE should eliminate it to `x=v, z=(x+x); t=z+1; rename [y→x; q→z; r→t]`, Notice how the later eliminations are dependent on the earlier ones. If we simply rename the remaining term every time we detect a variable to be redundant, then this algorithm would perform exponentially worse, because every renaming is a traversal over the whole remaining term, and CSE itself is already a traversal over the whole term. To keep everything with a single traversal, we adapt CSE to carry a renaming with it, which is applied just before a term is checked for redundancy.

CSE (Figure 7) takes a renaming, a naming, and an A_iNF term, and returns a new A_iNF term of the same type. A renaming is a list of pairs of variables of the same type, representing that the first variable is to be replaced by the second. A naming is a list of pairs of a primitive and a variable of the same type, representing that the primitive term has been previously bound to that variable. CSE works by structural recursion over the term. When the input term is just a variable, it simply applies the renaming. When the input term is a let-binding, then the renaming is applied to the term as well. The renamed term is looked up in the list of previously defined terms. If the term has not been bound to a variable name already (none), then the term is now let-bound to a variable, inside a renamed pattern matching context C . CSE proceeds with the remaining terms a , remembering that the term p' has been bound to σ , so that future redundant occurrences of p' can be eliminated. If the term has already been bound to a variable name (some x'), then no let-binding is produced, but only the renaming is extended to replace future references to x to the already existing x' instead. CSE proceeds with the remaining terms a , remembering that the term p' has been bound to σ , so that future redundant occurrences of p' can be eliminated.

4.3 Mechanization in Lean

In this section, we present excerpts from the Lean mechanization and relate them to the paper formalization. The type of terms `Tm` corresponds to $(\Gamma \vdash t)$ and features constructors for variables and constants (`var`, `cst0` etc.). In the paper, we do not write these constructors explicitly, so we would write `x` rather than `var x`. We define the following types corresponding to the above definitions of syntax (Figure 3) in Lean.

33:18 Compiling with Arrays

```

inductive Var : Ty → Type -- Variables Var
inductive Par : Ty → Type -- Indices Iidx

inductive Ty           -- Types t
inductive Const0 : Ty → Type      -- Constants c (nullary)
inductive Const1 : Ty → Ty → Type -- Constants c (unary)
inductive Const2 : Ty → Ty → Ty → Type -- Constants c (ternary)
inductive Tm (Γ: Ty → Type): Ty → Type -- Terms e

inductive Prim : Ty → Type -- Primitives p
inductive Env : Type       -- Scoped Contexts C
inductive AINF : Ty → Type -- AINF a

```

Lean

In particular, we define the following functions in Lean. The function `Ty.de` corresponding to denotation of types $\llbracket \cdot \rrbracket_\Gamma$, `quote` to η and `splice` to η' , `Const0.de`, `Const1.de`, `Const2.de` and `Tm.de` were shown as term, constant, and its denotations $\llbracket \cdot \rrbracket$. Finally, `norm` is defined using `term` denotations and `quote`.

```

def Ty.de (Γ : Ty → Type): Ty → Type

def quote {Γ} : {α : Ty} → Ty.de Γ α → Tm Γ α
def splice {Γ} : {α : Ty} → Tm Γ α → Ty.de Γ α

def Const0.de : Const0 α → Ty.de Γ α
def Const1.de : Const1 β α → Ty.de Γ β → Ty.de Γ α
def Const2.de : Const2 γ β α → Ty.de Γ γ → Ty.de Γ β → Ty.de Γ α
def Tm.de : Tm (Ty.de Γ) α → Ty.de Γ α

def Tm.norm : (forall (Γ), Tm Γ α) → Tm Γ α
| e => quote (Tm.de (e _))

```

Lean

The `smart_bnd` function takes an additional number argument, wrapped inside a reader monad, which is used for creating fresh variables. In the paper, we leave this out and just stipulate that the variable is fresh. The same applies to `toAINF`. When discussing CSE in the paper, we describe renamings. The `rename` functions define how a renaming is applied. CSE also requires us to check equality of expressions, which is done with the `beq` functions. The CSE function in the paper also calls `lookup`, which is not defined there. It corresponds to the built-in `ListMap.lookup`. Our code also contains a function `Env.or`, which merges two environments. This is used to allow CSE to remove redundancies which appear in different, but compatible, environments.

In particular, we define the following functions in Lean, corresponding to the functions above:

```

def Prim.beq : Prim α → Prim α → Bool
def AINF.beq : AINF α → AINF α → Bool
def AINF.smart_bnd : Env → Prim α → (VPar α → Counter (AINF β)) → Counter (AINF β)
def Tm.toAINF (e : Tm VPar α) : AINF α
def Var.rename : Ren → Var α → Var α
def VPar.rename (r: Ren): VPar α → VPar α
def Env.rename (r: Ren): Env → Env
def Prim.rename (r: Ren): Prim α → Prim α
def AINF.rename (r: Ren): AINF α → AINF α
def AINF.rename (r: Ren): AINF α → AINF α

```

```

def Env.or (Γ: Env) (Δ: Env): Tern → Option Env := fun t => match Γ, Δ with
def RAINF.upgrade : RAINF → Var b → Env → Option RAINF
def AINF.cse' : Ren → RAINF → AINF α → (RAINF × VPar α)
def merge: RAINF → VPar α → AINF α

def AINF.cse : Ren → RAINF → AINF α → AINF α
| r, σ, a => let (b, c) := a.cse' r σ; merge b.reverse c

```

Lean

4.4 Proofs

In this section, we show that normalization and translation to A_i NF are type-preserving, i.e. given a well-typed term, they always produce a valid term of the same type. We also show that translation to A_i NF produces maximally fissioned terms.

We use an intrinsically typed approach where the type system of the object language is included in the encoding of the data type for the language's syntax. Therefore, the host languages type system ensures only well-typed terms can be constructed.

Following an intrinsically typed approach means that the soundness properties hold simply because our (appropriately typed) definitions type check. We do not have to state and prove explicit, separate theorems, because the types of the functions already carry the necessary information.

► **Theorem 1** (Well-typedness of Optimization).

Our optimization procedure is terminating and type preserving.

Proof. Termination is ensured by Lean's built-in termination check. The fact that normalization terminates relies on POLARA being a total language. In particular, the absence of unbounded recursion and the combination of static array sizes with intrinsic typing avoids infinite loops and out-of-bounds accesses, ensuring that our normalization function always successfully terminates. Type preservation is ensured by intrinsically-typed mechanization; consider the types of normalization and CSE in Lean:

```

def Tm.norm : (forall (Γ : Type), Tm Γ α) → Tm Γ α
| e => quote (Tm.de (e _))
def AINF.cse : Ren → RAINF → AINF α → AINF α
| r, σ, a => let (b, c) := a.cse' r σ; merge b.reverse c

```

Lean

Intrinsic typing defines the typing of the object language (here, POLARA) using the typing of the host language (here, Lean), so the host language's type checker prevents the creation of ill-typed object language programs. This means that an element of $(\forall \Gamma, \text{Tm } \Gamma \alpha)$ is a well-typed POLARA program and an element of $\text{AINF } \alpha$ is a well-typed A_i NF term. Further, given a well-typed term, each function returns a well-typed term, which is what we mean by soundness with regard to the type system. ◀

► **Theorem 2** (Well-typedness of Translation).

Our translation procedure is terminating and type preserving.

Proof. Again, termination is guaranteed by Lean's termination checker. The argument for type preservation is similar to the one above: As both POLARA and A_i NF are defined using intrinsic typing, we can only construct well-typed programs. Consider the type of `toAINF` (we omit the definition):

```
def Tm.toAINF (e : Tm VPar α) : AINF α
```

Lean

If one tried to define `toAINF` in a way that produces an ill-typed program, the definition would be rejected by the type checker. ◀

Finally, $A_i\text{NF}$ is inductively defined to be maximally fissioned, i.e., as a list of primitives without subterms, therefore the act of translating POLARA terms into $A_i\text{NF}$ in a total programming language performs loop fission by definition.

► **Theorem 3 (Maximal Fission).**

Our translation into $A_i\text{NF}$ produces terms with maximal fission.

Proof. Consider the definition of $A_i\text{NF}$ terms:

```
inductive AINF : Ty → Type
| ret : VPar α → AINF α
| bnd : Env → Var α → Prim α → AINF β → AINF β
```

Lean

Here, a value of type $VPar \alpha$ can be a variable or a parameter. A value of type $Prim \alpha$ is a primitive (not nested) operation. The constructor bnd represents a variable assignment while ret returns a variable or parameter and represents the end of the program. From this inductive definition, it is apparent that all $A_i\text{NF}$ terms have a flat structure where nested expressions are impossible. Recall that, in $A_i\text{NF}$, each assignment is considered its own separate loop. Because the body of each assignment only contains a single primitive, each loop has a body only consisting of one operation and hence an $A_i\text{NF}$ term is guaranteed to be maximally fissioned. Because the translation function toAINF has output type $AINF \alpha$, it can *only* produce such maximally fissioned terms. Further, Lean’s termination checker ensures that toAINF is total, and so always returns an $A_i\text{NF}$ term in finite time. ◀

5 Related Work

5.1 Intermediate Languages

Early work by Steele [38] implemented a continuation-passing-style (CPS) IR in a functional compiler, stressing the suitability of CPS for compilation, as it closely mimics how control flow is expressed with jumps in hardware instructions, and makes evaluation order explicit in the syntax. Appel [2] observed that beta-reductions in the lambda calculus are unsound in the presence of side effects as they could duplicate the effect. Yet, CPS, which makes evaluation order explicit, enables to perform certain optimizations, such as dead code elimination (DCE), and common subexpression elimination (CSE), by exploiting that in CPS every subterm is referenced by a unique name.

Sabry and Felleisen [34] identified that additional power of compiling in CPS [30] corresponds to the additional rules of the monadic computational language [24]. Of particular importance is the so-called associativity law of the monad, i.e., the let-let commuting conversion, enabling the flattening of code. Then, Flanagan [11] coined the name “A-normal form (ANF)” for the now popular IR, which in contrast to CPS, expresses sequential execution by simple let-binding rather than continuations. The difference between ANF and the monadic language is that ANF forbids nested let-bindings, i.e., code must be normal with regard to the associativity rule of the monad.

However, Kennedy [18] showed that moving from CPS to ANF did not take into account branching. More precisely, while the let-let commuting conversion enables the flattening of code, the let-if commuting conversion *duplicates* code into each branch, in the worst case leading to blow-up of code size exponential in the number of branches. Given that recursion always includes a branch for base case(s) and step case(s), the same problem appears with recursion. Kennedy therefore argued for a return to CPS.

The issue was resolved by Maurer et al. [22], who provided an implementation of ANF for use in the Glasgow Haskell Compiler (GHC), and further simplified by Cong et al. [6] who provided implementations for MiniScala and Lightweight-Modular-Staging (LMS). Cong showed that it is possible to combine the simplicity of let-bindings for sequential execution and the power of continuations for further control flow, by adding control operators to ANF, which enable to capture the current continuation.

In our work, we highlight the importance of commuting conversions, and extend the idea of having an intermediate language that intrinsically encodes maximal let-let conversion to an intermediate language that also intrinsically encodes maximal let-for and let-if commuting conversion, without exponential blow-up of code size. Further, as this work lies in the context of array programming, recursion is not often necessary, and can thus be avoided.

The logical connection between polarity and common subexpression elimination has also been explored by Miller and Wu [23].

5.2 Array Programming

Shaikhha et al. [37] present a differentiable programming language which is an extension of the lambda calculus. For array computations, they use an approach based on higher-order functions. It directly represents the duality of functions and arrays through built-in functions `build` for creating an array from a function and `get` for turning an array into a function. The fact that `get` is a left inverse of `build` leads to the equivalence $\text{get}(\text{build } n \ e) i \equiv e i$, which can be used for optimization. Another strand of research makes use of the standard technique of *rewriting strategies* to optimize functional array programs [13, 4], suggesting the viability of standard techniques from term rewriting for optimizing array programs. Liu et al. [20] present a framework that can express a variety of optimizations through formally verified term rewriting, achieving competitive performance; however, CSE is not addressed. Their representation is first-order and features an array generation construct similar to the one in POLARA. Optimization in POLARA is not based on rewriting, but instead uses partial evaluation.

Feldspar [3] is a DSL for array computations in Haskell. It features a `parallel` construct similar to our `for` constructor, as well as `while` loops. Feldspar is compiled to C and performs standard optimizations like fusion, as well as copy propagation and loop unrolling. Feldspar's backend uses a dataflow graph and an imperative intermediate representation, whereas our intermediate representation is functional and specifically designed to support optimizations on array programs.

SaC [35] is a functional first-order array language. Array computations are expressed using *with-loops*, which consist of at least one generator and one operator. Each generator consists of an index range and an expression giving the value of the output array at a given index in the range. The operator can provide default values for indices not included in any generator, a base array that should be modified by the generators, or it can describe an aggregation. More recently, SaC has added support for *tensor comprehensions* [36], which drop the operator part and add pattern matching on indices as well as bound and shape inference, making the notation more lightweight. Similar to our approach, their tensor comprehensions do not support summation, which is added in the form of a built-in function. SaC's optimizations are not based on a logical foundation, but consist of a pipeline of optimization algorithms. In POLARA we derive our syntax form for pattern matching on arrays from polarization type theory, enabling additional commuting conversions and thus grounding our optimization algorithm on a logical foundation.

6 Conclusion

This paper introduced $A_i\text{NF}$, a novel intermediate representation for array computations, and POLARA, a surface array language. The proposed optimization algorithm for $A_i\text{NF}$, based on typed partial evaluation and common subexpression elimination, simplifies program optimization by interpreting arrays as positively polarized types. This approach avoids complexities associated with optimization schedules for conventional ANF. We formalized $A_i\text{NF}$ and POLARA. We proved sound the translation from POLARA to $A_i\text{NF}$ and optimization.

For future work, we are working on extending the language with automatic differentiation and probabilistic primitives, and proving these extensions correct as well. We are interested in applying our optimization to redundancies generated by automatic differentiation. Further, given that $A_i\text{NF}$, based on ANF, is related to monadic notation, it would be interesting to investigate whether Applicative notation [21, 33], Arrow notation [16], and Comonad Notation [27] provide similar insights for normalization by evaluation approach to optimization.

Pipit on the Post: Proving Pre- and Post-Conditions of Reactive Systems

Amos Robinson  

Sydney, Australia

Alex Potanin  

Australian National University, Canberra, Australia

Abstract

Synchronous languages such as Lustre and Scade are used to implement safety-critical control systems; proving such programs correct and having the proved properties apply to the compiled code is therefore equally critical. We introduce Pipit, a small synchronous language embedded in F^{*}, designed for verifying control systems and executing them in real-time. Pipit includes a verified translation to transition systems; by reusing F^{*}'s existing proof automation, certain safety properties can be automatically proved by k-induction on the transition system. Pipit can also generate executable code in a subset of F^{*} which is suitable for compilation and real-time execution on embedded devices. The executable code is deterministic and total and preserves the semantics of the original program.

1 Introduction

Safety-critical control systems, such as the anti-lock braking systems that are present in most cars today, need to be correct and execute in real-time. One approach, favoured by parts of the aerospace industry, is to implement the controllers in a high-level language such as Lustre [10] or Scade [13], and verify that the implementations satisfy the high-level specification using a model-checker, such as Kind2 [11]. These model-checkers can prove many interesting safety properties automatically, but do not provide many options for manual proofs when the automated proof techniques fail. Additionally, the semantics used by the model-checker may not match the semantics of the compiled code, in which case properties proved do not necessarily hold on the real system. This mismatch may occur even when the compiler has been verified to be correct, as in the case of Vélus [5]. For example, in Vélus, integer division rounds towards zero, matching the semantics of C; however, integer division in Kind2 rounds to negative infinity, matching SMT-lib [2, 25].

To be confident that our proofs hold on the real system, we need a single shared semantics for the compiler and the prover. In this paper we introduce Pipit¹, an embedded domain-specific language for implementing and verifying controllers in F^{*}. Pipit aims to provide a

high-level language based on Lustre, while reusing F^{*}'s proof automation and manual proofs for verifying controllers [31], and using Low^{*}'s C-code generation for real-time execution [34]. To verify programs, Pipit translates its expression language to a transition system for k-inductive proofs, which is verified to be an abstraction of the original semantics. To execute programs, Pipit can generate executable code, which is total and semantics-preserving.

In this paper, we make the following contributions:

- we motivate the need to combine manual and automated proofs of reactive systems with a strong specification language (Section 2);
- we introduce Pipit, a minimal synchronous language that supports rely-guarantee contracts and properties; crucially, proof obligations are annotated with a status – *valid* or *deferred* – allowing proofs to be delayed until more is known of the program context (Section 3);
- we describe a *checked semantics* for Pipit; after checking deferred properties, programs are *blessed*, which marks their properties as valid (Subsection 3.2);
- we describe an encoding of transition systems that can express under-specified rely-guarantee contracts as functions rather than relations; composing functions results in simpler transition systems (Section 4);
- we identify the invariants and lemmas required to prove that the abstract transition system is an abstraction of the original semantics (Subsection 3.3, Subsection 4.3);
- similarly, we offer a mechanised proof that the executable transition system preserves the original semantics (Section 5);
- finally, we evaluate Pipit by implementing the high-level logic of a Time-Triggered Controller Area Network (TTCAN) bus driver and verifying an abstract model of a key component (Section 6).

2 Pipit for time-triggered networks

To introduce Pipit, we consider a *time-triggered* network driver, which has a static schedule dictating the network traffic, and which all nodes on the network must adhere to. This driver is a simplification of the Time-Triggered Controller Area Network (TTCAN) bus specification [15] which we will discuss further in Section 6.

At a high level, the network schedule is described by a *system matrix* which consists of rows of *basic cycles*. Each basic cycle consists of a sequence of actions to be performed at specific time-marks. Actions in the schedule may not be relevant to all nodes; the node's *node matrix* contains only the relevant actions. The node matrix is represented in memory by a *triggers array* containing triggers sorted by their time-marks; trigger actions include sending and receiving application-specific messages, sending reference messages, and triggering “watch” alerts. Reference messages start a new basic cycle; a subset of nodes, designated as leaders, send reference messages to synchronise the network. Watch alerts are generally placed after an expected reference message to signal an error if no reference message is received.

Figure 1 (left) shows an example node matrix for a non-leader node. The matrix consists of two basic cycles C0 and C1 with messages sent at time-marks 0, 1 and 2. The node expects to receive a reference message at time-mark 7; the watch at time-mark 9 allows a grace period before triggering an error if the reference message is not received. Figure 1 (right) shows the corresponding triggers array.

The network has strict timing requirements which prohibit the driver from looping through the entire triggers array at each time-mark. Instead, the driver maintains an index that refers to the current trigger. At each time-mark, the driver checks if the current trigger has expired or is inactive, and if so, it increments the index.

	TM0	TM1	TM2	...	TM9	0:{ time = 0; enabled = {C0,C1}; action = SEND(A); }
C0	SEND A	SEND B	-	...	WATCH	1:{ time = 1; enabled = {C0}; action = SEND(B); }
C1	SEND A	-	SEND C	...	WATCH	2:{ time = 2; enabled = {C1}; action = SEND(C); }

Figure 1 Left: node matrix; right: corresponding triggers array configuration.

2.1 Deferring and proving properties

We implement a streaming function *count_when* to maintain the index into the triggers array; the function takes a constant natural number *max* and a stream of booleans *inc*. At each step, *count_when* checks whether the current increment flag is true; if so, it increments the previous counter, saturating at the maximum; otherwise, it leaves the counter as-is.

```
let count_when (max: N) (inc: stream B): stream N =
  rec count
    check? (0 ≤ count ≤ max);
    let count' = (0 fby count) + (if inc then 1 else 0) in
      if count' ≥ max then max else count'
```

The implementation of *count_when* first defines a recursive stream, *count*, which states an invariant about the count before defining the incremented stream *count'*. Inside *count'*, the syntax *0 fby count* is read as “the initial value of zero followed by the previous count”.

The syntax *check_? (0 ≤ count ≤ max)* asserts that the count is within the range [0, *max*]. The subscript _? on the check is the *property status*, which in this case denotes that the assertion has been stated, but it is not yet known whether it holds. A property status of _?, on the other hand, denotes that a property has been proved to hold. These property statuses are used to defer checking properties until enough is known about the environment, and to avoid rechecking properties that have already been proven. In practice, the user does not explicitly specify property statuses in the source language. The stated property (*0 ≤ count ≤ max*) is a stream of booleans which must always be true. Non-streaming operations such as *≤* are implicitly lifted to streaming operations, and non-streaming values such as 0 and *max* are implicitly lifted to constant streams.

We defer the proof of the property here because, at the point of stating the property inside the *rec* combinator, we don’t yet have a concrete definition for the *count* variable. In this case, we could have instead deferred the *statement* of the property by introducing a let-binding for the recursive count and putting the *check* outside of the *rec* combinator. However, it is not always possible to defer property statements: for example, when calling other streaming functions that have their own preconditions, it may not be possible to move the function call outside of its enclosing *rec*.

Pipit is an embedded domain-specific language. The program above is really syntactic sugar for an F^{*} program that takes a natural number and constructs a Pipit core expression with a free boolean variable. We will discuss the details of the core language in Section 3, but for now we focus on the source program with some minor embedding details omitted.

To actually prove the property above, we use the meta-language F^{*}’s tactics to translate the program into a transition system and prove the property inductively on the system. Finally, we *bless* the expression, which marks the properties as valid ([_? := _?]). Blessing is an intensional operation that traverses the expression and updates the internal metadata, but does not affect the runtime semantics.

```
let count_when? (max: N): stream B → stream N =
  let system = System.translate1(count_when max) in
  assert (System.inductive_check system) by (pipit_simplify ());
  bless1 (count_when max)
```

The subscript 1 in the translation to transition system and blessing operations refers to the fact that the stream function has one stream parameter. The *pipit_simplify* tactic in the assertion performs normalisation-by-evaluation to simplify away the translation to a first-order transition system; F*'s proof-by-SMT can then solve the inductive check directly.

Callers of *count_when* can now use the validated variant without needing to re-prove the count-range property. In a dedicated model-checker such as Kind2 [11] or Lesar [35], this kind of bookkeeping would all be performed under-the-hood. By embedding Pipit in a general-purpose theorem prover, we move some of the bookkeeping burden onto the user; however, we have increased confidence that the compiled code matches the verified code and, as we shall see, we also have access to a rich specification language.

2.2 Restrictions on the triggers array

Our driver may fall behind when trying to execute certain schedules, as the driver only processes one trigger per time-mark. To ensure that the schedule can be executed on time, the triggers array must allow sufficient time for the driver to skip over any disabled triggers before the next enabled trigger starts.

Recall our concrete triggers array from Figure 1, which contained trigger 1 (SEND B at time-mark 1 on cycle C0), and trigger 2 (SEND C at time-mark 2 on cycle C1). We could postpone trigger 1 to send B at time-mark 2, as the corresponding cell in the node matrix is empty. However, we *cannot* bring the trigger at index 2 forward to send message C at time-mark 1, as it takes two steps to reach trigger 2 from the start of the array.

We impose three restrictions on *valid* triggers arrays: the time-marks must be sorted; there must be an adequate time-gap between any two triggers that are enabled on the same cycle index; and each trigger's time-mark must be greater-than-or-equal to its index, so that it is reachable in time from the start of the array.

With these restrictions in place, we prove a lemma *lemma_can_reach_next*, which states that for all valid cycle indices and trigger indices, if the current trigger is enabled in the current cycle and there is another enabled trigger scheduled to occur somewhere in the array after the current one, then there is an adequate time-gap to allow the driver to skip over any disabled triggers in-between. These properties are straightforward in a theorem prover, but are difficult to state in a model-checker with a limited specification language.

2.3 Instantiating lemmas and defining contracts

We can now implement the trigger-fetch logic, which keeps track of the current trigger. We use the *count_when* streaming function to define the index of the current trigger; we tell *count_when* to increment the index whenever the previous index has expired or is inactive in the current basic cycle. We simplify our presentation here and only consider a constant cycle: the real system presented in Section 6 has some extra complexity such as resetting the index, incrementing the cycle index at the start of a new cycle, and using machine integers.

```
let trigger_fetch (cycle: N) (time: stream N): stream N =
  rec index.
    let inc = false fby ((time_mark index) ≤ time ∨ ¬(enabled index cycle)) in
    let index = count_when[trigger_count inc] in
    pose (lemma_can_reach_next cycle index);
    check[ ] (can_reach_next_active cycle time index);
    index
```

The *trigger_fetch* function takes a static cycle index and a stream denoting the current time. The increment flag and the index are mutually dependent – the increment flag depends on the previous value of the index, while the index depends on the current value of the increment flag – so we introduce a recursive stream for the index. We allow the index to go one past the end of the array to denote that there are no more triggers.

We use the *pose* helper function to lift the *lemma_can_reach_next* lemma to a streaming context and instantiate it. We then state an invariant as a deferred property. Informally, the invariant states that, either the current active trigger is not late, or the next active trigger after the current index is in the future and we can reach it in time.

With the explicitly instantiated lemma, we can prove the streaming invariant by straightforward induction on the transition system. To help compose this function with the rest of the system, we also abstract over the details of the trigger-fetch mechanism by introducing a rely-guarantee contract for *trigger_fetch*. The contract we state is that if we are called once per time-mark then we guarantee that we never encounter a late trigger.

```
let trigger_fetch□ (cycle: N): stream N → stream N =
  let contract = Contract.contract_of_stream1 {
    rely = (λtime. time = 0 fby (time + 1));
    guar = (λtime index. (index_valid index ∧ enabled index cycle)
              ⇒ (time_mark index) ≥ time);
    body = (λtime. trigger_fetch cycle time);
  } in
  assert (Contract.inductive_check contract) by (pipit_simplify ());
  Contract.stream_of_contract1 contract
```

In the implementation of the validated variant of *trigger_fetch*, we first construct the contract from streaming functions. The *Contract.contract_of_stream₁* combinator describes a contract with one input (the time stream), and takes stream transformers for each of the rely, guarantee and body. The combinator transforms the surface syntax into core expressions. The assertion (*Contract.inductive_check contract*) then translates the expressions into a transition system, and checks that if the rely always holds then the guarantee always holds, and that the as-yet-unchecked subproperties hold. Finally, *Contract.stream_of_contract₁* blesses the core expression and converts it back to a stream transformer, so it can be easily used by other parts of the program.

The key distinction between our streaming rely-guarantee contracts and imperative pre-post contracts is that the rely and guarantee are both *streams* of booleans, rather than instantaneous predicates. In this case, the rely (*time = 0 fby (time + 1)*) checks that the current time is exactly one time-mark after the time at the previous *tick* of computation. Expressing such a rely in an imperative setting would require extra encoding, as preconditions in imperative languages do not generally have an innate notion of the previous value with respect to a global shared clock.

When *trigger_fetch* is used in other parts of the program, the caller must ensure that the environment satisfies the rely clause. In the core language, this is tracked by another deferred property status attached to the contract; we will discuss this further in Section 3.

3 Pipit core language

We now introduce the core Pipit language. Note that this form differs slightly from the surface syntax presented earlier in Section 2, which used the syntax of the metalanguage F*, as well as including proofs in F* itself.

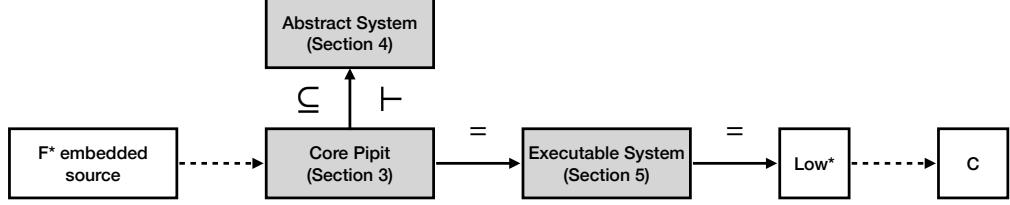

Figure 2 Architecture of Pipit. The gray boxes and solid arrows are defined in this paper. The white boxes and dashed arrows are trusted components. The labels denote verified properties of the translation: abstraction (\subseteq), entailment of proof obligations (\vdash), and equivalence (=).

$e, e' := v \mid x \mid p(\bar{e})$	(values, variables and operations)
$v \text{ fby } e \mid \text{rec } x. e[x]$	(delayed and recursive streams)
$\text{let } x = e \text{ in } e'[x]$	(let-expressions)
$\text{check}_\pi e_{\text{prop}}$	(checked properties)
$\text{contract}_\pi \{e_{\text{rely}}\} e_{\text{body}} \{x. e_{\text{guar}}[x]\}$	(rely-guarantee contracts)
$v := n \in \mathbb{N} \mid b \in \mathbb{B} \mid r \in \mathbb{R} \mid \dots$	(values)
$p := (+) \mid (-) \mid (\times) \mid \text{if-then-else} \mid \dots$	(primitives)
$\pi := \checkmark \mid \text{?}$	(property statuses: valid or unknown)
$V := \cdot \mid V; v$	(streams of values)
$\sigma := \{x \mapsto v\}$	(heaps)
$\Sigma := \cdot \mid \Sigma; \sigma$	(streaming history environments)
$\tau, \tau' := \mathbb{N} \mid \mathbb{B} \mid \tau \times \tau \mid \dots$	(value types)
$\Gamma := \cdot \mid x : \tau, \Gamma$	(type environments)

Figure 3 Core grammar: expressions e , values v , primitive operations p , and property statuses π .

Figure 2 shows the high-level architecture of Pipit. On the left-hand-side, the surface syntax embedded in F^* is shown; this includes some Pipit-specific syntactic sugar. The translation from the surface syntax to the core language is trusted. There are two targets from the core language: abstract transition systems for verification, and executable transition systems for extraction to C. The translation to abstract systems is verified to be an abstraction according to the dynamic semantics (Subsection 3.1). The translation to abstract systems also generates proof obligations, which are verified to correspond to the proof obligations on the original program. The translation to executable transition systems is proven to be semantics-preserving, as is the subsequent translation to Low^* . The translation from Low^* to C is external to this paper and forms part of our trusted computing base.

Figure 3 defines the grammar of Pipit. The expression form e includes standard syntax for values (v), variables (x) and primitive applications ($p(\bar{e})$). Most of the expression forms were introduced informally in Section 2 and correspond to the clock-free expressions of Lustre [10].

The expression syntax for delayed streams ($v \text{ fby } e$) denotes the previous value of the stream e , with an initial value of v when there is no previous value.

Recursive streams are defined using the fixpoint operator (`rec` x . $e[x]$); the syntax $e[x]$ means that the variable x can occur in e . As in Lustre, recursive streams can only refer to their previous values and must be *guarded* by a delay: the stream (`rec` x . 0 `fby` $(x + 1)$) is well-defined and counts from zero up, but the stream (`rec` x . $x + 1$) is invalid and has no computational interpretation. This form of recursion differs slightly from standard Lustre, which uses a set of mutually-recursive bindings. Although we cannot express mutually-recursive bindings in the core syntax here, we can express them as a notation on the surface syntax by combining the bindings together into a record or tuple.

Checked properties and contracts are annotated with their property status π , which can either be valid (✓) or unknown (✗). For checked properties `check π e`, the property status denotes whether the property has been proved to be valid.

Contracts `contract π { e_{rely} } e_{body} { x . $e_{\text{guar}}[x]$ }` allow modular reasoning by replacing the implementation with an abstract specification. Contracts involve two verification conditions. Firstly, when a contract is *defined*, the definer must prove that the body satisfies the contract: roughly, if e_{rely} is always true, then $e_{\text{guar}}[x := e_{\text{body}}]$ is always true. Secondly, when a contract is *instantiated*, the caller must prove that the environment satisfies the precondition: that is, e_{rely} is always true. Conceptually, then, a contract could have two property statuses: one for the definition and one for the instantiation. However, in practice, it is not useful to defer the proof of a contract definition – one could achieve a similar effect by replacing the contract with its implementation. For this reason, we only annotate contracts with one property status, which denotes whether the instantiation has been proved to satisfy the precondition.

For example, the core expression (`rec sum. (0 fby sum) + ints`) computes the sum of values from a stream of integers ints by defining a recursive stream sum , which is delayed and given an initial value of zero. If we were to use this sum in a context that required a strictly positive integer, we could give it a contract that states that if the input stream is always positive, then the resulting sum is also positive:

```
contract✗ {ints > 0} (rec sum. (0 fby sum) + ints) {sum. sum > 0}
```

To be considered a valid program, we must prove that the contract definition itself holds, as with our earlier contract (Subsection 2.3). The unknown property status here allows us to defer the caller’s proof that the input stream is always positive until the contract is used.

The remaining grammatical constructs of Figure 3 describe streams, value environments, types and type environments. Streams V are represented as a sequence of values; streaming history environments Σ are streams of heaps. Types τ and type environments Γ are standard. For the presentation of the formal grammar here, we consider only a fixed set of values and primitives; in practice, the implementation is parameterised by a primitive table which we extend with immutable array operations for the TTCAN driver logic in Section 6.

We define the typing judgments for Pipit in Figure 4. Most of the typing rules are standard for an unclocked Lustre. The typing judgment $\Gamma \vdash e : \tau$ denotes that, in an environment of streams Γ , expression e denotes a stream of type τ . This core typing judgment differs from the surface syntax used in Section 2, which used an explicit stream type; for the core language, we instead assume that everything is a stream.

We use an auxiliary function $\text{prim-value-type}(v) = \tau$ to denote that value v has type τ ; for primitives $\text{prim-type}(p) = (\tau_1 \times \dots \times \tau_n) \rightarrow \tau'$ denotes that p takes arguments of type τ_i and returns a result of type τ' . Primitives are pure, non-streaming functions.

Rules TVALUE, TVAR, TPRIM and TLET are standard.

Rule TFBY states that expression $v \text{ fby } e$ requires both v and e to have equal types.

Rule TREC states that a recursive stream `rec` x . e has the recursive stream bound inside e . The recursion must also be guarded, in that any recursive references to x are delayed, but this requirement is performed as a separate syntactic check described in Subsection 3.3.

$$\boxed{\Gamma \vdash e : \tau}$$

$$\begin{array}{c}
\frac{\text{prim-value-type}(v) = \tau}{\Gamma \vdash v : \tau} \text{ (TVALUE)} \quad \frac{}{\Gamma, x : \tau, \Gamma' \vdash x : \tau} \text{ (TVAR)} \\
\\
\frac{\text{prim-type}(p) = (\tau_1 \times \dots \times \tau_n) \rightarrow \tau' \quad \Gamma \vdash e_1 : \tau_1 \quad \dots \quad \Gamma \vdash e_n : \tau_n}{\Gamma \vdash p(\bar{e}) : \tau'} \text{ (TPRIM)} \\
\\
\frac{\text{prim-value-type}(v) = \tau \quad \Gamma \vdash e' : \tau}{\Gamma \vdash v \text{ fby } e' : \tau} \text{ (TFBY)} \quad \frac{\Gamma, x : \tau \vdash e : \tau}{\Gamma \vdash \text{rec } x. e[x] : \tau} \text{ (TREC)} \\
\\
\frac{\Gamma \vdash e : \tau \quad \Gamma, x : \tau \vdash e' : \tau'}{\Gamma \vdash \text{let } x = e \text{ in } e'[x] : \tau'} \text{ (TLET)} \quad \frac{\Gamma \vdash e : \mathbb{B}}{\Gamma \vdash \text{check}_\pi e : \text{unit}} \text{ (TCHECK)} \\
\\
\frac{\Gamma \vdash e_{\text{rely}} : \mathbb{B} \quad \Gamma \vdash e_{\text{body}} : \tau \quad \Gamma, x : \tau \vdash e_{\text{guar}} : \mathbb{B}}{\Gamma \vdash \text{contract}_\pi \{e_{\text{rely}}\} e_{\text{body}} \{x. e_{\text{guar}}[x]\} : \tau} \text{ (TCONTRACT)}
\end{array}$$

Figure 4 Typing rules for Pipit; the judgment $\Gamma \vdash e : \tau$ denotes that expression e describes a stream of values of type τ . Auxiliary functions are used for values and primitive operations.

Rule TCHECK states that checked properties $\text{check}_\pi e$ require a boolean property e .

Finally, rule TCONTRACT applies for a contract $\text{contract}_\pi \{e_{\text{rely}}\} e_{\text{body}} \{x. e_{\text{guar}}[x]\}$ with a body expression of type τ . The overall expression has result type τ . Both rely and guarantee must be boolean expressions, and the guarantee can refer to the result as x .

3.1 Dynamic semantics

The dynamic semantics of Pipit are defined in Figure 5. We present our semantics in a big-step form. This differs somewhat from traditional *reactive* semantics of Lustre [10]. Our big-step semantics emphasises the equational nature of Pipit, as it is substitution-based and syntax-directed, while the reactive semantics emphasises the finite-state streaming execution of the system. We use transition systems for reasoning about the finite-state execution (Section 4), which is fairly standard [9, 11, 35]. Previous work on the W-CALCULUS [17] for linear digital-signal-processing filters makes a similar distinction and provides a non-streaming semantics for reasoning about programs and a streaming semantics for executing programs.

The judgment form $\Sigma \vdash e \Downarrow v$ denotes that expression e evaluates to value v under streaming history Σ . The streaming history is a stream of heaps; in practice, we only evaluate expressions with a non-empty streaming history.

At a high level, evaluation unfolds recursive streams to determine a value. For example, to evaluate the earlier sum example with input $\text{ints} = [1; 2]$, we start with the judgment:

$$\{ \text{ints} \mapsto 1 \}; \{ \text{ints} \mapsto 2 \} \vdash (\text{rec } \text{sum}. (0 \text{ fby } \text{sum}) + \text{ints}) \Downarrow v$$

First, we unfold the recursive stream one step to get $(0 \text{ fby } (\text{rec } \text{sum}. (0 \text{ fby } \text{sum}) + \text{ints})) + \text{ints}$. Evaluation of primitives is standard. To evaluate variables, we look for the variable in the current (rightmost) heap:

$$\frac{}{\{ \text{ints} \mapsto 1 \}; \{ \text{ints} \mapsto 2 \} \vdash \text{ints} \Downarrow 2} \text{ (VAR)}$$

$$\begin{array}{c}
\boxed{\Sigma \vdash e \Downarrow v} \\
\begin{array}{ccc}
\frac{}{\Sigma; \sigma \vdash x \Downarrow \sigma(x)} \text{ (VAR)} & \frac{}{\Sigma \vdash v \Downarrow v} \text{ (VALUE)} & \frac{\Sigma \vdash e'[x := e] \Downarrow v}{\Sigma \vdash \text{let } x = e \text{ in } e'[x] \Downarrow v} \text{ (LET)} \\
\\
\frac{\Sigma \vdash e_1 \Downarrow v_1 \quad \dots \quad \Sigma \vdash e_n \Downarrow v_n}{\Sigma \vdash p(\bar{e}) \Downarrow \text{prim-sem}(p, \bar{v})} \text{ (PRIM)} & & \\
\\
\frac{}{\sigma \vdash v \text{ fby } e' \Downarrow v} \text{ (FBY}_1\text{)} & \frac{\text{length}(\Sigma) > 0 \quad \Sigma \vdash e' \Downarrow v'}{\Sigma; \sigma \vdash v \text{ fby } e' \Downarrow v'} \text{ (FBY}_S\text{)} & \\
\\
\frac{\Sigma \vdash e[x := \text{rec } x. e] \Downarrow v}{\Sigma \vdash \text{rec } x. e[x] \Downarrow v} \text{ (REC)} & & \frac{}{\Sigma \vdash \text{check}_{\pi} e \Downarrow ()} \text{ (CHECK)} \\
\\
\frac{\Sigma \vdash e_{\text{body}} \Downarrow v}{\Sigma \vdash \text{contract}_{\pi} \{e_{\text{rely}}\} e_{\text{body}} \{x. e_{\text{guar}}[x]\} \Downarrow v} \text{ (CONTRACT)} & & \\
\\
\boxed{\Sigma \vdash e \Downarrow^* V} & & \boxed{\Sigma \vdash e \Downarrow^{\square} \top} \\
\\
\frac{}{\cdot \vdash e \Downarrow^*.} \text{ (STEPS}_0\text{)} & \frac{\Sigma \vdash e \Downarrow V \quad \Sigma; \sigma \vdash e \Downarrow v}{\Sigma; \sigma \vdash e \Downarrow V; v} \text{ (STEPS}_S\text{)} & \\
\\
\frac{\Sigma \vdash e \Downarrow^* \top; \dots}{\Sigma \vdash e \Downarrow^{\square} \top} \text{ (ALWAYS)} & &
\end{array}
\end{array}$$

Figure 5 Dynamic semantics for Pipit; the judgment form $\Sigma \vdash e \Downarrow v$ denotes that evaluating expression e under streaming history Σ results in value v .

For delays, we discard the current heap and continue evaluation with the history prefix:

$$\frac{\{ints \mapsto 1\} \vdash (\text{rec } sum. (0 \text{ fby } sum) + ints) \Downarrow 1 \quad \{ints \mapsto 1\}; \{ints \mapsto 2\} \vdash 0 \text{ fby } (\text{rec } sum. (0 \text{ fby } sum) + ints) \Downarrow 1}{\{ints \mapsto 1\}; \{ints \mapsto 2\} \vdash 0 \text{ fby } (\text{rec } sum. (0 \text{ fby } sum) + ints) \Downarrow 1} \text{ (FBY}_S\text{)}$$

Returning to Figure 5, rule VAR evaluates a variable x under some non-empty stream history $\Sigma; \sigma$, where σ is the most recent heap. Rules VALUE and LET are standard. Rule PRIM evaluates a primitive p applied to many arguments e_1 to e_n by evaluating each argument separately; we then apply the primitive with prim-sem metafunction.

For delay expressions $v \text{ fby } e$, we have two cases depending on whether there is a previous value. When there is no previous value – the streaming history only contains the current heap – rule FBY₁ evaluates to the default value v . Otherwise, rule FBY_S applies; we evaluate the previous value of e by discarding the most recent entry from the streaming history.

Rule REC evaluates a recursive stream $\text{rec } x. e$ by unfolding the recursion one step. For causal expressions (Subsection 3.3), where each recursive occurrence of x is guarded by a followed-by, this unfolding eventually terminates as each followed-by shortens the history.

Rule CHECK ignores the property when evaluating check expressions. We do not dynamically check the property here; this is done in the checked semantics (Subsection 3.2).

Similarly, rule CONTRACT ignores preconditions and postconditions when evaluating contracts. From an abstraction perspective, it would be valid to return an arbitrary value that satisfies the contract. However, such an abstraction would make evaluation non-deterministic and, for contracts with unsatisfiable postconditions, non-total. The deterministic and total nature of evaluation is key to our proofs and metatheory.

We also define two auxiliary judgment forms: $\Sigma \vdash e \Downarrow^* V$ and $\Sigma \vdash e \Downarrow^\square \top$.

Judgment form $\Sigma \vdash e \Downarrow^* V$ denotes that, under history Σ , expression e evaluates to the stream V . This judgment performs iterated application of single-value evaluation.

Judgment form $\Sigma \vdash e \Downarrow^\square \top$ denotes that a boolean expression e evaluates to the stream of trues under history Σ . Informally, it can be read as “ e is always true in history Σ ”.

3.2 Checked semantics

In addition to the big-step semantics above, we also define a judgment form for checking that the properties and contracts of a program hold for a particular streaming history. We call these the *checked* semantics; they are comparable to checking runtime assertions.

The checked semantics have the judgment form $\Sigma \vdash_\pi e$ valid, which denotes that under streaming history Σ , the properties and contracts of e with status π hold. The property status dictates which properties should be checked and which should be ignored.

We consider a program to be *valid* if its checks hold for all histories ($\forall \Sigma. \Sigma \vdash_\square e$ valid). The checked semantics are a specification describing what it means to be a valid program. We do not generally verify programs directly using the checked semantics; instead, we translate to an abstract transition system and construct the proofs there (Section 4).

To check a property ($\text{check}_\pi e$) in history Σ , we check that e is always true ($\Sigma \vdash e \Downarrow^\square \top$).

Checking contracts is more involved. For whole-program correctness, it would suffice to check that a contract’s rely and guarantee both hold. However, the purpose of contracts is to enable modular reasoning about parts of the program: we need to be able to check contracts independently of their context. Conceptually, then, contracts involve two kinds of checks: one for the definition and one for the call-site. To check a contract definition, we check that the body satisfies the guarantee for all *valid* contexts – that is, those where the rely holds. Then, to check a contract instance, we just need to check that the call-site satisfies the rely.

For example, recall our earlier contract that the sum of strictly positive integers is positive:

```
let sum i = contract[ ] {i > 0} (rec sum. (0 fby sum) + i) {sum. sum > 0}
```

To check the contract definition on a concrete input $i = [1; 2]$, we first evaluate the body:

$$\{i \mapsto 1\}; \{i \mapsto 2\} \vdash (\text{rec } sum. (0 \text{ fby } sum) + i) \Downarrow^* [1; 3]$$

We then check that, assuming all inputs are positive, then all results are positive:

$$\{i \mapsto 1\}; \{i \mapsto 2\} \vdash i > 0 \Downarrow^\square \top \implies \{i \mapsto 1, sum \mapsto 1\}; \{i \mapsto 2, sum \mapsto 3\} \vdash sum > 0 \Downarrow^\square \top$$

It is critical that the rely is true *at all points* in the stream. Consider if we had instead used the input stream $i = [-10; 1]$; the rely is false at the first step, but is instantaneously true at the second step. In this case, the sum is -10 at the first step, and -9 at the second step. At both steps the output is negative and the guarantee is false, even though the rely becomes true at the second step. The contract itself remains valid, however, as the assumption is invalid: the input did not satisfy the rely at all steps.

The checked semantics of Pipit is defined in Figure 6.

Rules CHKVALUE and CHKVAR state that values and variables are always valid.

Rule CHKPRIM checks a primitive application by descending into the subexpressions. Similarly, rule CHKFBY descends into followed-by expressions.

Rule CHKREC checks a recursive-expression `rec` $x. e$ by evaluating the overall expression to a stream of values V . The rule then extends the streaming environment Σ with x bound to the values from V ; this extended environment is used to descend into the recursive expression.

$$\begin{array}{c}
 \boxed{\Sigma \vdash_{\pi} e \text{ valid}} \\
 \frac{}{\Sigma \vdash_{\pi} v \text{ valid}} \text{ (CHKVALUE)} \quad \frac{}{\Sigma \vdash_{\pi} x \text{ valid}} \text{ (CHKVAR)} \\
 \frac{\Sigma \vdash_{\pi} e_1 \text{ valid} \quad \dots \quad \Sigma \vdash_{\pi} e_n \text{ valid}}{\Sigma \vdash_{\pi} p(\bar{e}) \text{ valid}} \text{ (CHKPRIM)} \quad \frac{\Sigma \vdash_{\pi} e' \text{ valid}}{\Sigma \vdash_{\pi} v \text{ fby } e' \text{ valid}} \text{ (CHKFBY)} \\
 \frac{\Sigma \vdash \text{rec } x. e \Downarrow^* V \quad \Sigma[x \mapsto V] \vdash_{\pi} e \text{ valid}}{\Sigma \vdash_{\pi} \text{rec } x. e[x] \text{ valid}} \text{ (CHKREC)} \\
 \frac{\Sigma \vdash_{\pi} e \text{ valid} \quad \Sigma \vdash e \Downarrow^* V \quad \Sigma[x \mapsto V] \vdash_{\pi} e' \text{ valid}}{\Sigma \vdash_{\pi} \text{let } x = e \text{ in } e'[x] \text{ valid}} \text{ (CHKLET)} \\
 \frac{(\pi = \pi' \implies \Sigma \vdash e \Downarrow^* \top) \quad \Sigma \vdash_{\pi} e \text{ valid}}{\Sigma \vdash_{\pi} \text{check}_{\pi'} e \text{ valid}} \text{ (CHKCHECK)} \\
 \frac{\begin{array}{c} \Sigma \vdash e_{\text{body}} \Downarrow^* V \\ (\pi = \pi' \implies \Sigma \vdash e_{\text{rely}} \Downarrow^* \top) \\ (\pi = \square \implies \Sigma \vdash e_{\text{rely}} \Downarrow^* \top \implies \Sigma[x \mapsto V] \vdash e_{\text{guar}} \Downarrow^* \top) \\ \Sigma \vdash_{\pi} e_{\text{rely}} \text{ valid} \end{array}}{(\Sigma \vdash e_{\text{rely}} \Downarrow^* \top \implies \Sigma \vdash_{\pi} e_{\text{body}} \text{ valid} \wedge \Sigma[x \mapsto V] \vdash_{\pi} e_{\text{guar}} \text{ valid})} \text{ (CHKCONTRACT)}
 \end{array}$$

Figure 6 Checked semantics for Pipit; the judgment form $\Sigma \vdash_{\pi} e \text{ valid}$ denotes that evaluating expression e under streaming history Σ satisfies the checks and rely-guarantee contract requirements that are labelled with property status π .

Rule CHKLET checks a let-expression `let` $x = e$ `in` e' descends into both sub-expressions. To check the body e' , the rule first evaluates e and extends the streaming environment.

Finally, the heavy lifting is performed by rules CHKCHECK and CHKCONTRACT.

Rule CHKCHECK checks the properties marked π in an expression $\text{check}_{\pi'} e$. If the check-expression has the same status as what we are checking ($\pi = \pi'$), then we evaluate the expression e and require it to be true at all steps. We then unconditionally descend into the subexpression to check any nested properties. Such nested properties are unlikely to be written directly by the user, but might occur after inlining.

Rule CHKCONTRACT applies when checking property status π of a contract with expression $\text{contract}_{\pi'} \{e_{\text{rely}}\} e_{\text{body}} \{x. e_{\text{guar}}[x]\}$. This rule checks both the contract definition and the call-site. We evaluate the body to a stream V ; these values are used to check that the body satisfies guarantee. Although the contract only has one property status, conceptually there are two distinct properties: one for the caller (π') and one for the definition (assumed to be \square). To check the caller property when $\pi = \pi'$, we evaluate the rely e_{rely} and require it to hold. To check the definition property when $\pi = \square$, we assume that the rely holds, and check that the body satisfies the guarantee. We also descend into the subexpressions to check them; when checking the body and guarantee, we can assume that the rely holds.

3.2.1 Blessing expressions and contracts

Blessing is a meta-operation that replaces the property statuses in an expression so that all checks and contracts are marked as valid (\checkmark). Blessing an expression requires a proof that, for all input streams, assuming the valid checks hold, then the unknown checks hold:

$$\frac{\forall \Sigma. \Sigma \vdash_{\square} e \text{ valid} \implies \Sigma \vdash_{\square} e \text{ valid}}{\text{bless } e} \text{ (BLESSEXPRESSION)}$$

We generally prove the required properties by first translating the program to an abstract transition system, as described in Section 4.

Blessing is different for contract definitions, as we need to separate the definition of the contract from the instantiation. To check that a contract definition is valid, we show that if the rely clause is always true for a particular input, then the body satisfies the guarantee for the same inputs. We also assume that the valid properties in the rely, body and guarantee hold, and show the corresponding unknown properties:

$$\begin{aligned} \text{let contract_valid } & \{e_{\text{rely}}\} \{e_{\text{body}}\} \{e_{\text{guar}}\} : \text{prop} = \\ & \forall \Sigma. (\Sigma \vdash_{\square} (e_{\text{rely}}, e_{\text{body}}, e_{\text{guar}}[x := e_{\text{body}}]) \text{ valid} \wedge \Sigma \vdash e_{\text{rely}} \Downarrow^{\square} \top) \\ & \implies (\Sigma \vdash_{\square} (e_{\text{rely}}, e_{\text{body}}, e_{\text{guar}}[x := e_{\text{body}}]) \text{ valid} \wedge \Sigma \vdash e_{\text{guar}}[x := e_{\text{body}}] \Downarrow^{\square} \top) \end{aligned}$$

After proving that the contract is valid for all inputs, we can bless the contract definition. Blessing the contract definition blesses the subexpressions for the rely, body and guarantee, but leaves the contract's *instantiation* property status as unknown:

$$\frac{\text{contract_valid } \{e_{\text{rely}}\} \{e_{\text{body}}\} \{e_{\text{guar}}\}}{\text{bless_contract } \{e_{\text{rely}}\} \{e_{\text{body}}\} \{e_{\text{guar}}\}} \text{ (BLESSCONTRACT)}$$

3.3 Causality and metatheory

To ensure that recursive streams have a computational interpretation, we implement a causality restriction, similar to standard Lustre [10]. This restriction checks that all recursive streams are guarded by a followed-by delay. We implement this as a simple syntactic check: each `rec` $x. e$ can only mention x inside a followed-by. This check ensures productivity of recursive streams, but can be too strict: for example, the expression `rec` $x. (\text{let } x' = x + 1 \text{ in } 0 \text{ fby } x')$ mentions the recursive stream x outside of the delay and is outlawed, but after inlining the let, it would be causal. We hope to relax this restriction in future work.

The causality restriction gives us some important properties about the metatheory. The most important property is that the dynamic semantics form a total function: given a streaming history and a causal expression, we can evaluate the expression to a value. These properties are mechanised in F^* .

► **Theorem 1** (bigstep-is-total). *For any non-empty streaming history Σ and causal expression e , there exists some value v such that e evaluates to v ($\Sigma \vdash e \Downarrow v$).*

The relationship between substitution and the streaming history is also important. In general, we have a substitution property that states that evaluating a substituted expression $e[x := e']$ under some context Σ is equivalent to evaluating e' and adding it to the context Σ :

► **Theorem 2** (bigstep-substitute). *For a streaming history Σ and causal expressions e and e' , if $e[x := e']$ evaluates to a value v ($\Sigma \vdash e \Downarrow v$), then we can evaluate e' to some stream V ($\Sigma \vdash e' \Downarrow^* V$) and extend the streaming history to evaluate e to the original value ($\Sigma[x \mapsto V] \vdash e \Downarrow v$). The converse is also true.*

```

type system (input:  $\Gamma$ ) (result:  $\tau$ ) = {
    state:  $\Gamma$ ;
    free:  $\Gamma$ ;
    init: heap state;
    step: heap input  $\rightarrow$  heap free  $\rightarrow$  heap state  $\rightarrow$  step_result state result;
}

type step_result (state:  $\Gamma$ ) (result:  $\tau$ ) = {
    update: heap state;
    value: result;
    rely: prop;
    guar: prop;
}

```

■ **Figure 7** Abstract transition system type definitions.

The big-step semantics in Figure 5 for a recursive expression `rec` $x. e$ performs one step of recursion by substituting x for the recursive expression. An alternative non-syntax-directed semantics would be to have the environment outside the semantics supply a stream V such that if we extend the streaming history with $x \mapsto V$, then e evaluates to V itself. The above substitution theorem can be used to show that, for causal expressions, these two semantics are equivalent. We can additionally show that, when evaluating e with $x \mapsto V$, the most recent value in V does not affect the result. This fact can be used to “seed” evaluation by starting with an arbitrary value:

► **Theorem 3** (bigstep-rec-causal). *For a streaming history $\Sigma; \sigma$ and a causal recursive expression `rec` $x. e$, if $(\Sigma; \sigma \vdash e \Downarrow v)$, then updating $\sigma[x]$ with any value v' results in the same value: $(\Sigma; \sigma[x \mapsto v'] \vdash e \Downarrow v)$.*

4 Abstract transition systems

To prove properties about Pipit programs, we translate to an *abstract* transition system, so-called because it abstracts away the implementation details of contract instantiations. For extraction we also translate to *executable* transition systems, which we discuss in Section 5.

Figure 7 shows the types of transition systems. A transition system is parameterised by its input context and the result type. It also contains two internal contexts: firstly, the state context describes the private state required to execute the machine; secondly, the free context contains any extra input values that the transition system would like to existentially quantify over. The free context is used to allow the system to ask for arbitrary values from the environment, when it would not otherwise be able to return a concrete value.

For recursive streams and contract instantiations, which hide their implementation, the natural translation to a transition system would involve existentially quantifying a result that satisfies the specification. Unfortunately, using an existential quantifier requires a step *relation* rather than a step *function*. Using a step relation complicates the resulting transition system, as other operations such as primitive application must also introduce existential quantifiers; such quantifiers block simplifications such as partial-evaluation and result in a more complex transition system. Instead, the free context provides the step function with a fresh unconstrained value of the desired type, which the step function can then constrain.

Back to Figure 7, the step-result contains the updated state for the transition system, as well as the result value. The step-result additionally contains two propositions; one for the “rely”, or assumptions about the execution environment, and another for the “guarantee”, or obligations that the transition system must show. For the transition system corresponding to an expression e , these propositions are roughly analogous to the known checked semantics $\Sigma \vdash \square e$ valid and unknown checks $\Sigma \vdash ? e$ valid respectively.

For example, recall again the sum contract:

```
let sum ints = contract[?] {ints > 0} (rec sum. (0 fby sum) + ints) {sum.sum > 0}
```

To verify the contract definition, we first translate it to an abstract transition system whose input environment contains an integer $ints$, and whose result type is also an integer. The followed-by delay results in a local state variable called sum_fby , and we encode the existentially-quantified recursive stream as a free context variable called sum :

```
let sum_def: system (ints: Z) Z = {
    state   = (sum_fby: Z);
    free    = (sum: Z);
    init    = { sum_fby = 0 };
    step    = λi f s. {
        update = { sum_fby = f.sum };
        value  = f.sum;
        rely   = (f.sum = s.sum_fby + i.ints) ∧ i.ints > 0;
        guar   = f.sum > 0; } }
```

The initial state of 0 corresponds to the initial value of the followed-by. In the step function, argument i refers to the input heap containing $i.ints$, f refers to the free heap containing the recursive stream $f.sum$, and s refers to the state heap containing $s.sum_fby$. In the rely of the step result, $f.sum$ is constrained to be the translated body of the recursive stream. The translated rely also includes the contract’s rely that the input integer is positive. Finally, the translated guarantee includes the contract’s guarantee that the output is positive.

To verify the transition system, we prove inductively that if the rely always holds, then the guarantee holds; we discuss proofs of system validity further in Subsection 4.2.

The translation for contract instantiations is similar, except that the contract body is replaced by an arbitrary value from the free context. For example, we can use the sum contract to implement the Fibonacci sequence with $rec fib.sum (1 fby fib)$. This program does not require any input values, so we leave the input context empty. The state context includes an entry for the $1 fby fib$ followed-by expression, but does not include the followed-by expressions inside the contract definition. Similarly, the free context includes an entry for the recursive stream, and an entry for the abstract, underspecified value of the contract:

```
let fib_def: system () Z = {
    state   = (fib_fby: Z);
    free    = (fib: Z; sum_contract: Z);
    init    = { fib_fby = 1 };
    step    = λi f s. {
        update = { fib_fby = f.fib };
        value  = f.fib;
        rely   = (f.fib = f.sum_contract)
                ∧ (s.fib_fby > 0 ⇒ f.sum_contract > 0);
        guar   = s.fib_fby > 0; } }
```

$$\begin{aligned}
\llbracket v \rrbracket_{\text{state}} &= \cdot \\
\llbracket x \rrbracket_{\text{state}} &= \cdot \\
\llbracket p(\bar{e}) \rrbracket_{\text{state}} &= \bigcup_i \llbracket e_i \rrbracket_{\text{state}} \\
\llbracket v \text{ fby } e \rrbracket_{\text{state}} &= x_{\text{fby}(e)} : \tau, \llbracket e \rrbracket_{\text{state}} \quad (\text{fresh } x_{\text{fby}(e)}) \\
\llbracket \text{rec } x. e \rrbracket_{\text{state}} &= \llbracket e \rrbracket_{\text{state}} \\
\llbracket \text{let } x = e \text{ in } e' \rrbracket_{\text{state}} &= \llbracket e \rrbracket_{\text{state}} \cup \llbracket e' \rrbracket_{\text{state}} \\
\llbracket \text{check}_\pi e \rrbracket_{\text{state}} &= \llbracket e \rrbracket_{\text{state}} \\
\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{state}} &= \llbracket e_r \rrbracket_{\text{state}} \cup \llbracket e_b \rrbracket_{\text{state}}
\end{aligned}$$

$$\begin{aligned}
\llbracket v \rrbracket_{\text{free}} &= \cdot \\
\llbracket x \rrbracket_{\text{free}} &= \cdot \\
\llbracket p(\bar{e}) \rrbracket_{\text{free}} &= \bigcup_i \llbracket e_i \rrbracket_{\text{free}} \\
\llbracket v \text{ fby } e \rrbracket_{\text{free}} &= \llbracket e \rrbracket_{\text{free}} \\
\llbracket \text{rec } x. e \rrbracket_{\text{free}} &= x : \tau, \llbracket e \rrbracket_{\text{free}} \\
\llbracket \text{let } x = e \text{ in } e' \rrbracket_{\text{free}} &= \llbracket e \rrbracket_{\text{free}} \cup \llbracket e' \rrbracket_{\text{state}} \\
\llbracket \text{check}_\pi e \rrbracket_{\text{free}} &= \llbracket e \rrbracket_{\text{free}} \\
\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{free}} &= x : \tau, \llbracket e_r \rrbracket_{\text{free}} \cup \llbracket e_b \rrbracket_{\text{state}}
\end{aligned}$$

Figure 8 Transition system typing contexts of expressions; for an expression e , $\llbracket e \rrbracket_{\text{state}} : \Gamma$ and $\llbracket e \rrbracket_{\text{free}} : \Gamma$ describe the heaps used to store the expression’s internal state and extra inputs.

As before, the translated rely includes the assumption that the recursive stream’s value ($f.\text{fib}$) agrees with its body ($f.\text{sum_contract}$). Additionally, the rely includes the assumption that the contract’s rely implies the guarantee: if sum’s input ($s.\text{fib_fby}$) is positive, then its output ($f.\text{sum_contract}$) is positive too. Finally, the translated guarantee encodes the obligation that the environment satisfies the *contract’s rely* – the input to sum is positive.

Note that the transition system requires the rely to hold *at the current step*, while the “true” semantics of contracts requires the rely to hold *at every step so far*. This minor optimisation is sound, as we define system validity to require all steps to satisfy the rely.

4.1 Translation

We now present the details of the translation. For causal expressions, the translated transition system is verified to be an abstraction of the original expression’s dynamic semantics, and the generated proof obligations imply that the original expression satisfies the checked semantics.

Figure 8 defines the internal state and free contexts required for an expression. For most expression forms, the state and free contexts are defined by taking the union of the contexts of subexpressions. Followed-by delays introduce a local state variable $x_{\text{fby}(e)}$ in which to store the most recent stream value. We generate a fresh variable here, although the implementation uses de Bruijn indices. Recursive streams and contracts both introduce new bindings into the free context; we assume that their binders x are unique.

Figure 9 defines the translation for expressions. Values and variables have no internal state. For variables, we look for the variable binding in either of the input or free heaps; bindings are unique and cannot occur in both. We omit the rely and guarantee definitions here; both are trivially true.

To translate primitives, we union together the initial states of the subexpressions; updating the state is similar. For the rely and guarantee definitions, we take the conjunction: we can assume that all subexpressions rely clauses hold, and must show that all guarantees hold.

$\llbracket v \rrbracket_{\text{init}}$	$= ()$
$\llbracket v \rrbracket_{\text{value}}(i, f, s)$	$= v$
$\llbracket x \rrbracket_{\text{init}}$	$= ()$
$\llbracket x \rrbracket_{\text{value}}(i, f, s)$	$= (i \cup f).x$
$\llbracket p(\bar{e}) \rrbracket_{\text{init}}$	$= \bigcup_i \llbracket e_i \rrbracket_{\text{init}}$
$\llbracket p(\bar{e}) \rrbracket_{\text{value}}(i, f, s)$	$= \text{prim-sem}(p, \overline{\llbracket e \rrbracket_{\text{value}}(i, f, s)})$
$\llbracket p(\bar{e}) \rrbracket_{\text{update}}(i, f, s)$	$= \bigcup_i \llbracket e_i \rrbracket_{\text{update}}(i, f, s)$
$\llbracket p(\bar{e}) \rrbracket_{\text{rely}}(i, f, s)$	$= \bigwedge_i \llbracket e_i \rrbracket_{\text{rely}}(i, f, s)$
$\llbracket p(\bar{e}) \rrbracket_{\text{guar}}(i, f, s)$	$= \bigwedge_i \llbracket e_i \rrbracket_{\text{guar}}(i, f, s)$
$\llbracket v \mathbf{fby} e \rrbracket_{\text{init}}$	$= \llbracket e \rrbracket_{\text{init}} \cup \{x_{\mathbf{fby}(e)} \mapsto v\}$
$\llbracket v \mathbf{fby} e \rrbracket_{\text{value}}(i, f, s)$	$= s.x_{\mathbf{fby}(e)}$
$\llbracket v \mathbf{fby} e \rrbracket_{\text{update}}(i, f, s)$	$= \llbracket e \rrbracket_{\text{update}}(i, f, s) \cup \{x_{\mathbf{fby}(e)} \mapsto \llbracket e \rrbracket_{\text{value}}(i, f, s)\}$
$\llbracket v \mathbf{fby} e \rrbracket_{\text{rely}}(i, f, s)$	$= \llbracket e \rrbracket_{\text{rely}}(i, f, s)$

$\llbracket \text{check}_\pi e \rrbracket_{\text{guar}}(i, f, s)$	$= (\pi = \square \implies \llbracket e \rrbracket_{\text{value}}(i, f, s)) \wedge \llbracket e \rrbracket_{\text{guar}}(i, f, s)$
$\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{init}}$	$= \llbracket e_r \rrbracket_{\text{init}} \cup \llbracket e_g \rrbracket_{\text{init}}$
$\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{value}}(i, f, s)$	$= f.x$
$\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{update}}(i, f, s)$	$= \llbracket e_r \rrbracket_{\text{update}}(i, f, s) \cup \llbracket e_g \rrbracket_{\text{update}}(i, f, s)$
$\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{rely}}(i, f, s)$	$= (\llbracket e_r \rrbracket_{\text{value}}(i, f, s) \implies \llbracket e_g \rrbracket_{\text{value}}(i, f, s))$ $\wedge (\pi = \square \implies \llbracket e_r \rrbracket_{\text{value}}(i, f, s))$ $\wedge \llbracket e_r \rrbracket_{\text{rely}}(i, f, s)$
$\llbracket \text{contract}_\pi \{e_r\} e_b \{x. e_g\} \rrbracket_{\text{guar}}(i, f, s)$	$= (\llbracket e_r \rrbracket_{\text{value}}(i, f, s) \implies \llbracket e_g \rrbracket_{\text{rely}}(i, f, s))$ $= (\pi = \square \implies \llbracket e_r \rrbracket_{\text{value}}(i, f, s))$ $\wedge \llbracket e_r \rrbracket_{\text{guar}}(i, f, s) \wedge \llbracket e_g \rrbracket_{\text{guar}}(i, f, s)$

Figure 9 Transition system semantics; for an expression $\Gamma \vdash e : \tau$, $\llbracket e \rrbracket_{\text{init}}$ is the initial state. For each field of the step-result type, we define a translation function that takes the input, free and state heaps: for example, we define the value-result of a step with type $\llbracket e \rrbracket_{\text{value}} : \text{heap } \Gamma \rightarrow \text{heap } \llbracket e \rrbracket_{\text{free}} \rightarrow \text{heap } \llbracket e \rrbracket_{\text{state}} \rightarrow \tau$.

To translate a followed-by $v \text{ fby } e$, we initialise the followed-by's unique binder $x_{\text{fby}(e)}$ to the followed-by's default value v . At each step, we return the value in the local state before updating the local state to the subexpression's new value.

To translate a recursive expression $\text{rec } x. e$ of type τ , we require an arbitrary value $x : \tau$ in the free heap. The rely proposition constrains the free variable x to be the result of evaluating e with the binding for x passed along, thus closing the recursive loop.

To translate let-expressions $\text{let } x = e \text{ in } e'$, we extend the input heap with the value of e before evaluating e' . The presentation here duplicates the computation of the value of e , but the actual implementation introduces a single binding.

To translate a check property, we inspect the property status. If the property is known to be valid, then we can assume the property is true in the rely clause. Otherwise, we include the property as an obligation in the guarantee clause. In either case, we also include the subexpression's rely and guarantee clauses.

Finally, to translate contract instantiations, we use the contract's rely and guarantee and ignore the body. As with recursive expressions, we require an arbitrary value $x : \tau$ in the free heap. The translation's rely allows us to assume that the contract definition holds: that is, the contract's rely implies the contract's guarantee. If the contract instantiation is known to be valid, we can also assume that the contract's rely holds. Otherwise, we include the contract's rely as an obligation by putting it in the translation's guarantee.

4.2 Proof obligations and induction

To verify that the translated system satisfies its proof obligations – that is, the checked properties and contract relies hold – we can perform induction on the system's sequence of steps. A system satisfies its proof obligations if, for any sequence of steps that all satisfy its rely or assumptions, the system's guarantee also holds for all of the steps.

Inductive proofs on Lustre programs generally use a non-standard definition of induction, as the property we wish to show is a function of the *step result*, rather than being a function of the *state*. This means that the base case must take a single step from the initial state to be able to state the property that, if the step result's rely holds, then its guarantee holds:

```
let inductive_check_base (sys : system input  $\tau$ ) : prop =
   $\forall(i : \text{heap input})(f : \text{heap sys.free}).$ 
  let stp = sys.step i f sys.init in
  stp.rely  $\implies$  stp.guar
```

For the inductive step case, we allow the system to take *two* steps from an arbitrary state, assuming that both steps satisfy the rely and the first step satisfied the inductive property:

```
let inductive_check_step (sys : system input  $\tau$ ) : prop =
   $\forall(i_0 i_1 : \text{heap input})(f_0 f_1 : \text{heap sys.free})(s_0 : \text{heap sys.state}).$ 
  let stp1 = sys.step i0 f0 s0 in
  let stp2 = sys.step i1 f1 stp1.state in
  stp1.rely  $\implies$  stp1.guar  $\implies$  stp2.rely  $\implies$  stp2.guar
```

This inductive scheme also generalises to *k-induction*, which allows the inductive case to assume the previous *k* steps satisfied the inductive property, rather than just assuming that the one previous step holds. K-induction is a fairly standard invariant strengthening technique; intuitively, it allows the proof to use more context of the history of execution [21, 11, 16].

To reason about system validity in general, we define a predicate *system_holds_all* that formally defines a valid system as: for all sequences of inputs and their corresponding steps, if all of the steps' relies hold, then the guarantees also hold. Validity is implied by (k-)induction.

$$\begin{array}{c}
 \boxed{\Sigma \vdash e \sim s} \\
 \frac{}{\Sigma \vdash v \sim s} \text{ (IVALE) } \qquad \qquad \frac{}{\Sigma \vdash x \sim s} \text{ (IVAR) } \\
 \frac{\Sigma \vdash e_1 \sim s \quad \dots \quad \Sigma \vdash e_n \sim s}{\Sigma \vdash p(\bar{e}) \sim s} \text{ (IPRIM) } \qquad \qquad \frac{s.x \mathbf{fby}(e') = v \quad \cdot \vdash e' \sim s}{\cdot \vdash v \mathbf{fby} e' \sim s} \text{ (IFBY}_0\text{) } \\
 \frac{\Sigma; \sigma \vdash e' \Downarrow s.x \mathbf{fby}(e') \quad \Sigma; \sigma \vdash e' \sim s}{\Sigma; \sigma \vdash v \mathbf{fby} e' \sim s} \text{ (IFBY}_S\text{) } \\

 \end{array}$$

Figure 10 Transition system state invariant.

4.3 Translation correctness proofs

We prove that the transition system is an abstraction of the dynamic semantics: that is, if the expression evaluates to v under some context, then there exists some execution of the transition system that also results in v . The transition system itself is deterministic, but the free context provides the non-determinism which may occur from underspecified contracts; our theorem statement existentially quantifies the free heap.

The results presented here rely heavily on the totality and substitution metaproPERTIES described in Subsection 3.3. Figure 10 defines the invariant for the abstraction proof; the judgment form $\Sigma \vdash e \sim s$ checks that s is a valid state heap. We use the invariant to state that, if executing the transition system for e on the entire streaming history Σ results in state heap s , then s is a valid state.

As most expressions do not modify the state heap, the invariant for most expressions simply descends into the subexpressions. Where new bindings are added, we use the dynamic semantics to extend the context with the new values. The invariant for followed-by expressions asserts that the initial state of the followed-by is the default value; on subsequent steps, the state corresponds to the dynamic semantics. With this invariant, we can prove abstraction:

► **Theorem 4** (translation-abstraction). *For a well-typed causal expression e and streaming history Σ , if e evaluates to stream V ($\Sigma \vdash e \Downarrow^* V$), then there exists a sequence of free heaps Σ_F such that repeated application of the transition system's step results in V .*

Finally, we can show the main entailment result that if the proof obligations hold on the system, then the original program is valid according to the checked semantics:

► **Theorem 5** (translation-entailment). *For a well-typed causal expression e and its translated system s , if the system holds ($\text{system_holds_all } s$), and the checked properties in e hold ($\forall \Sigma. \Sigma \vdash \square e \text{ valid}$), then the unknown properties in e also hold ($\forall \Sigma. \Sigma \vdash \square? e \text{ valid}$)*

The above theorem allows us to *bless* the expression and mark all properties as valid (Subsubsection 3.2.1). Importantly, the assumption that the checked properties hold lets us re-use previously-verified properties without re-proving them, allowing for modular proofs.

5 Extraction

Pipit can generate executable code which is suitable for real-time execution on embedded devices. The code extraction uses a variation of the abstract transition system described in Section 4, with two main differences to ensure that the result is executable without relying on the environment to provide values for the free context. Contracts are straightforward to execute by using the body of the contract rather than abstracting over the implementation.

To execute recursive expressions $\text{rec } x. e : \tau$, we require an arbitrary value of type τ to seed the fixpoint, as described in Subsection 3.3. We first call the step function to evaluate e with x bound to \perp_τ . This step call returns the correct value, but the updated state is invalid, as it may refer to the bottom value. To get the correct state, we call the step function again, this time with x bound to the correct value, v .

For example, for the *sum* contract with body $(\text{rec } sum. (0 \text{ fby } sum) + ints)$, we generate an executable system that takes an input context containing integer variable *ints*, with a single state variable for the followed-by, and returning an integer:

```
let sum_def: system (ints:  $\mathbb{Z}$ )  $\mathbb{Z} = \{$ 
    state = (sum_fby:  $\mathbb{Z}$ );
    init = { sum_fby = 0; };
    step =  $\lambda i s.$ 
        let (fby0, s0) = (s.sum_fby, s {sum_fby =  $\perp_{\mathbb{Z}}$ }) in
        let (sum0, s0) = (fby0 + i.ints, s0) in
        let (fby1, s1) = (s.sum_fby, s {sum_fby = sum0}) in
        let (sum1, s1) = (fby1 + i.ints, s1) in
        (sum0, s1) }
```

Here, the step function takes heaps of the input and state contexts, and returns a pair of the result value and the updated state. The first two bindings correspond to the seeded evaluation with the recursive value for the sum set to $\perp_{\mathbb{Z}}$; as such, the resulting state s_0 is invalid. The last two bindings recompute the state, this time with the correct recursive value sum_0 used in the state. This duplication of work can often be removed by the partial evaluation and dead-code-elimination which we perform during code extraction.

This translation to transition systems is verified to preserve the original semantics. The invariant is very similar to that of Subsection 4.3, except that the invariant descends into the implementations of contracts. For the abstract systems we only showed abstraction; to prove that executable systems are equivalent to the original semantics, we use the fact that the original semantics and transition systems are both deterministic and total (Subsection 3.3).

► **Theorem 6** (execution-equivalence). *For a well-typed causal expression e and streaming history Σ , e evaluates to stream V ($\Sigma \vdash e \Downarrow^* V$) if-and-only-if repeated application of the transition system's step on Σ also results in V .*

To extract the program, we use a *hybrid embedding* as described in [23], which is similar to staged-compilation. The hybrid embedding involves a deep embedding of the Pipit core language, while the translation to executable transition systems produces a shallow embedding. We use the F^{*} host language's normalisation-by-evaluation and tactic support [31] to partially-evaluate the application of the translation to a particular input program. This partial-evaluation results in a concrete transition system that fits in the Low^{*} subset of F^{*}, which can then be extracted to statically-allocated C code [34].

The generated C code for *sum*² includes a struct type to hold the state information, as well as reset and step functions:

```
struct sum_state { uint32_t sum_fby; }
void sum_reset(struct sum_state* state);
int sum_step(struct sum_state* state, uint32_t ints);
```

The reset function takes the pointer to the state struct and sets it to its initial values. The step function takes the pointer to the state struct and the inputs, and returns the result integer. The state struct is updated in-place. The implementations of these functions avoid dynamic (heap) allocation and are suitable for embedded systems. This interface is standard for Lustre compilers [5, 19] and other synchronous languages.

Unfortunately, our current approach is unsuitable for generating imperative array code, as our pure transition system only supports pure arrays. In the future, we intend to support efficient array computations and fix the above work duplication by introducing an intermediate imperative language such as Obc [3], a static object-based language suitable for synchronous systems. Even with an added intermediate language, we believe that a variant of our current translation and proof-of-correctness will remain useful as an intermediate semantics.

6 Evaluation

To evaluate Pipit, we have implemented the high-level logic of a Time-Triggered Controller Area Network (TTCAN) bus driver [1], described earlier in Section 2. The CAN bus is common in safety-critical automotive and industrial settings. The time-triggered network architecture defines a static schedule of network traffic; by having all nodes on the network adhere to the schedule, the reliability of periodic messages is significantly increased [15].

The TTCAN protocol can be implemented in two levels of increasing complexity. In the first level, reference messages, which perform synchronisation between nodes, contain the index of the newly-started cycle. In the second level, the reference messages also contain the value of a global fractional clock and whether any gaps have occurred in the global clock, which allows other nodes to calibrate their own clocks. We implement the first level as it is more amenable to software implementation [22].

The implementation defines a streaming function that takes a stream describing the current time, the state of the hardware, and any received messages. It returns a stream of commands to be performed, such as sending a particular reference message. The implementation defines a pure streaming function. To actually interact with the hardware we assume a small hardware-interop layer that reads from the hardware registers and translates the commands to hardware-register writes, but we have not yet implemented this. We package the driver's inputs into a record for convenience:

² This interface is for a variant of the sum contract with 32-bit integers instead of unbounded integers.

```
type driver_input = {
    local_time: network_time_unit;
    mode_cmd: option mode;
    tx_status: tx_status;
    bus_status: bus_status;
    rx_ref: option ref_message;
    rx_app: option app_message_index;
}
```

Here, the local-time field denotes the time-since-boot in *network time units*, which are based on the bitrate of the underlying network bus. The mode-command is an optional field which indicates requests from the application to enter configuration or execution mode. The transmission-status describes the status of the last transmission request and may be none, success, or various error conditions. The bus-status describes whether the bus is currently idle, busy, or in an error state. The two receive fields denote messages received from the bus; for application-specific messages the time-triggered logic only needs the message identifier.

The driver-logic returns a stream of commands for the hardware-interop layer to perform:

```
type commands = {
    enable_acks: bool;
    tx_ref: option ref_message;
    tx_app: option app_message_index;
    tx_delay: network_time_unit;
}
```

The enable-acknowledgements field denotes whether the hardware should respond to messages from other nodes with an acknowledgement bit; in the case of a severe error acknowledgements are disabled, as the node must not write to the bus at all. The transmit fields denote whether to send a reference message or an application-specific message. For application-specific messages, the hardware-interop layer maintains the transmission buffers containing the actual message payload. To meet the schedule as closely as possible, the driver anticipates the next transmission and includes a transmission delay to tell the hardware exactly when to send the next message.

6.1 Runtime

The implementation includes an extension of the trigger-fetch logic described in Section 2, as well as state machines for tracking node synchronisation, master status and fault handling. We generate real-time C code as described in Section 5. We evaluated the generated C code by executing with randomised inputs and measuring the worst-case-execution-time on a Raspberry Pi Pico (RP2040) microcontroller. The runtime of the driver logic is fairly stable: over 5,000 executions, the measured worst-case execution time was $140\mu s$, while the average was $90\mu s$ with a standard deviation of $1.5\mu s$. Earlier work on fault-tolerant TTCAN [41] describes the required slot sizes – the minimum time between triggers – to achieve bus utilisation at different bus rates. For a 125Kbit/s bus, a slot size of approximately $1,500\mu s$ is required to achieve utilisation above 85 per cent. For the maximum CAN bus rate of 1Mbit/s, the required slot size is $184\mu s$. Further evaluation is required to ensure that the complete runtime including the hardware-interop layer is sufficient for full-speed CAN.

Our code generation can be improved in a few ways. A common optimisation in Lustre is to fuse consecutive if-statements with the same condition [5]; such an optimisation seems useful here, as our treatment of optional values introduces repeated unpacking and repacking.

```

function next(index: int; c: cycle)
    returns (result: int)
var next_array: int ^ COUNT;
let
    next_array[i] =
        if trigger_enabled(COUNT - 1 - i, c)
        then COUNT - 1 - i
        else if i <= 0
        then NO_NEXT_TRIGGER
        else next_array[i - 1];
    result =
        next_array[COUNT - 1 - index];
tel

```

Figure 11 Left: next-trigger logic in F^{*}; right: Kind2 encoding as array scan. In F^{*}, the *Tot* τ (*decreases* ...) syntax declares a total function with the given termination measure. In Kind2, the *int*[^]*COUNT* syntax denotes the type of an array of integers of length *COUNT*, while the *next_array*[*i*] declaration defines the elements of the array as a function of the index *i*.

Some form of array fusion [37] may also be useful for removing redundant array operations. Our current extraction generates a transition-system with a step function which returns a tuple of the updated state and result. Composing these step functions together results in repeated boxing and unboxing of this tuple; we currently rely on the F^{*} normaliser to remove this boxing. In the future, we plan to build on the current proofs to implement a more-sophisticated encoding that introduces less overhead.

6.2 Verification

We have verified a simplified trigger-fetch mechanism, as presented earlier (Section 2). For comparison, we implemented the same logic in the Kind2 model-checker [11]. The restrictions placed on the triggers array – that triggers are sorted by time-mark, that there must be an adequate time-gap between a trigger and its next-enabled, and that a trigger’s time-mark must be greater-than-or-equal-to its index – are naturally expressed with quantifiers. The Kind2 model-checker includes experimental array and quantifier support [26]. Due to the experimental nature of these features, we had to work around some limitations: for example, the use of arrays and quantifiers disables IC3-based invariant generation; quantified variables cannot be used in function calls; and the use of top-level constant arrays caused runtime errors that rendered most properties invalid [27].

We were able to express equivalent properties in Kind2 and in Pipit, aside from some encoding issues. For example, the specification-only function that finds the next trigger is naturally recursive. Kind2 does not support recursive functions, but we were able to encode it by introducing a temporary array and using Kind2’s array comprehension syntax for scanning over arrays. Additionally, while the recursive call *increases* the index, the array scan can only depend on values with lower indices. Figure 11 illustrates this encoding with a simplified version of the next-trigger logic.

We compare against two Kind2 implementations: one corresponds closely to the Pipit development, while the other includes a critical simplification to modify the trigger-enabled set to be a single cycle index. In TTCAN proper, the enabled set is implemented as a cycle-offset and repeat-factor. Checking if a trigger is enabled in the current cycle requires

size	Kind2				Pipit	
	simple enable-set		full enable-set		wall-clock	CPU time
	wall-clock	CPU time	wall-clock	CPU time		
1	1.48s	1.06s	1.57s	2.26s	5.25s	5.03s
2	1.51s	1.26s	1.71s	2.93s	5.25s	5.03s
4	1.57s	1.62s	2.08s	4.78s	5.25s	5.03s
8	1.76s	3.07s	4.21s	16.98s	5.25s	5.03s
16	3.36s	11.91s	13.82s	65.57s	5.25s	5.03s
32	12.15s	62.38s	269.14s	1230.05s	5.25s	5.03s
64	1701.01s	9096.99s	(timeout)		5.25s	5.03s
128	(timeout)		(timeout)		5.25s	5.03s

Figure 12 Verification time for trigger-fetch; simple enable-set uses a simplified version of the enable-set, while full enable-set uses bitwise arithmetic as in the TTCAN specification. The wall-clock time denotes the elapsed time that an engineer must spend waiting for the result; the CPU time denotes the total time spent computing by all of the CPU cores. The verification time for Pipit is a once-and-for-all proof that is parametric in the size of the array. The time limit was one hour.

nonlinear arithmetic, which is difficult for SMT solvers. In our Pipit development, we can treat the definition of the cycle set abstractly. However, in the Kind2 development, quantified formulas cannot contain function calls, which means that we cannot hide the implementation of the enabled-set check by providing an abstract contract. This limitation also makes the specification quite unwieldy, as we must manually inline any functions in quantified formulas.

Figure 12 shows the verification runtime for different sizes of arrays; the Pipit version is parametric in the array size, and is thus verified for all sizes of arrays. We ran these experiments in Docker on an Intel i5-12500 with 32GB of RAM. Both Kind2 and Pipit developments of the trigger-fetch logic are roughly the same size, on the order of two-hundred lines of code including comments. Ignoring whitespace and comments, the Pipit implementation of trigger-fetch has 26 lines of actual executable code, while the Kind2 code has 32. The majority of the remaining code comprises the definition of valid schedules (34 for Pipit, 28 for Kind2), and the lemma statements and invariants (12 for Pipit, 31 for Kind2), as well as contract statements and boilerplate.

We were able to verify the Kind2 implementation of the complete trigger-fetch mechanism for up to 32 triggers; above that, our verification timed out after one hour. For the simplified trigger-fetch mechanism, we were able to verify up to 64 triggers. For reference, hardware implementations of TTCAN such as M_TTCAN support up to 64 triggers [36].

We plan to verify the remainder of the TTCAN implementation and publish it separately. Prior work formalising TTCAN has variously modeled the protocol itself [39, 33, 30], instances of the protocol [20], and abstract models of TTCAN implementations [29], but we are unaware of any prior work that has verified an *executable* implementation of TTCAN.

Separately, Pipit has also been used to implement and verify a real-time controller for a coffee machine reservoir control system [38]. The reservoir has a float switch to sense the water level and a solenoid to allow the intake of water. The specification includes a simple model of the water reservoir and shows that the reservoir does not exceed the maximum level under different failure-mode assumptions.

7 Related work

Using existing Lustre tools to verify *and* execute the time-triggered CAN driver from Section 2 is nontrivial. Compiling the triggers array with an unverified compiler such as Lustre V6 [24] or Heptagon [19] is straightforward; however, the verified Lustre compiler Vélus [7] does not support arrays, records, or a foreign-function interface. Recent work on translation validation for LustreC [9] also does not yet support arrays.

Verifying the time-triggered CAN driver is trickier, as the restrictions placed on the triggers array – that triggers are sorted by time-mark, there must be an adequate time-gap between a trigger and its next-enabled, and a trigger’s time-mark must be greater-than-or-equal-to its index – naturally require quantifiers. As described in Section 6, Kind2 does include experimental array and quantifier support, but in our experiments was unable to verify the full logic for arrays up to the 64 triggers, which is the size supported by hardware implementations of TTCAN. Additionally, due to the limitations that require the constant triggers array to be passed as an argument, compiling the program with Lustre V6 would result in the entire triggers array being copied to the stack each iteration, which is unlikely to result in acceptable performance.

Other model-checkers for Lustre such as Lesar [35], JKind [16] and the original Kind [21] do not support quantifiers. It may be possible to encode the quantifiers as fixed-size loops in those that support arrays, but ensuring that these loops do not affect the execution or runtime complexity of the generated code does not appear to be straightforward.

These model-checkers have definite usability advantages over the general-purpose-prover approach offered here: they can often generate concrete counterexamples and implement counterexample-based invariant-generation techniques such as ICE [18] and PDR [8, 14]. However, even when the problem can be expressed, these model-checkers do not provide much assurance that the semantics they use for proofs matches the compiled code. In the future, we would like to investigate integrating Pipit with a model-checker via an unverified extraction: such an extraction may allow some of the usability benefits such as counterexamples and invariant generation. If this integration were used solely for debugging and suggesting candidate invariants, then such a change would not necessarily expand the trusted computing base – that is, we could augment our end-to-end verified workflow with *unverified but validated* invariant generation.

Recent work has also introduced a form of refinement types for Lustre [12]. Rather than using transition systems, this work generates self-contained verification conditions based on the types of streams. Such a type-based approach promises to allow abstraction of the implementation details. However, for general-purpose functions such as *count_when* from Section 2, it is not clear how to give it a specification that actually *abstracts* the implementation: a simple specification that the result is within some range would hide too much and be insufficient for verifying the rest of the system. For such functions, the best specification is likely to include a re-statement of the implementation itself.

The embedded language Copilot generates real-time C code for runtime monitoring [28]. Recent work has used translation validation to show that the generated C code matches the high-level semantics [40]. Copilot supports model-checking via Kind2; however, the model-checking has a limited specification language and does not support contracts.

Early work embedding a denotational semantics of Lucid Synchrone in an interactive theorem prover focussed on the semantics itself, rather than proving programs [4]. There is ongoing work to construct a denotational semantics of Vélus for program verification [6]. We believe that the hybrid SMT approach of F^{*} will allow for a better mixture of automated

proofs with manual proofs. Compared to Vélus alone, the trusted computing base of Pipit is larger: we depend on all of F^{*}, Low^{*}'s unverified C code extraction and the Z3 SMT solver; in comparison, Vélus' C code generation is verified and does not depend on any SMT solver.

The deferred aspect of our proofs is similar to the deferred proofs of verification conditions for imperative programs, such as [32]. However, such verification conditions are *syntactically* deferred so that the verification condition can be proved later; in our case, the verification conditions are *semantically* deferred, so that more knowledge of the enclosing program can be exploited in the proof. In imperative programs, this sort of extra knowledge is generally provided explicitly as loop invariants, and non-looping statements have their weakest precondition computed automatically. In Lustre-style synchronous languages such as ours, programs tend to be composed of many nested recursive streams, which perform a similar function to loops. Explicitly specifying an invariant for each recursive stream would be cumbersome; deferring the proof allows such invariants to be implicit.

8 Conclusion

We have presented Pipit, a verified compiler and proof system for reactive systems. Our implementation of the TTCAN driver logic shows that, by embedding pure F^{*} functions for array operations, Pipit can express programs which are currently unsupported by other verified Lustre compilers. Pipit can also verify high-level program properties which are difficult to express and prove in existing Lustre model-checkers. Our development includes verified translations to both abstract and executable transition systems; both are shown to preserve the dynamic semantics. We also introduced a checked semantics, which describes the semantics of checked properties and contracts; proof obligations generated by translation to abstract transition system are verified to correspond to these semantics.

In the future, we intend to verify the remainder of the TTCAN driver logic. We also intend to increase the expressivity of Pipit by adding *clocks*, which are used to describe partially-defined streams [10]. Clocks are important for composing complex systems together and avoiding unnecessary computation; they may be useful if it becomes necessary to optimise the runtime of the TTCAN driver.

We are interested in further pursuing the intersection of model-checking with interactive theorem proving. A smart-contract called Djed [42] currently uses a mixture of Kind2 [11] and manual Isabelle/HOL proofs to show that the contract is well-behaved. In future work, we would like to further investigate whether Pipit's integration of streaming proofs with F^{*}'s automated proof system would be able to provide similar proofs, without introducing any semantic gap between the two systems.

Abstract

Partial Redundancy Elimination (PRE) is a powerful and well-known code optimization. The idea to combine Common Subexpression Elimination and Loop Invariant Code Motion optimizations into a single optimization was originally conceived by Morel and Renvoise. Their algorithm is bidirectional in nature and was not *complete* and *optimal*. Later, Knoop et al. proposed the first complete and optimal algorithm, Lazy Code Motion (LCM), which takes four unidirectional data flow analyses. In a recent paper, Roy et al. proposed an algorithm for PRE that uses three iterative data flow analyses. Here, we propose an efficient algorithm for PRE, which takes only two iterative data flow analyses followed by two computation passes over the program. The algorithm is both *computationally* and *lifetime* optimal. The proposed algorithm computes the information required for performing the transformation in two passes over the program without considering *safety*. The two iterative data flow analyses are required for making the transformation *safe*. The use of well-known data flow analyses, i.e., *available expressions* analysis and *anticipated expressions* analysis, makes the algorithm simple to understand and easy to prove its correctness. The proposed algorithm is more efficient than the existing algorithms since it takes only two iterative data flow analyses. The efficiency of the proposed algorithm is demonstrated by implementing it in LLVM Compiler Infrastructure and comparing the time taken with other selected best-known algorithms.

1 Introduction

Partial Redundancy Elimination (PRE) is a code optimization technique used in compiler design to eliminate redundant computations in a program. It focuses on identifying and eliminating computations that are partially redundant, i.e., the computations that occur more than once in a path in the input program. PRE helps reduce the number of instructions executed and can lead to significant performance improvements in a program. Partial redundancy elimination involves the insertion and deletion of computations at appropriate points in the program so that after the transformation, the program contains less than or equal number of occurrences of the original computation in any path. To preserve the semantics of the original program, the insertions of computations corresponding to the transformation must be safe, i.e., the program must not introduce new computations along any path in the original program.

¹ corresponding author

PRE can be either lexical-based or value-based. Lexical-based PRE focuses on eliminating lexically identical expressions on a path, while a value-based PRE eliminates expressions with identical values on a path. In this work, we focus on lexical-based partial redundancy elimination and anticipate that the insights from this work may find its application in the value-based approach as well. Here, we propose an efficient algorithm for partial redundancy elimination using two iterative data flow analyses followed by two computation passes over the program. The data flow analyses used are the well-known classical analyses, i.e., available expressions analysis and anticipated expressions analysis. Unlike the existing works [6, 9, 14, 16], the proposed algorithm requires only two iterative data flow analyses to perform partial redundancy elimination resulting in a significant efficiency gain. The contributions of our work are:

1. A new algorithm for lexical-based PRE, which takes only two iterative data flow analyses compared to at least three analyses in the existing well-known algorithms [6, 9, 14, 16].
2. Correctness proof of the proposed algorithm.
3. An experimental comparison of the proposed algorithm with the selected existing algorithms [9, 16] demonstrating its efficiency and precision.

1.1 Background

Morel and Renvoise, in their seminal work on partial redundancy elimination (PRE) [12], observed that an algorithm for partial redundancy elimination could potentially address both redundancy elimination and the loop invariant code motion simultaneously. Their approach involved four bidirectional data flow analyses. Morel and Renvoise's algorithm did not achieve computational optimality, i.e., it could not eliminate all partially redundant expressions in a program. Subsequently, Dhamdhere [5] improved upon Morel and Renvoise's algorithm by introducing the concept of edge placement, eliminating more partial redundancies. Another challenge in Morel and Renvoise's algorithm was the occurrence of redundant code motion, an issue that Dhamdhere [5] and Drechsler et al. [7] tackled as they implemented various improvements.

Knoop, Ruthing, and Steffen introduced the *lazy code motion algorithm* for partial redundancy elimination (PRE) [9], incorporating four unidirectional data flow analyses. This algorithm stands out for its computational and lifetime optimality, using a hoisting-followed-by-sinking approach. Knoop et al. devised a method to identify the *earliest* and *latest* points for performing the transformation. Another aspect of their algorithm is the preprocessing step, which involves inserting dummy nodes at the edges of nodes with multiple predecessors. Unfortunately, this step leads to unnecessary edge insertions, resulting in overhead. In response to these considerations, Knoop et al. later refined the lazy code motion algorithm to enhance its practical utility [10]. Additionally, Drechsler and Stadel [8] proposed a variant of the lazy code motion algorithm with a primary focus on practical applicability.

In the realm of partial redundancy elimination (PRE), Paleri et al. presented an algorithm utilizing classical data flow analyses, i.e., *availability*, *anticipability*, *partial availability*, and *partial anticipability* [14]. Notably, the introduction of the path concept in their paper enhances the algorithm's comprehensibility. Furthermore, this algorithm is both computationally and lifetime optimal. Originally designed for nodes containing single statements, Paleri et al. later modified their algorithm to nodes containing multiple instructions, such as the standard basic block [15]. In a work akin to the approach by Paleri et al., Dhamdhere introduced the concept of eliminability paths to address the optimal placement of computations [6]. Like those of prior researchers, Dhamdhere's approach relies on four unidirectional

analyses to eliminate partial redundancies. Recent work by Roy et al. [16] describes an algorithm for PRE that is more efficient than the other computationally optimal algorithms available in the literature since it takes only three iterative data flow analyses - *anticipated expressions*, *safe partially available expressions*, and *safe redundancy path* - compared to four analyses taken by the other algorithms.

One limitation of the presented PRE algorithm is its exclusive focus on lexically equivalent expressions. In contrast, a value-based PRE approach can potentially uncover a greater number of redundancies. The value-based method identifies equivalent expressions based on their actual values rather than relying solely on lexical equivalence. This distinction makes it a more powerful optimization technique for effectively eliminating redundant expressions, reported in the literature [4, 11, 13, 17].

2 Notations and Definitions

We found the formal definitions and notations from [14] appropriate for the proposed algorithm. In this section, we give an informal description of the terms used in the algorithm.

2.1 Control Flow graph

We represent a program as a Control Flow Graph (CFG) $G = (N, E, \text{entry}, \text{exit})$ where N represents the set of nodes in the graph and E is the set of edges in the graph. We assume that the CFG has two empty basic blocks, an *entry* node which represents the starting point of the graph and an *exit* node to which all exits of the graph go. An *entry* is the unique entry node with no predecessor nodes, and *exit* is the unique exit node without any successor nodes. Each node in the CFG contains at most one statement in the three-address code form. The assignment statement is of the form $x = e$, where x is a variable, and e is an expression built of variables, constants, and operators. The edge from node i to node j is represented as (i, j) . The sets of immediate predecessors and immediate successors of a node n are denoted as $\text{pred}(n)$ and $\text{succ}(n)$, respectively, where $\text{pred}(n) = \{m | (m, n) \in E\}$ and $\text{succ}(n) = \{m | (n, m) \in E\}$.

2.1.1 Annotated Control Flow Graph

An annotated control flow graph (ACFG) is a CFG annotated with the information obtained from a data flow analysis at every program point in the CFG, i.e., the input and output points of the basic blocks in the CFG.

2.2 Boolean Properties Associated with the Expressions

An expression e is said to be *locally available* from node i , i.e., available at the output point of node i (AvLoc_i), if e appears in node i , and the statement in node i does not modify the operands in e . An expression e is said to be *locally anticipated* from node i (ANTLoc_i), i.e., anticipated at the input point of node i if e appears in node i . An expression e is said to be *transparent* in node i (TRANSP_i), if the execution of the statement in node i does not modify the operands in e .

An expression is *available* at a point if it has been computed along all paths reaching this point with no changes to its operands since the computation. An expression is said to be *anticipated* at a point if every path from this point has a computation of that expression with no changes to its operands in between. An expression e is *partially available* at point p if there is at least one path from *entry* to p which computes e , and after the last such computation before reaching p there is no modification to its operands. An expression e , occurring at a point p , is partially redundant if e is *partially available* at p . An expression e is *partially anticipated* at p if there is at least one path from p to *exit* which computes e with no changes to its operands in between p and the point of occurrence of e . A point is *safe* for insertion of an expression e if the expression is either *available* or *anticipated* at that point. An expression is *safe partially available* at a point p if the expression is *partially available* at p and the path from point k to p is *safe*, where k is the point from which expression is *partially available* at p . The path formed by connecting adjacent program points where the expression is *safe partially available* is known as *safe partially available path*. An expression is said to be *safe partially anticipated* at a point p if the expression is *partially anticipated* at p and the path from point p to k is *safe*, where k is the point from which e is *partially anticipated* at p . A path is said to be a *safe redundancy path* for an expression if the expression is both *safe partially available* and *safe partially anticipated* at all points on the path.

The notations used for the properties defined in this section, corresponding to an expression e are described below:

Notations	Data flow properties
AvLOC_i	: Locally Available at the output point of node i
ANTLOC_i	: Locally Anticipated at the input point of node i
TRANSP_i	: Transparent in node i
$\text{AVIN}_i/\text{AVOUT}_i$: Available at input/output point of node i
$\text{ANTIN}_i/\text{ANTOUT}_i$: Anticipated at input/output point of node i
$\text{SPAVPATHIN}_i/\text{SPAVPATHOUT}_i$: Input/output point of node i is on Safe Partially Available Path
$\text{SREDPATHIN}_i/\text{SREDPATHOUT}_i$: Input/output point of node i is on Safe Redundancy Path

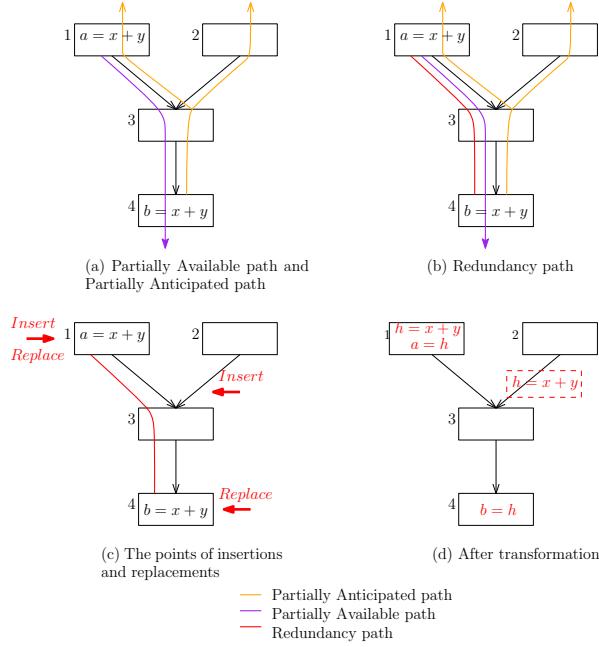

The properties for all the nodes in the CFG are expressed in terms of Boolean equations. We used the symbols summation/product (i.e., \sum / \prod) for the confluence operator, $+$ and \cdot for Boolean connectives *or* and *and*, and \neg for Boolean negation.

3 Basic Concept

We build on the basic concepts from [14]. The basic idea in [14] is briefly outlined below.

Partial Redundancy Elimination consists of two stages: detection and elimination. An expression e at a point p is said to be *partially redundant* if the expression is *partially available* at p . Thus, to detect partially redundant expressions, we require only the information regarding the *partially available expressions*. This information is obtained through *partially available expressions* analysis. In order to eliminate the partially redundant expressions, we require additional information on *partially anticipated expressions*, which is obtained through *partially anticipated expressions* analysis.

The fundamental idea behind partial redundancy elimination is to find *redundancy paths*. To identify the redundancy paths, we first *mark* all the program points where the expression under consideration is both *partially available* and *partially anticipated*. Now, we identify the redundancy paths by connecting the adjacent program points which are *marked*. Partial redundancy elimination is done by *insertions* and *replacements* of expressions

■ **Figure 1** An example for partial redundancy elimination.

at appropriate points in the program [See Fig. 1(c)]. As the initial transformation step, all partially redundant expressions are made totally redundant by inserting the statement $h = e$, where e is the expression of interest, at the edges that enter the junction nodes on the redundancy paths. Now, we insert the statement $h = e$ at the starting points of the redundancy paths. The next step involves the elimination of all the redundant expressions through replacements. The replacement involves the redundant expressions being replaced by the temporary variable h .

We consider the same example in [16] to explain the basic concept. In Fig. 1(a), the purple line represents the path where the expression is *partially available* at all points on the path. Similarly, the orange line denotes the path where the expression is *partially anticipated* at all points on the path. The *redundancy path* is marked in the red line in Fig. 1(b). The insertion points are the input point of node 1 and the edge (2, 3), and the replacement points are nodes 1 and 4, as shown in Fig. 1(c) based on the basic idea explained above. The CFG after the transformation is given in Fig. 1(d).

3.1 The New Approach

As stated above, *redundancy path* is the basic idea behind PRE. We observe an important characteristic of a *redundancy path* corresponding to an expression e . In a *redundancy path*, the first and last nodes contain the expression e [See Fig. 1(c)]. To identify this *redundancy path* for e , we need to visit the nodes in the CFG in a systematic fashion such that e must be *partially available* and *partially anticipated* in the nodes.

A *partially available path* for an expression e starts at a node (say s) containing e in the CFG and moves in the forward direction. We propagate the *partially available* information of e from the node s forward until e is killed or the exit node of the CFG is reached. A *partially anticipated path* for an expression e starts at a node (say t) containing e and moves

in the backward direction. We propagate *partially anticipated* information of e from the node t along the *partially available path* computed earlier until e is no longer *partially available*. The path from s to t along which the expression e is both *partially available* and *partially anticipated* forms the *redundancy path*. Thus, the *redundancy path* is obtained using just two computations – not two iterative data flow analyses.

To preserve the semantics of the original program, the insertions of computations corresponding to the transformation done during the PRE algorithm must be safe. We use the notion of *safety* to preserve the semantics of the transformed program. A point p is *safe* for insertion of an expression e if e is *available* or *anticipated* at p . Hence, instead of a simple *redundancy path*, we identify a *safe redundancy path* in the proposed algorithm. The information required to compute *safety* is obtained using two classical data flow analyses: *available expressions* analysis and *anticipated expressions* analysis. After computing *safety* information, *safe redundancy paths* are computed the same way as the computation of *redundancy paths* where propagation must additionally satisfy the *safety* property. Thus, the *safe redundancy path* is identified using just two computations: *safe partially available path* computation and *safe redundancy path* computation, which are detailed in Section 4.

Overall, the algorithm takes two iterative data flow analyses followed by two computation passes over the program.

4 The Proposed Algorithm for PRE

The proposed algorithm consists of two phases: a data flow analysis phase and a computation phase. The first phase has two classical unidirectional data flow analyses: *available expression* analysis and *anticipated expression* analysis. The second phase contains the computations for *safe partially available path* and *safe redundancy path*. The algorithm is presented for a single arbitrary expression e . However, an independent combination of all the expressions in a program will result in a global algorithm for partial redundancy elimination.

A detailed description of the data flow analyses and computations is presented in this section.

4.1 Data Flow Analysis Phase

4.1.1 Available Expression analysis

The available expression analysis (definition provided in Section 2.2) is done in the forward direction of the control flow graph. To solve the forward *available expression* analysis, we need to initialize $\text{AvOUT}_{\text{entry}}$ with the value FALSE because the expression is not available at the output point of the *entry* node. Note that an *entry* node is the first node of a CFG with no instructions in it. We initialize $\text{AvOUT}_i = \text{TOP}$ (TOP is denoted by \top) for all other nodes, as this value will allow the iterative algorithm to converge to the desired value. Note that for a value x , $x \wedge \top = x$. The iterative data flow analysis to compute available expression information is given in Algorithm 1.

Algorithm 1 Iterative data flow analysis to compute available expression information.

Input : Control Flow Graph(CFG), a program expression e .
Output: Input CFG annotated with *availability* information at all points for the expression e .

```

1 Procedure AvailExpr(CFG, e)
2   AvOUTentry = FALSE
3   for each node  $i \neq entry$  do
4     | AvOUTi =  $\top$ 
5   end
6   while changes to any AvOUT occur do
7     | for each node  $i \neq entry$  do
8       | | AvINi =  $\prod_{p \in pred(i)} AvOUT_p$ 
9       | | AvOUTi = AVLOCi + AvINi.TRANSPi
10      | end
11    end
12 end
```

4.1.2 Anticipated Expression analysis

The anticipated expression analysis (definition provided in Section 2.2) is carried out in the backward direction of the control flow graph. To solve the backward *anticipated expression* analysis, we need to initialize ANTIN_{exit} with the value FALSE because the expression is not anticipated at the input point of the *exit* node. We initialize ANTIN_i = \top for all other nodes, as this value will allow the iterative algorithm to converge to the desired value. The iterative data flow analysis to compute anticipated expression information is given in Algorithm 2.

Algorithm 2 Iterative data flow analysis to compute anticipated expression information.

Input : Control Flow Graph(CFG), a program expression e .
Output: Input CFG annotated with *anticipated* information at all points for the expression e .

```

1 Procedure AntExpr(CFG, e)
2   ANTINexit = FALSE
3   for each node  $i \neq exit$  do
4     | ANTINi =  $\top$ 
5   end
6   while changes to any ANTIN occur do
7     | for each node  $i \neq exit$  do
8       | | ANTOUTi =  $\prod_{s \in succ(i)} ANTIN_s$ 
9       | | ANTINi = ANTLOCi + ANTOUTi.TRANSPi
10      | end
11    end
12 end
```

4.2 Computation Phase

The second phase in the proposed algorithm consists of computations for *safe partially available path* and *safe redundancy path*. During this phase, the necessary information is computed by propagating data from specific points along predefined paths. It is important to note that the paths for data propagation are different for the two distinct computations. The worklist method is used to compute both computations.

4.2.1 Worklist

The basic idea of a work list is to maintain a list of nodes to be processed until the list becomes empty. There are three stages in the use of the worklist in the algorithm:

- **Initialization:** The WORKLIST is initialized with a set of nodes in the CFG containing the expression of interest.
- **Processing WorkList:**
 - GetNode: The node n to be processed next is taken out from the WORKLIST.
 - Process: Perform the computations on the node n .
 - Update: If there is a change in the value computed for the node n in the processing step, successor or predecessor nodes of n — for *safe partially available path* and *safe redundancy path* computations respectively — are added to the WORKLIST.
- **Termination:** The algorithm terminates when the WORKLIST becomes empty, indicating that all the required nodes are processed.

This worklist algorithm propagates the property, i.e., *safe partially available path* or *safe redundancy path*, from specific nodes, with which the worklist is initialized, through the nodes in the control flow graph until the property becomes FALSE. The algorithm is designed in such a way that each point in the CFG is processed only once.

The computations are detailed in the following sections.

4.2.2 Safe Partially Available Path Computation

In the initialization step of the *safe partially available path* computation, the nodes containing the expression of interest are collected and arranged in the reverse post-order sequence of their appearance within the CFG. This order facilitates efficient computation of information in the forward direction, commencing from each expression found within the CFG.

The basic idea is to compute *safe partially available path* for an expression by traversing a *safe path* in the forward direction and marking the points where the expression is also *partially available*. We get a *safe path* by connecting all the adjacent program points that are *safe*. Note that a point p is *safe* for insertion of an expression e if e is either *available* or *anticipated* at p .

The information required to compute *safety* is obtained during the first phase of the algorithm. After collecting *available* expression and *anticipated* expression information in the first phase, instead of computing *safety* as an independent computation, we integrate safety within the safe partially available path computation for efficiency. The computation of *safe partially available path* begins from a node with the expression of interest e and continues forward along the *safe path* until *partial availability* becomes FALSE. Note that *partial availability* becomes FALSE when expression e is *killed*.

Algorithm 3 Computation of safe partially available path for an expression e .

Input : Control Flow Graph annotated with *available* and *anticipated* information for e .

Output : Input CFG annotated with *safe partially available path* information for e .

```

1 Procedure SafeParAvailExpr(ACFG)
2   Create empty WORKLIST;
3   for each node  $i$  do // The order of traversal is reverse post order
4     SPAVPATHIN $_i$  = FALSE
5     SPAVPATHOUT $_i$  = FALSE
6     VISITEDIN $_i$  = FALSE
7     VISITEDOUT $_i$  = FALSE
8     if node  $i$  contains expression  $e$  then
9       WORKLIST.add( $i$ )
10    end
11   while !WORKLIST.isEmpty() do
12      $i$  = WORKLIST.remove()
13     if !VISITEDOUT $_i$  then
14       SPAVPATHOUT $_i$  = AvLOC $_i$  + SPAVPATHIN $_i$ . TRANSP $_i$  1
15       VISITEDOUT $_i$  = TRUE
16       if change to SPAVPATHOUT $_i$  occur then
17         for each node  $s \in \text{succ}(i)$  do
18           if !VISITEDIN $_s$  then
19             if SAFEIN $_s$  then // SAFEIN $_s$  = AvIN $_s$  + ANTIN $_s$ 
20               SPAVPATHIN $_s$  = TRUE
21               VISITEDIN $_s$  = TRUE
22               WORKLIST.add( $s$ )
23           end
24     end
25   end
```

4.2.3 Safe Redundancy Path Computation

In the initialization phase of the computation for *safe redundancy path*, the nodes containing the expression of interest are stored in the post-order sequence of their appearance within the CFG. This arrangement facilitates the efficient computation of information in a backward direction, commencing from each expression found within the CFG.

The basic idea is to compute *safe redundancy path* for an expression e by traversing a *safe partially available path* in the backward direction and marking the points where the expression is also *partially anticipated*. After computing *safe partially available path*, the *safe redundancy path* computation begins from a node in the initialized work list, and it progresses in a backward direction along the safe partially available path until the *partially anticipated* property becomes FALSE. Note that *partially anticipated* property becomes FALSE when expression e is *killed*.

¹ $\text{AvLOC}_i \implies \text{SAFEOUT}_i$ and $\text{SPAVPATHIN}_i \cdot \text{TRANSP}_i \implies \text{SAFEOUT}_i$

Algorithm 4 Computation of safe redundancy path for an expression e .

Input : Control Flow Graph annotated with *safe partially available path* information for e .

Output : Input CFG annotated with *safe redundancy path* information for e .

```

1 Procedure SafeRedPath(ACFG)
2   Create empty WORKLIST;
3   for each node  $i$  do           // The order of traversal is post order
4     SREDPATHIN $_i$  = FALSE
5     SREDPATHOUT $_i$  = FALSE
6     VISITEDIN $_i$  = FALSE
7     VISITEDOUT $_i$  = FALSE
8     if node  $i$  contains expression  $e$  then
9       WORKLIST.add( $i$ )
10    end
11   while !WORKLIST.isEmpty() do
12      $i$  = WORKLIST.remove()
13     if !VISITEDIN $_i$  then
14       SREDPATHIN $_i$  = SPAVIN $_i$ . (ANTLOC $_i$  + SREDPATHOUT $_i$ . TRANSP $_i$ )
15       VISITEDIN $_i$  = TRUE
16       if change to SREDPATHIN $_i$  occur then
17         for each node  $p \in \text{pred}(i)$  do
18           if !VISITEDOUT $_p$  then
19             if SPAVPATHOUT $_p$  then
20               SREDPATHOUT $_p$  = TRUE
21               VISITEDOUT $_p$  = TRUE
22               WORKLIST.add( $p$ )
23         end
24      end
25   end
26 
```

4.3 The Main Algorithm

The main algorithm for PRE is given in this section. After computing the required information from the two phases of the algorithm given in sections 4.1 and 4.2, the points of transformation are identified. We can divide the conceptual idea behind the algorithm into three stages:

1. Identification of partially redundant computations.
2. Conversion of partially redundant computations into totally redundant computations through insertions of expressions at program points identified. During insertions, we insert an assignment of the form $h = \text{expr}$, where h is a new temporary variable.
3. Elimination of all the redundant expressions through replacements at the identified program points. During replacements, we replace some of the original computations of expr by h .

We denote the insertion at the entry of node i by INSERT_i , insertion on edge (i, j) by $\text{INSERT}_{(i,j)}$, and replacement in node i by REPLACE_i . These terms compute Boolean values, and we use this information to detect the places of insertions and replacements. The proposed algorithm for partial redundancy elimination is given as Algorithm 5. The $\text{TRANSFORM}()$ function in Algorithm 5 does the necessary transformation using the information computed earlier in the algorithm.

Algorithm 5 Algorithm for Partial Redundancy Elimination.

Input : Control Flow Graph(CFG), a program expression e
Output: The input CFG with the partial redundancies of e eliminated.

```

1 Procedure PRE (CFG,  $e$ )
2   AVAILEXPR(CFG,  $e$ )
3   ANTEXPR(CFG,  $e$ )
4   SAFEPRAVAILPATH(ACFG)2           // A computation using work list
      algorithm
5   SAFEREDPATH(ACFG)3           // A computation using work list algorithm
6   for each node  $i$  in the CFG do
7     INSERT $_i$  =  $\neg$  SREDPATHIN $_i$  . SREDPATHOUT $_i$ 
8     REPLACE $_i$  = AVLOC $_i$ .SREDPATHOUT $_i$  + ANTLOC $_i$ .SREDPATHIN $_i$ 
9   end
10  for each edge  $(i,j)$  in CFG do
11    INSERT $_{(i,j)}$  =  $\neg$  SREDPATHOUT $_i$ 
12    .
13    SREDPATHIN $_j$ 
14  end
15  TRANSFORM(CFG, INSERT $_{1\dots n}$ , INSERT $_{(1\dots n, 1\dots n)}$ , REPLACE $_{1\dots n}$ )          /*  $n$ 
      represents the number of nodes in the CFG */
16 end
```

4.4 Example

In Fig. 2, we present an example [14] to illustrate the operation of the proposed algorithm. In Fig. 2(a), the blue line represents the anticipated path. In Fig. 2(b), the orange line shows the available path. The adjacent points which are either blue or orange are joined to form the safe path. The red dotted line in Fig. 2(b) represents safe path. The red line in Fig. 2(c) signifies the safe partially available paths. The brown line in Fig. 2(d) represents the safe redundancy path, which is computed by traversing the safe partially available path in a backward direction and identifying the points where the expression is also partially anticipated. The transformed CFG with insertions and replacements is shown in Fig. 3. The data flow analysis and the transformation information are given in Table 1.

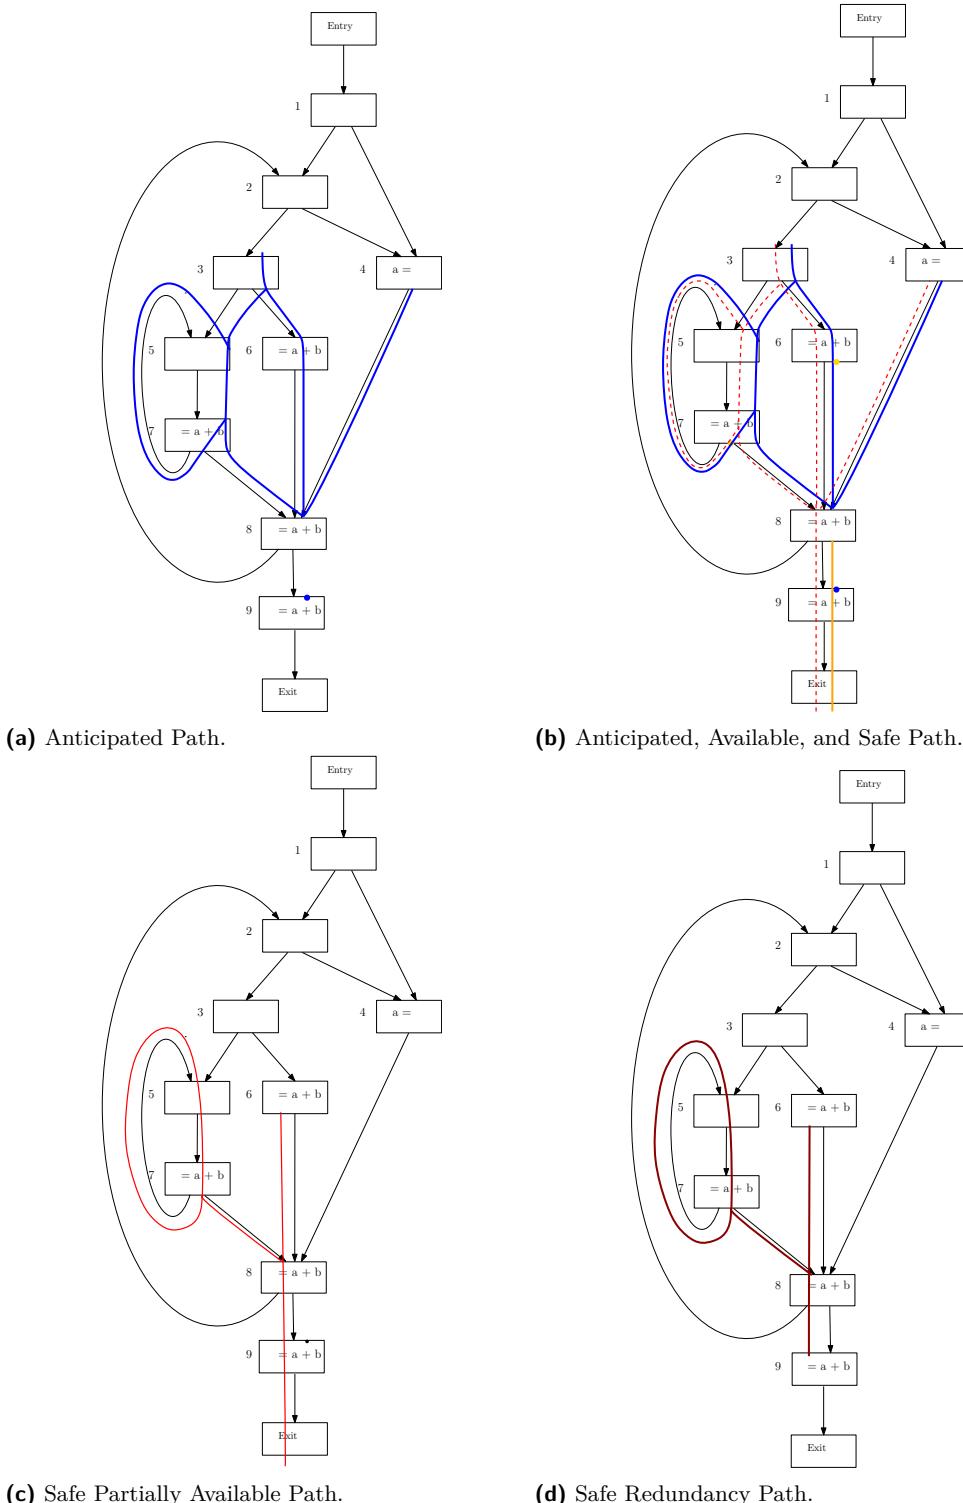

5 Proof of Correctness and Optimality

In this section, we prove the correctness of the analyses performed in the proposed PRE algorithm. In the algorithm, two well-known classical analyses are presented. Therefore, we only provide proof of the correctness of the algorithms for computations in the PRE algorithm. For the proof, as in the algorithm, we consider only one expression e in the input program. Also, our CFG nodes have only a single statement. We assume that a statement of the form $x = x + 1$ is transformed into two statements, $t = x + 1$ and $x = t$, where t is a unique temporary variable.

5.1 Correctness of Safe Partially Available Path computation

► **Theorem 1** (Correctness). *The computation of the safe partially available path is done correctly.*

Proof. We have to show that every point computed as safe partially available by the safe partially available path computation (Algo.3) is correct. Let N represent the set of nodes in the input CFG.

Axiom 1. $\{\forall i: i \in N: (\text{SPAVPATHIN}_i = \text{FALSE}) \wedge (\text{SPAVPATHOUT}_i = \text{FALSE})\}$ at the beginning.

[From initialisation in lines 4-5]

Axiom 2. For an expression e , the input point of node i is on a safe partially available path if the input point of i is safe and the output point of at least one predecessor of node i is on the safe partially available path.

i.e., $\text{SPAVENT}_{\text{IN}_i} = \text{SAFEIN}_i \cdot (\sum_{p \in \text{pred}(i)} \text{SPAVENT}_{\text{OUT}_p})$ [By definition, Section 2.2]

Axiom 3. In the algorithm, $\text{SPAVENT}_{\text{IN}_i}$ is set to TRUE for a node i iff
 $\{\exists p: p \in \text{pred}(i): \text{SPAVENT}_{\text{OUT}_p} \cdot \text{SAFEIN}_p\}$ [Lines 16, 19-20]

► **Lemma 2.** *The computation of the safe partially available path at the input point of node i , i.e., $\text{SPAVENT}_{\text{IN}_i}$, is done correctly.*

Proof. Proof is as follows:

$$\begin{array}{ll} \text{Axiom 2 and Axiom 3} & \Rightarrow \text{SPAVENT}_{\text{IN}_i} \text{ is set to TRUE at the input point of node } i \\ & \text{if and only if safe partial availability is true} \quad - (1) \\ (1) \text{ and Axiom 1} & \Rightarrow \text{The input point of node } i \text{ which is not safe partially available remains FALSE} \\ & \quad - (2) \\ (1) \text{ and (2)} & \Rightarrow \text{Lemma 2} \end{array} \blacktriangleleft$$

Axiom 4. For an expression e , the output point of node i is on a safe partially available path, if e is locally available or the input point of node i is on safe partially available path and e is transparent in i . i.e., $\text{SPAVENT}_{\text{OUT}_i} = \text{AVLOC}_i + \text{SPAVENT}_{\text{IN}_i} \cdot \text{TRANSP}_i$. [By definition, Section 2.2]

► **Lemma 3.** *The computation of the safe partially available path at the output point of node i , i.e., $\text{SPAVENT}_{\text{OUT}_i}$, is done correctly.*

Proof. $\text{SPAVENT}_{\text{OUT}_i}$ is changed only for the nodes that are added to the work list. Therefore, we consider the nodes that are added to the work list. If a node i is added to the work list, then either of the following cases holds.

Case 1. Node i contains expression e . [Line 9]

$$\begin{aligned} &\Rightarrow \text{AVLOC}_i && - (3) \\ &\text{[Note that in our CFG, a block has only one instruction. Also, an instruction of the form } x = x + 1 \text{ is transformed into two statements,} \\ &\quad t = x + 1 \text{ and } x = t.] \\ &\Rightarrow \text{SPAVENT}_{\text{OUT}_i} && \text{[By Axiom 4]} - (4) \end{aligned}$$

Case 2. Node i does not contain the expression e (i.e. AVLOC_i is FALSE) and $\text{SPAVENT}_{\text{IN}_i}$ is TRUE. [Lines 20, 22] – (5)

We need to prove that, under the condition (5), $\text{SPAVENT}_{\text{OUT}_i}$ is set to TRUE if and only if TRANSP_i is TRUE (as given in line 14).

$$\begin{aligned} \text{SPAVENT}_{\text{OUT}_i} &\equiv \text{AVLOC}_i + \text{SPAVENT}_{\text{IN}_i} \cdot \text{TRANSP}_i && \text{[By Axiom 4]} \\ &\equiv \text{FALSE} + \text{SPAVENT}_{\text{IN}_i} \cdot \text{TRANSP}_i && \text{[AVLOC}_i = \text{FALSE, From (5)]} \\ &\equiv \text{SPAVENT}_{\text{IN}_i} \cdot \text{TRANSP}_i && \text{[FALSE} + \text{P} \equiv \text{P}] \\ &\equiv \text{TRUE} \cdot \text{TRANSP}_i && \text{[SPAVENT}_{\text{IN}_i} = \text{TRUE, From (5)]} \\ &\equiv \text{TRANSP}_i && \text{[TRUE} \cdot \text{P} \equiv \text{P}] \end{aligned}$$

i.e., $\text{SPAVENT}_{\text{OUT}_i}$ is TRUE iff node i is transparent.

Hence, $\text{SPAVENT}_{\text{OUT}_i}$ is set to TRUE correctly in case 2. – (6)

- (4) and (6) \Rightarrow SPAVPATHOUT_i is set to TRUE at the output point of node *i* if and only if safe partial availability is true. – (7)
- (7) and Axiom 1 \Rightarrow The output point of node *i* which is not safe partially available remains FALSE. – (8)
- (7) and (8) \Rightarrow Lemma 3

Lemma 2 and Lemma 3 \Rightarrow Theorem 1

► **Theorem 4** (Completeness). *The computation of the safe partially available path identifies all points that are safe partially available.*

Proof. We take three stages in the computation to prove the completeness:

- *Starting node of a safe partially available path:* A safe partially available path begins at the output point of a node containing the expression *e*. A node *i* containing the expression *e* is added to the work list in lines 8-9. The node *i* is then taken out from the work list (line 12) and safe partial availability information at the output point of node *i* is computed correctly in line 14.
- *Propagation of information:* The safe partial availability information at the output point of node *i* is then propagated to the input point of each of the successor nodes, say *j*, if the input point of node *j* is safe (lines 17-20), and those successor nodes are added to the work list (line 22). Each of these successor nodes is later taken out from the work list (line 12), and the information is further propagated from the input point to the output point of node *j* if node *j* is transparent (line 14).
- *End node of a safe partially available path:* The propagation ends under two conditions:
 - (i) The propagation from the input point to the output point of node *i* ends if *e* is killed in *i*.
 - (ii) The propagation from the output point of node *i* to the input point of its successor node *j* ends if input point of node *j* is not safe.

Hence, all possible safe partially available paths starting from a node *i* are computed correctly during this process.

This process of propagation of safe partial availability information is performed from each node containing *e* in the given input program. Hence, the computation identifies all points on the safe partially available path.

► **Theorem 5** (Termination). *Safe partially available path computation terminates.*

Proof. The algorithm terminates when the work list is empty (line 11). Initially, the work list contains nodes with the expression *e* from the input program (lines 8-9). After that, a node *i* is added to the work list if there is a change of value in SPAVPATHOUT_p where *p* \in pred(*i*) (lines 16, 22). The value in SPAVPATHOUT_i of a node *i* can change from the initialized value FALSE (line 5) to TRUE at most once (line 14), owing to the fact that once the value becomes TRUE, it remains TRUE. Hence, the number of nodes added to the work list after initialization equals the number of value changes for SPAVPATHOUT. If the total number of nodes in the CFG is *N*, then there can be at most *N* number of value changes. Since the nodes from the work list are removed (line 12) for computing SPAVPATHOUT, and the number of node additions is at most *N*, eventually the work list becomes empty. Hence, the algorithm terminates.

5.2 Correctness of Safe Redundancy Path computation

► **Theorem 6** (Correctness and Completeness). *The computation of the safe redundancy path is correct and complete.*

The line of reasoning is similar to the reasoning given for *safe partially available path*, except for the fact that the propagation in this case is in the backward direction and necessary changes accordingly. Hence, the formal proof is avoided here.

5.3 Optimality of Transformation

► **Theorem 7.** *The transformation in the proposed PRE algorithm is computationally and lifetime optimal.*

The proposed algorithm is based on the idea of the safe redundancy path in [14]. The transformation done on the safe redundancy path is proved to be both computationally and lifetime optimal in [14].

6 Experimental Results

In this section, we perform an experimental evaluation to compare the proposed algorithm with existing ones. For comparison, we consider two aspects: the number of redundancies detected (i.e., precision) and the running time of the algorithms. We have selected two of the existing algorithms which are computationally and lifetime optimal for comparison. The algorithms chosen for this comparison are: LCM [9], the well-known PRE algorithm which takes four analyses, and PRE-3 [16], which takes three analyses.

In the proposed work, the algorithm is designed for an arbitrary expression e . For implementation, we employ bit-vector representation to extend the algorithm to all the n expressions within the program. At a program point in the CFG, each property (e.g., SPAVPATHOUT_i in Algo. 3) is represented by a bit vector. Each bit in the bit vector corresponds to an expression where TRUE means the property is true for the expression, while FALSE means the property is false.

To illustrate how a bit vector facilitates parallel computation of all n expressions within the program, let's examine the computation $\text{SPAVPATHOUT}_i = \text{AvLOC}_i + \text{SPAVPATHIN}_i \cdot \text{TRANSP}_i$ in Algorithm 3. Consider the computation $\text{SPAVPATHIN}_i \cdot \text{TRANSP}_i$, where SPAVPATHIN_i and TRANSP_i are bit-vectors representing the information for n expressions. An AND operation between the bit-vectors SPAVPATHIN_i and TRANSP_i results in the bit-vector representing the property SPAVPATHOUT_i for all the n expressions at the output point of node i .

We used LLVM compiler infrastructure [1, 2] for our implementation. The results were obtained on a machine with a 1.8 GHz Intel Core i5 processor having 8 GB RAM for selected programs from the SPEC CPU2006 benchmark suite [3]. The analyses are intraprocedural. The algorithm is implemented for demonstrating its *completeness* and *efficiency*. Accordingly, we have decided to consider a subset of instructions i.e., instructions involving signed and unsigned integer arithmetic operators (+, -, *, ÷, %) to simplify the implementations. The LLVM IR instructions considered are *add*, *sub*, *mul*, *udiv*, *sdiv*, *urem* and *srem* as well as the *load* and *store* instructions of normal variables which includes both local and global variables. For other instructions, we made conservative assumptions. For example, consider a statement with pointer assignment, $*p = \dots$. This statement may change the value of normal variables of the program. So, we made a conservative assumption that all the variables are killed at the output point of such an instruction.

For our experiment, we begin with some preprocessing steps. We employ the *-instnamer* pass in LLVM to assign names to any unnamed values within the LLVM IR code. This is necessary as these values are not accessible through the *getName()* method we have used. We wanted only the instructions that can be reached from the entry node. To achieve this, we execute the *-unreachableblockelim* pass provided by LLVM. For Algorithm 3 and Algorithm 4, the worklist is implemented with the *InstructionWorkList* in llvm. This *InstructionWorkList* is implemented using a stack in llvm.

6.1 Efficiency

In this section, we compare the execution time of the proposed algorithm against the other two chosen algorithms: the LCM algorithm developed by Knoop et al. and PRE-3 by Roy et al. The algorithms were implemented as passes in the LLVM compiler and were run on selected programs from the SPEC CPU2006 benchmark suite [3] using the *-time-pass* optimizer tool of LLVM to measure execution time. The time taken for analyses by the CPU is measured where the reported time is the sum of the CPU time in user mode and the CPU time in system mode. We execute each benchmark program ten times, employing the *time-pass* functionality. We then calculate the average time from these ten runs. The time taken for analysis by each algorithm is then presented in seconds.

In Table 2, the second column displays the overall count of LLVM IR instructions within each benchmark program. The third column provides the total count of expressions considered, adhering to our conservative assumptions. The subsequent columns provide the time taken by each algorithm under consideration. The final row of the table presents the average time taken by each algorithm, taking into account all the selected benchmark programs.

The proposed algorithm performs better since it takes only two iterative data flow analyses compared to four by LCM and three by PRE-3. The proposed algorithm achieves 51% and 21% reduction in time over LCM and PRE-3, respectively, for the selected set of benchmark programs. The experimental results demonstrate that the proposed algorithm is more efficient in terms of the time taken for analysis compared to the other algorithms.

6.2 Precision

This section looks at the precision of the chosen algorithms, specifically focusing on their completeness in identifying redundant expressions. For the LCM algorithm, we record the count of insertions identified at nodes, the count of insertions specifically at the dummy nodes generated during preprocessing, replacement counts, and the total number of redundant expressions identified. In the case of PRE-3 and the proposed algorithm, we present the count of node insertions, edge insertions, replacements, and the total number of redundant expressions identified. Table 3 provides the information computed during the process. The total number of node insertions for LCM is displayed in column 2, which includes dummy nodes. Column 3 displays the number of dummy nodes created by the algorithm for LCM and used for insertions. Dummy node insertions in LCM are the *edge insertions* in PRE-3 and the Proposed Algorithm. The table demonstrates that the proposed algorithm detects the same number of redundancies as LCM and PRE-3, affirming the completeness of the algorithm. Moreover, upon examining the data in the table, it becomes evident that the identified points of insertions, replacements, and edge insertions are the same for all three algorithms.

Table 2 Comparison of Efficiency.

7 Conclusion

In this paper, we presented a novel algorithm for lexical-based partial redundancy elimination. The proposed algorithm takes two iterative data flow analyses followed by two computation passes over the program to perform the transformation. The use of well-known data flow analyses, i.e., *available expressions* analysis and *anticipated expressions* analysis, makes it easy to comprehend the algorithm and prove its correctness. We have provided the proof for the correctness of the algorithm. The algorithm is more efficient compared to other computationally and lifetime optimal algorithms in the literature, as it takes only two iterative data flow analyses, in contrast to at least three analyses required by other methods. The algorithm is both computationally and lifetime optimal. To substantiate these claims, we implemented the algorithm using the LLVM Compiler Infrastructure and compared the number of redundant expressions detected and the time taken for analyses against the existing algorithms. The results from the experiments conducted demonstrate

that the proposed algorithm detects the same number of redundant expressions and performs significantly better compared to the existing well-known algorithms considered. Although our algorithm is lexical-based, we believe that its fundamental principles hold significant potential for guiding the transition to a value-based approach, which could ultimately result in an efficient value-based PRE.

Abstract

Interprocedural data-flow analysis is important for computing precise information on whole programs. In theory, the popular algorithmic framework *interprocedural distributive environments* (IDE) provides a tool to solve distributive interprocedural data-flow problems efficiently. Yet, unfortunately, available state-of-the-art implementations of the IDE framework start to run into scalability issues for programs with several thousands of lines of code, depending on the static analysis domain. Since the IDE framework is a basic building block for many static program analyses, this presents a serious limitation. In this paper, we report on our experience with making the IDE algorithm scale to C/C++ applications with up to 500 000 lines of code. We analyze the IDE algorithm and its state-of-the-art implementations to identify their weaknesses related to scalability at both a conceptual *and* implementation level. Based on this analysis, we propose several optimizations to overcome these weaknesses, aiming at a sweet spot between reducing running time and memory consumption. As a result, we provide an improved IDE solver that implements our optimizations within the PhASAR static analysis framework. Our evaluation on real-world C/C++ applications shows that applying the optimizations speeds up the analysis on average by up to 7×, while also reducing memory consumption by 7× on average as well. For the first time, these optimizations allow us to analyze programs with several hundreds of thousands of lines of LLVM-IR code in reasonable time and space.

1 Introduction

Over the recent years static program analysis has become an important tool for finding bugs and security vulnerabilities [7, 11, 16, 26–28, 30]. To produce results that actually help developers in these tasks, static analyses are ideally both sound (or at least soundy [14]) and precise, i.e., they report only true findings without missing any real bugs and vulnerabilities. The analyses need to obtain a complete picture about the program under analysis and therefore have to be interprocedural, i.e., following procedure calls. But it is a major challenge to develop sound and precise inter-procedural analyses that scale well with large real-world target programs [6, 19, 31, 32].

The *interprocedural distributive environments* (IDE) framework [20] operates on data-flow problems whose flow functions distribute over the analysis' merge operator. Following the functional approach to interprocedural analysis [24], for such distributive data-flow problems IDE constructs fine-grained, per-fact, procedure summaries that can be reapplied in each subsequent calling context of a given procedure. This allows IDE to scale to larger programs relatively well even though its time complexity is $\mathcal{O}(|N| \cdot |D|^3)$, where N is the set of nodes of the target program's interprocedural control-flow graph and D is the symbol domain of the data-flow analysis.

Common static analysis frameworks such as Heros [5] and PhASAR [22] provide generic and parameterizable IDE solver implementations; they even implement the simpler IFDS [17] algorithm in terms of IDE. For an analysis problem on the desired target program to be solved in an automated manner, users of these frameworks merely have to specify its flow (and edge) functions and provide this specification to the IDE implementation. Current IDE implementations, also known as solvers, aim at analyzing real-world target programs in a fully flow and context-sensitive manner, computing precise and informative results depending on the quality of the flow (and edge) functions' specification. Nonetheless, the authors of this paper can tell from many years of experience in program analysis that all publicly available IDE implementations run into severe scalability issues for larger target programs – a major problem. This effectively impedes or even prevents the analysis of many real-world programs, or forces analysis developers to resort to simpler analysis domains, which reduces the precision and usefulness of the analysis results. Sattler et al., for instance, present a novel concept to combine program analysis and repository mining that addresses numerous relevant software engineering problems [21]. This approach, however, requires one to run an exhaustive IDE-based taint analysis that needs to generate and propagate *all* program variables, which, in turn, produces millions of data flows. In this vein, we use PhASAR's current IDE implementation to demonstrate that sound and precise analyses that produce more than 100 million data flow edges cannot be completed using ordinary consumer hardware. Such a huge number of data flows can easily arise already when analyzing programs that comprise fewer than 100 000 instructions in LLVM's [13] intermediate representation (IR). The number of IR instructions is relevant, since PhASAR performs its analyses on the LLVM-IR level, and even seemingly small C/C++ programs can lead to a large number of IR instructions. Still, using an IR enables analysis writers to develop analyses for programs originating from complex languages, such as C++, that would otherwise add drastic implementation overhead. Further, we can support analyzing programs from multiple different source languages (in our case C and C++) with just one analysis implementation, whereas a source-level analysis would need different implementations per language. Therefore, we prefer analyzing LLVM IR and handle the program size from within the solver.

In this work, we report on our experiences analyzing real-world programs with the IDE framework, identifying two critical optimization levers when implementing a generic state-of-the-art IDE solver. Specifically, using 31 real-world C and C++ target programs, we evaluate PhASAR’s state-of-the-art IDE solver implementation with regard to runtime and memory consumption. Based on insights gained from these experiments, we propose and evaluate two optimizations that we have devised to improve the performance of the IDE implementation. One optimization chooses an optimized data layout for storing required data, while the other one extends the garbage collection procedure from Arzt [1].

The improved IDE solver, which incorporates the abovementioned optimizations and insights, reduces analysis running times as well as memory consumption by up to $7\times$ on average, depending on the client-analysis problem that should be solved. The experiments show that this allows one to conduct sound and precise inter-procedural data-flow analyses on interesting target programs such as FASTDOWNWARD, a domain-independent planning system, in reasonable time and space.

In summary, we make the following contributions:

- We analyze the IDE algorithm as described in the literature and its state-of-the-art, openly-available implementations with regard to runtime and memory consumption.
- Based on the analysis, we propose optimizations that overcome these weaknesses.
- We report on an empirical study on our optimized IDE solver, showing that it improves runtime and memory usage of IDE-based analysis by up to $7\times$ on average.
- We provide an open-source implementation of the IDE algorithm that incorporates our optimizations within PhASAR [22] and make it available as supplementary material¹.

The remainder of this paper is structured as follows: Section 2 gives an introduction to the IDE algorithm and Section 3 analyzes the state-of-the-art in IDE-based analysis and describes the problems that we identify. Section 4 presents our optimizations to IDE to mitigate these problems and Section 5 describes the highlights of our implementation. In Section 6, we detail on our empirical evaluation on real-world C/C++ programs and Section 8 concludes this paper.

2 Background on IDE

In this section, we introduce the conceptual *Interprocedural Distributive Environments* (IDE) [20] algorithm. IDE solves a data-flow problem by constructing an *exploded supergraph* (ESG). By construction, a data-flow fact d holds at instruction n , if a node (n, d) in the ESG is reachable from a special, tautological node (n_0, Λ) for an entry point statement n_0 . The ESG is constructed by replacing each node in the target program’s *interprocedural control-flow graph* (ICFG) with a bipartite graph representation of the respective flow functions. IDE requires all flow-functions to distribute over the merge operator (usually set union). Such distributive flow functions can be represented as bipartite graphs without loss of precision. The common flow functions *identity*, *gen* (generate), and *kill* (remove) are distributive and thus, all *gen/kill* data-flow problems can be encoded in IDE.

To enable a context-sensitive, interprocedural analysis, IDE follows the summary-based approach [24] to inter-procedural static data-flow analysis: It constructs per-fact summaries for sequences of instructions by composing their flow functions. The composition $h = g \circ f$ of two flow functions f and g , called *jump function*, can be produced by merging the nodes

¹ Supplementary Material: <https://zenodo.org/doi/10.5281/zenodo.13137081>

of g with the corresponding nodes of the domain of f . A jump function ranging from a given procedure p 's starting point to its exit point builds up a summary ψ of p . Once summary ψ has been constructed for procedure p , it can be re-applied in any other context in which the procedure p is called. The runtime complexity of IDE is $\mathcal{O}(|N| \cdot |D|^3)$, where N is the set of nodes of the target program's ICFG and D is the data-flow domain of the analysis.

In addition, IDE allows to annotate the ESG's edges with lambda functions – so-called *edge functions* $f \in J$ – which operate on a separate value domain V and encode an additional value-computation problem. The value-computation problem specified using the ESG edges is solved when performing a reachability check. This way, IDE is able to effectively encode problems with infinite domains such as linear-constant propagation with $D = \mathcal{V}$, where \mathcal{V} is the set of program variables and $V = \mathbb{Z}_\perp^\top$. In this setup, IDE would propagate constant variables through the program and compute their constant values using the edge functions. An exemplary ESG for a linear-constant propagation encoded in the aforementioned manner is shown in Figure 1. The ESG nodes are visualized in a matrix structure where the rows represent the program statements n_1, \dots, n_4 and the columns represent the data-flow facts a, b, p and the special Λ fact. This way, Figure 1 also shows the bipartite nature of the encoded flow functions.

The jump functions constructed by the IDE algorithm describe data flows (and corresponding value computations). They comprise quadruples $\langle d_1, n, d_2, f \rangle$, where $d_1 \in D$ is the data-flow fact that holds at the source instruction (or node in the ICFG) $s_p \in N$, $n \in N$ is the target instruction, $d_2 \in D$ is the data-flow fact at the target instruction, and $f \in J$ is a function that describes the respective value computation. The source instruction s_p is implicit – it is the first instruction of the procedure that is being analyzed. In Figure 1, the jump function that describes that the data-flow fact a holds at ICFG node (n_4) in the program shown thus is: $\langle \Lambda, n_4, a, \lambda \ell. \ell \circ \lambda \ell. \ell + 2 \circ \lambda \ell. 1 \rangle \equiv \langle \Lambda, n_4, a, \lambda \ell. 3 \rangle$. Its evaluation yields that variable a carries the constant value 3 at ICFG node (n_4).

If an ESG node (n, d) is reachable along multiple program paths, the edge functions associated with the respective jump functions are combined using a *join* operation. Similar to flow functions, edge functions must distribute over the *join* operation. Hence, edge functions must be evaluable functions supporting regular function composition as well as the binary *join* operation and an *equality* relation. These operations – and the implementations for the flow and edge functions – need to be specified by analysis writers for the specific data-flow problem at hand.

The number of edges in an ESG is in $\mathcal{O}(|N| \cdot |D|^2)$. Even though D must be finite, D can be very large. Constructing the full ESG can easily lead to a graph containing millions of nodes and edges even for moderately-sized programs. Nearly all open-source state-of-the-art IDE implementations therefore construct only the valid paths reachable from the entry point $(s_{\text{main}}, \Lambda)$ in an on-the-fly manner, as proposed by Naeem et al. [15].

Naeem's on-the-fly algorithm requires the following essential structures to solve an analysis problem:

- *JumpFn* ($D \times N \times D \rightarrow J$): Jump functions $\langle d_1, n, d_2, f \rangle$ tabulated by the IDE algorithm that describe the data-flow facts reachable from $(s_{\text{main}}, \Lambda)$.
- *Incoming* ($N \times D \rightarrow N \times D$): A set that records nodes $\langle s_p, d \rangle$ that the analysis has observed to be reachable and predecessors of $\langle s_p, d \rangle$, where $s_p \in N$ a start point of procedure p . Using this set avoids the need to compute inverse flow functions, which might not be possible for all analysis problems.
- *EndSummary* ($N \times D \rightarrow N \times D \times J$): A table that stores jump functions that summarize the effect of a complete procedure p : $\langle s_p, d_1, e_p, d_2, f \rangle$, where $e_p \in N$ an exit point of p .

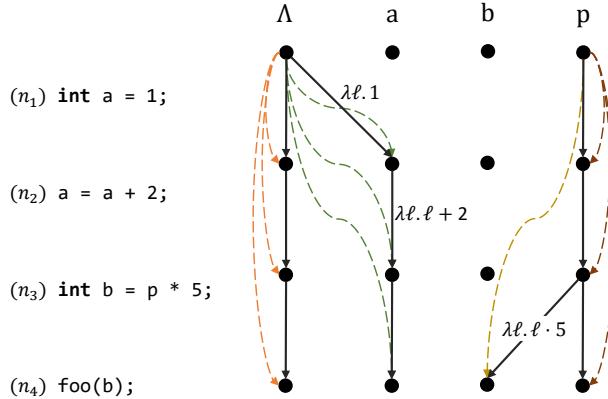

Figure 1 An example exploded supergraph for a linear constant analysis encoded in IDE [17]. The solid edges represent the individual flow functions, whereas the jump functions are denoted by the colored dashed edges. All (solid) flow edges are annotated with their edge functions; identity edge functions have been omitted to avoid cluttering. By following the flow edges in backwards direction, we can see that at (n_4) variable a is reachable from Λ and thus holds as data-flow fact. This information is also encoded as green dashed jump function from (n_1, Λ) to (n_4, a) . Composing the annotated edge functions, we can see that at (n_4) , variable a has the constant value 3.

These per-fact procedure summaries are reapplied in each subsequent context p is called.

2.1 IDE Algorithm Overview

The IDE algorithm works in two phases: (I) Constructing the relevant part of the ESG and (II) computing the values associated to the node-data-flow-fact pairs (n, d) by evaluating all edge functions f annotated to the jump functions in the ESG. We provide a copy of the original IDE algorithm as part of our supplementary website for this paper².

Phase I works as fixed point iteration starting from initial ESG nodes, called *seeds*. Based on the ICFG and the set of flow- and edge functions, the procedure `ForwardComputeJump-FunctionsSLRPs` (see algorithm Phase I) incrementally extends the ESG by adding new edges or updating the annotated edge functions of existing edges. This extending and updating of the ESG is performed by the `Propagate` (see algorithm Propagate) procedure, which gets iteratively called by the solver until a fixed point is reached. The final ESG for the example code snippet in Figure 1 is shown in the same figure (excluding the content of function `foo`).

Phase II (see algorithm Phase II) works in two steps: *value propagation* and *value computation*. First, in the value propagation phase, the initial edge values are propagated iteratively through the ESG from the seeds to the beginning of all analyzed procedures. After that, in the value computation phase, the edge functions of all remaining jump functions are evaluated with the values previously aggregated at the beginning of the respective procedure.

For example, consider the code snippet in Figure 1. Assuming that it is part of a function that gets called with $p = 4$, the value propagation will create the relation $(n_1, p) \mapsto 4$. If the code snippet is called with multiple different values for p , the relation gets updated using the lattice join of the value domain. Further, to aggregate the starting values for all procedures, the value propagation computes the relevant edge values for the call-site, in this case for b at n_4 . It computes $b = (\lambda\ell.\ell \cdot 5)(4) = 20$ and iteratively propagates it into `foo`. After the value-propagation phase has finished, all remaining result relations can be computed, which leads to $(n_2, a) \mapsto 1, (n_2, p) \mapsto 4, (n_3, a) \mapsto 3$, etc.

3 The State of the Art

In many years of developing static data-flow analyses, we have found that state-of-the art analysis implementations, many of them implementing IDE (or a subset of it), do not scale to large programs comprising several hundreds of thousands to millions of lines of code. In the following, we report on the problems with current IDE implementations, with the example of PhASAR, that has lead us to define the optimizations to IDE that we present in Section 4.

To show the performance of a current state-of-the-art IDE implementation, we use the current `IDESolver` from PhASAR³ in version v2403, which is the most recent stable version of the open-source framework at the time. To assess the state-of-the-art, we have applied the `IDESolver` to 31 real-world C and C++ programs⁴ denoted in Table 1 and solved a typestate analysis (TSA), a linear constant analysis (LCA), and an instruction-interaction analysis (IIA) [21]. In Table 1 the columns with the analysis problems are sorted in ascending order by analysis complexity.

Measuring runtime and memory usage of the analysis runs, as Table 1 shows, we observed that, with increased analysis complexity, the number of recorded timeout (t/o) and out-of-memory (OOM) events grows. While the `IDESolver` was able to complete the LCA and TSA on almost all target programs, the solver performed worse on the IIA: In fact, we observed that six out of 31 could not be run on an ordinary developer machine, seven others ran out-of-memory while four others timed out.

The current situation, as illustrated by Table 1, that many interesting data-flow analyses cannot be solved on medium-sized to large target programs is unacceptable. While long runtimes can be tackled by running the analysis less often (e.g., in a CI/CD pipeline) or by increasing the time budget, the high memory requirements are often impossible to solve due to hardware limits; more memory might be integrated which then—depending on the system—would incur high procurement- and operating costs.

As some state-of-the-art IDE implementations, such as PhASAR and Heros, are open-source, we are able to analyze them to gain insights where the performance bottlenecks are and propose optimizations (cf. Section 4) for lowering the time- and memory requirements of IDE.

4 Optimizations

To mitigate the scalability issues of IDE identified in Section 3, we reviewed state-of-the art literature regarding IDE implementations, profiled the IDE solver implementation within the PhASAR framework, and identified two aspects that suggest to offer potential for effective optimizations in terms of both runtime and memory consumption. Although the IDE algorithm works in two phases (see Subsection 2.1), we can tell from our experience that IDE spends the majority of its time during phase I—the part that IFDS and IDE have in common. Thus, we aim to optimize phase I.

First, while computing the target analysis' fixed point, an IDE implementation must efficiently store the set of jump functions. This corresponds to the *JumpFn* map [20] in the original algorithm. The jump-functions table stores all ESG edges that are computed by the IDE solver. That is, it stores quadruples drawn from $(D \times N \times D) \rightarrow J$. The size of the jump-functions table is therefore bound by $\mathcal{O}(|N| \cdot |D|^2)$. As it is unlikely to

³ PhASAR: <https://github.com/secure-software-engineering/phasar/tree/v2403>

⁴ Subsection 6.2 provides details on how the results were obtained and how the analyses were configured.

Table 1 On the left, we see all evaluation targets with additional information, such as the revision we analyzed and the amount of LLVM-IR code. The IR code size is important because PhASAR’s IDE solver works at the IR level. In addition, we report the number of procedures (Proc), the number of globals (Glob), and the number of call-sites (Calls) in the IR, which may influence the performance of the analysis. The three rightmost columns show time [s] and memory consumption [MiB] of the benchmarked analyses utilizing the IDESolver from PhASAR. Orange cells indicate that the memory of a common consumer machine (32 GiB) was exceeded. Dark orange cells indicate that even a compute cluster with 128 GiB would be insufficient. Red cells indicate the analysis ran out-of-memory with a memory limit of 250 GiB, and blue cells represent timeout (t/o) events exceeding four hours of analysis time.

reduce this worst case bound, we propose in Subsection 4.1 to lower the constant factors of these bounds by optimizing the memory layout of the jump-functions table, which enables practical performance gains. Second, most jump functions computed by IDE are just needed temporarily to craft the procedure summaries ψ . Once a summary has been created, the corresponding intermediate jump functions are no longer needed. Hence, to reduce IDE’s memory footprint, we propose in Subsection 4.2 to remove such intermediate entries from the jump-functions table. In fact, we extend the work from Arzt [1] by designing a garbage collector for jump functions that—in contrast to the one proposed by Arzt—is applicable to arbitrary IDE problems.

It is important to note that our optimizations do not target just one particular implementation; our optimizations are generally applicable.

4.1 Data Structures for the Exploded Supergraph

While solving an IDE data-flow analysis problem, the solver incrementally creates jump functions (see Section 2) that need to be stored in memory. To solve the analysis problem efficiently, the jump functions need to be stored efficiently, allowing for short lookup and insertion times as well as for a small memory footprint.

$(d_1, n, d_2) \mapsto f$
$(\Lambda, n_1, \Lambda) \mapsto \lambda \ell. \ell$
$(p, n_1, p) \mapsto \lambda \ell. \ell$
$(\Lambda, n_2, \Lambda) \mapsto \lambda \ell. \ell$
$(p, n_2, p) \mapsto \lambda \ell. \ell$
$(\Lambda, n_2, a) \mapsto \lambda \ell. 1$
$(\Lambda, n_3, \Lambda) \mapsto \lambda \ell. \ell$
$(p, n_3, p) \mapsto \lambda \ell. \ell$
$(\Lambda, n_3, a) \mapsto \lambda \ell. 3$
$(\Lambda, n_4, \Lambda) \mapsto \lambda \ell. \ell$
$(p, n_4, p) \mapsto \lambda \ell. \ell$
$(\Lambda, n_4, a) \mapsto \lambda \ell. 3$
$(p, n_4, b) \mapsto \lambda \ell. \ell \cdot 5$

Figure 2a. The jump-functions table similar to the *FastSolver* of FLOWDROID. Without nesting, the whole jump functions $\langle d_1, n, d_2, f \rangle$ of the ESG for Figure 1 are stored in one level which may lead some of d_1 , d_2 , and n being stored redundantly.

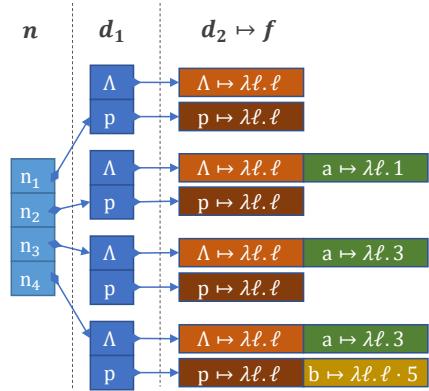

Figure 2b. The main jump-functions table from PhASAR and Heros. For each jump function $\langle d_1, n, d_2, f \rangle$, it maps the nodes n to inner maps, which map the source data-flow facts d_1 to the respective target facts d_2 and edge functions f . This avoids some nodes n and source facts d_1 to be stored multiple times, as they would be in Figure 2a, but adds extra cost for the inner mappings.

▀ **Figure 2** Different jump-functions table layouts currently used by open-source IDE implementations.

4.1.1 Jump Functions Table Analysis

Existing IDE solver implementations such as Heros [5], PhASAR [22] and FLOWDROID [4] use different representations to store jump functions, each of which comes with different performance properties. PhASAR and Heros use nested mappings $N \rightarrow (D \rightarrow (D \rightarrow J))$ that map a target node $n \in N$ to a map of source data-flow fact $d_1 \in D$ to a map of target fact $d_2 \in D$ to the associated edge function $f \in J$. Yet, to speed up algorithm-specific lookup and insert tasks, Heros and PhASAR store each jump function redundantly in two additional maps, effectively modeling a multi-index table. In what follows, when referring to the jump-functions table structure used by PhASAR and Heros, we focus on the nested mapping described above, but keep in mind that the multi-index may have a drastic impact on the overall memory consumption of the solving process.

FLOWDROID uses a flat $(N \times D \times D) \rightarrow D$ representation to map a full jump function $(n, d_1, d_2) \in N \times D \times D$ to the same target fact d_2 . As FLOWDROID only implements IFDS, which is a subset of IDE where all edge functions are implicitly the identity function $\lambda x.x$, it does not need to store edge functions $f \in J$. It stores the target fact twice for implementation-specific support for path-tracking. As path tracking is out of scope for this work, we concentrate on the $(N \times D \times D)$ part of the data structure.

Both data structures (nested and flat) have their advantages and drawbacks. Consider the example in Figure 1. Having no nested mappings, as shown in Figure 2a, makes lookup and insertion fast, since they only consist of a single hash-map operation. In contrast, the nested approach, as shown in Figure 2b, requires three hash-map operations for each lookup or insert as for each of n , d_1 and d_2 in a jump-function entry a separate hash-map lookup or insertion is required.

In both designs, the noticeable duplication of the edge functions f could be solved by storing them in a separate cache. PhASAR, in fact, supports such a cache already. However, even with caching edge functions, nodes n and source facts d_1 may be stored redundantly in memory. This is, because it is likely that there are multiple jump functions

that lead to the same target node, which corresponds to the existence of the jump functions $(d_{1,1}, n, d_{2,1}), \dots, (d_{1,k}, n, d_{2,m})$ for $n \in N$, $\{d_{1,1}, \dots, d_{1,k}, d_{2,1}, \dots, d_{2,m}\} \subseteq D$ and $k, m \in \mathbb{N}$. Such jump functions may store the target node n multiple times in a flat structure, such as Figure 2a, but store n only once in a nested representation such as Figure 2b.

In the same vein, when generating data-flow facts, it is also likely that there are multiple target facts for the same source-fact and target node, for example, jump functions of the form $(d_1, n, d_{2,1}), \dots, (d_1, n, d_{2,m})$ for $n \in N$, $\{d_1, d_{2,1}, \dots, d_{2,m}\} \subseteq D$ and $m \in \mathbb{N}$. For instance, the jump functions $(\Lambda, n_2, \Lambda, \lambda \ell. \ell)$ and $(\Lambda, n_2, a, \lambda \ell. 1)$ from Figure 1 fall in that category. In a flat representation such as of Figure 2a, jump functions store both source fact d_1 and target node n redundantly, but avoid the redundant storage in a nested representation as shown in Figure 2b.

In summary, nested mappings store less data from the jump functions redundantly and therefore are likely to expose a lower memory usage than a shallow representation. Conversely, common operations such as lookup and insertion of jump functions in the table are likely to be faster in the flat representation as there are fewer indirections and fewer hashing operations. Furthermore, map data structures themselves have implementation-specific memory overhead. Therefore, a nested representation is more memory efficient than a flat one only if the additionally introduced maps grow beyond an implementation-specific threshold to compensate the overhead of these maps.

4.1.2 Optimized Jump Functions Table

Given the analysis in Subsubsection 4.1.1, we propose a compromise between nested and flat data structure representations that harnesses the advantages of both to drastically improve both the memory usage as well as the runtime of the IDE algorithm. We acknowledge that a nested mapping is necessary to avoid duplicate storage of nodes and data-flow facts. However, to keep lookup times low and to keep the individual maps sufficiently large, we aim at reducing the nesting depth as well. Specifically, we propose a two-level nested map as a compromise between fast lookup times and low memory usage. For a design with two levels of nesting, there are six possible mappings to store jump functions:

- | | |
|---------------------------------------|-------------------------------------|
| 1. $(n, d_1) \mapsto (d_2 \mapsto f)$ | 4. $n \mapsto (d_1, d_2) \mapsto f$ |
| 2. $(n, d_2) \mapsto (d_1 \mapsto f)$ | 5. $d_1 \mapsto (n, d_2) \mapsto f$ |
| 3. $(d_1, d_2) \mapsto (n \mapsto f)$ | 6. $d_2 \mapsto (n, d_1) \mapsto f$ |

To reduce the number of candidate representations, we consider one more optimization: As we limit ourselves to two-level nested maps, each jump functions access requires at least two indirections. However, with intelligent batch-processing, the effective number of indirections can be reduced. We observe that during ESG construction in the IDE algorithm(cf. Subsection 2.1), the only direct access to the jump-functions table is inside the `Propagate` function depicted on the left side of Algorithm 1. Here, the expression $JumpFn(e)$ performs the jump-functions table access where e represents a complete jump edge consisting of the target node n and the source- and target data-flow facts d_1 and d_2 . We further observe that in the original algorithm `Propagate` is always called from within a loop where parts of n , d_1 , or d_2 are loop-invariant.

So, if we design the jump-functions table accordingly, we can optimize the `Propagate` procedure (shown on the right side of Algorithm 1), by batching the access to the outer map for multiple jump functions accesses together. Here, `Propagate` receives an additional parameter j that denotes a view into the jump-functions table where the loop-invariant parts

Algorithm 1 The modifications in the `Propagate` procedure that support batch processing. An exemplary use of `Propagate` for the case in which the target node n is loop-invariant is shown in Lines 8-11. To highlight changes compared to the original algorithm from Sagiv et al. [20], additions are shown in **green** and removals are shown in **red**.

<pre> 1 Procedure Propagate(e, f) 2 let $f' = f \sqcap \text{JumpFn}(e)$; 3 if $f' \neq \text{JumpFn}(e)$ then 4 $\text{JumpFn}(e) = f'$; 5 Insert e into <i>PathWorkList</i>; 6 end 7 end // Example use: 8 9 for ... do 10 Propagate($\langle s_p, d_1 \rangle \rightarrow \langle n, d_2 \rangle, f$); 11 end </pre>	<pre> Procedure Propagate(j, e, f) let $f' = f \sqcap j(e)$; if $f' \neq j(e)$ then $j(e) = f'$; Insert e into <i>PathWorkList</i>; end // Example use: j = JumpFn($\langle *, * \rangle \rightarrow \langle n, * \rangle$); for ... do Propagate($j, \langle s_p, d_1 \rangle \rightarrow \langle n, d_2 \rangle, f$); end </pre>
--	---

Table 2 Access patterns of the jump-functions table with their number of occurrences within the original IDE algorithm [20] (cf. Subsection 2.1).

Invariant parts	# Occurrences
n	1 (call-flow)
n, d_1	2 (call-to-return-flow, summary-flow)
n, d_2	1 (return-flow)
d_1	1 (normal-flow)

are already fixed. In the example, j only contains jump functions where the target node is a previously fixed n . It is important that the extraction of j happens outside of the loop that calls `Propagate`. Using the smaller map j for accessing the jump functions instead of the complete table JumpFn may improve the performance of `Propagate`. In fact, if j is one of the inner maps of our two-level nested jump-functions representation, using j effectively reduces the nesting depth of the table within `Propagate`, which in turn reduces the runtime cost of accessing individual jump functions.

Efficiently extracting the view j from the jump-functions table requires that the jump-functions table is laid out in a way that supports this operation. This can be achieved by placing the loop-invariant parts as keys into the outer map and the loop-variant parts into the inner maps. To decide which view j is best suited to achieve maximum performance improvement, we have to analyze which parts, n , d_1 , or d_2 , of a jump function are most frequently loop-invariant.

Based on careful analysis of the original algorithm [20], we identify four different access patterns, as depicted in Table 2. Although n is not strictly invariant in the normal-flow case, it may still be beneficial to consider n as invariant for the purpose of selecting a jump-functions representation, as most intraprocedural control-flow nodes mostly have only one (statement-sequence) or two (conditional branch) successors. Furthermore, to propagate all normal flows, the algorithm needs to iterate over all relevant n, d_2 pairs which is usually implemented as nested loop, effectively making n or d_2 temporarily loop-invariant. This consideration has no influence on the algorithmic correctness, but on the effectiveness of batch-processing jump functions accesses in the table.

Based on these observations, we conclude that it is beneficial to store the target fact d_2 in the inner map and n in the outer map. This enables us to filter out most of the six possible mappings presented above, leaving only

$$\begin{array}{ll} \text{1. } (n, d_1) \mapsto (d_2 \mapsto f) & \text{4. } n \mapsto (d_1, d_2) \mapsto f \end{array}$$

as possible candidates, which we call JF_{ND} and JF_N , respectively, denoting the domain used in the outer map.

Furthermore, we also conjecture that a multi-index representation of the jump-functions table is not necessary. With any of JF_{ND} or JF_N we can efficiently model all access patterns that occur in the IDE algorithm. Hence, we introduce a third jump-functions representation, JF_{old} , that uses the deep nesting from PhASAR and Heros ($n \mapsto d_1 \mapsto d_2 \mapsto f$), but avoids the multi-index.

Our theoretical analysis also yields that, with JF_{ND} , we already have efficient access to the procedure summaries, eliminating the need for an extra *EndSummary* table that was proposed by Naeem et al. [15]. To access a summary⁵ of procedure p , we can directly lookup the necessary jump functions at p 's exit statements. With JF_N , to find matching summaries without the *EndSummary* table, one requires a linear search over the inner maps at p 's exit statements. Depending on the size of these inner maps, this linear search may still be fast, so we split JF_N into two candidates: JF_N and JF_{NE} where JF_{NE} uses the explicit *EndSummary* table while JF_N omits it.

4.1.3 Discussion

From the observations in Subsubsection 4.1.2, one could conclude that JF_{ND} is superior to JF_N because, in three out of the five `Propagate` calls, d_1 is loop-invariant. However, in JF_{ND} (depicted in Figure 3a) the outer map is larger than in JF_N (depicted in Figure 3b) as its key space is larger: $|N| \leq |N \times D|$. Therefore, JF_{ND} needs to store more inner maps than JF_N although, in the end, both store the exact same number of jump functions. Furthermore, the inner maps in JF_{ND} are smaller than the inner maps in JF_N , as there are more of them and depending on the concrete implementation-specific overhead of a single inner map, the memory cost of the inner maps might outweigh their potential benefit. Hence, from a sole theoretical analysis, we cannot conclude which jump-functions representation performs better in practice; we need to perform an empirical evaluation to draw a final conclusion (Section 6).

4.2 Garbage Collection of Jump Functions

As discussed in Subsection 4.1, the jump-functions table has a great influence on the overall memory consumption of the IDE algorithm. Arzt [1] has shown that it is possible to remove entries in the jump-functions table without preventing the algorithm from reaching a fixed point. They present a garbage collector (GC) that runs concurrently to the actual IDE implementation, improving both memory usage and runtime of the underlying analysis. The GC removes jump functions when they are no longer needed. This applies when the complete data flow represented by a jump function has already been composed to a summary.

One limitation of the approach of Arzt [1] is that it only applies to an IFDS analysis and therefore does not need to deal with edge functions. In IDE, the value computation problem on data-flow edges can only be performed if the corresponding jump functions are

⁵ Processing summaries as described in line 15.2 by Naeem et al. [15].

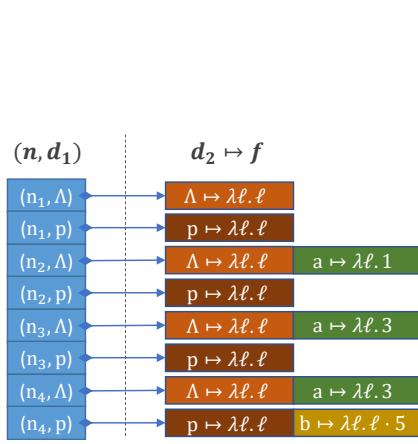

Figure 3a. jump-functions representation JF_{ND} for the example shown in Figure 1. The outer map has a two-dimensional key space consisting of the target node n and the source fact d_1 , which reduces the size of the inner maps, containing only the target fact d_2 and the edge function f .

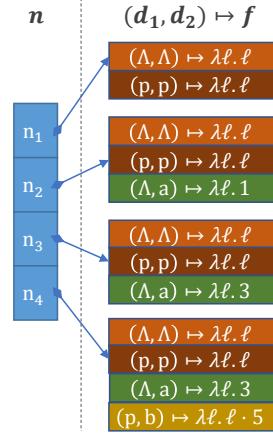

Figure 3b. jump-functions representation JF_N for the example shown in Figure 1. The outer map has a one-dimensional key space only consisting of the target node n , whereas the inner maps have a two dimensional key space containing the source- and target facts d_1 and d_2 as well as the associated edge functions f . Compared to JF_{ND} , JF_N contains fewer inner maps which in turn grow larger.

■ **Figure 3** Exemplary jump-functions tables using the proposed representations JF_{ND} and JF_N .

present. This makes garbage collecting jump functions more complicated in a general IDE setting with associated edge functions. Although Arzt describes a possible extension of the GC to IDE as trivial, we recognize that the correct handling of corner cases makes it less obvious than it seems on the first glance. Especially, we need to ensure that subsequent result queries can still evaluate the edge-functions correctly that are annotated to the jump functions. Secondly, the garbage collection by Arzt [1] exploits multithreading at the level of the data-flow analysis solver. This requires the complete analysis toolchain to be thread safe. While some IDE implementations do satisfy this requirement and make use of multiple cores to speedup the solving process, other implementations are only single-threaded and do not provide thread-safe data structures. Specifically, PhASAR’s analyses are not thread-safe and even LLVM—which PhASAR builds upon—is not generally thread-safe. Additionally, since we conduct a comprehensive study evaluating the runtime and memory consumption of IDE, we need to ensure that external factors, such as OS scheduling do not influence our evaluation results. Hence, we prefer using only a single thread, which eliminates many of these issues by removing non-determinism from the implementation.

In the following, we describe how we mitigate both limitations, the restriction to a subset of IDE and the enforced multi-threading.

4.2.1 Single-Threaded Garbage Collection

To keep the GC scalable, Arzt designed it to work on a procedure-level. That is, all jump functions corresponding to procedure p can be erased once there is no longer any worklist item that contains a node from inside p or from any procedure that can be transitively called by p [1]. We call this the *GC Condition*. Unfortunately, the order in which the ESG is constructed is not specified by the underlying algorithm [20], which is why one cannot precisely predict these points. If the garbage collector runs concurrently to the

actual analysis-solving thread, it can be invoked periodically based on a timer. Additional computations that the GC needs to perform to determine for which procedures the jump functions can be erased do not necessarily pause the analysis. However, as explained above, we decided to aim for a single-threaded solution here. The GC thus needs to be called explicitly at suitable points within the IDE algorithm and will pause the data-flow analysis for the garbage collection.

We observe that a procedure p can only become a candidate for garbage collection once the analysis within p has reached an exit statement. In theory, it is possible to invoke the GC after exiting any procedure, yet this has a non-negligible overhead that would render the analysis unscalable. Hence, we aim for finding a point in the IDE algorithm to place the GC, such that it gets called frequently enough to keep it effective, but not too frequent to keep it scalable. This means, that the GC should be invoked, once a sufficient amount of procedures have computed their summary.

There are several ways of deciding when the GC should be invoked, each with different characteristics and implications. One approach is to increment a counter, whenever a procedure has computed a new summary, and invoke the GC when the counter reaches a certain threshold. This approach has the advantage that it is easy to implement. On the downside, it does not decide to invoke the GC based on concrete information on the internal solver state, such as the content of the worklist or the jump-functions table. Therefore, many candidate procedures may actually fail the *GC Condition* and are not eligible for garbage collection yet. Hence, its performance may not be predictable and requires a decent amount of tuning. An alternative is to take the contents of the solver's worklist into account when deciding on when to invoke the GC. Since the *GC Condition* is based on the content of the worklist, we can invoke the GC when it is guaranteed that the candidate procedures will pass the *GC Condition*. In our implementation, we opted for this more informed procedure.

For deciding, when to invoke the GC, we split IDE's worklist into two separate worklists: One *Path WorkList* for top-down propagations, which stores jump functions in $D \times N \times D \times J$ to be processed, and another worklist, *Ret Worklist*, for bottom-up summary applications that stores entries of the form $(d_1, p) \in D \times P$, where P is the domain of callable procedures in the target program. On a high level, the fixed-point iteration uses the *Path WorkList*, but also fills the *Ret Worklist* on-the-fly when a procedure has reached its exit point. Once the *Path WorkList* becomes empty, the algorithm handles the work-items from the *Ret Worklist*, which may fill the *Path WorkList* again. Although the data-flow propagations have stayed the same, using two worklists we now have structured the fixed-point iteration into stages (a stage ends, whenever the *Path WorkList* becomes empty) that allow placing a call to the GC.

For the two worklists to function properly, we modify the IDE algorithm as sketched in Algorithm 2. The pseudo code for handling procedure exit points that we removed in Line 9 of Algorithm 2 has moved to a new outer loop depicted in Algorithm 3. As applying procedure summaries may lead to new intra-procedural propagations at their return sites, the whole process runs in a loop until *both* worklists are empty, as shown in Algorithm 3.

Note that in subsequent iterations, the `ForwardComputeJumpFunctionsSLRPs` procedure must skip its initialization phase to not over-write the already computed results. Apart from that, we did not change the original IDE algorithm, as we describe in Paragraph 4.2.1.1.

Using two worklists, the garbage collection condition now slightly changes. The jump functions of a procedure p can only be collected if none of the *Path WorkList* and the *Ret Worklist* contain a node from inside p or its transitive callees. This is, because when processing the worklist items (d_1, p) from the *Ret Worklist*, the callers of p may be added to the *Path WorkList* again preventing garbage collection for p . Whenever the *Path WorkList* is

■ **Algorithm 2** Modification in the `ForwardComputeJumpFunctionsSLRPs` procedure from the original IDE algorithm [20].

```

1 Procedure ForwardComputeJumpFunctionsSLRPs(... )
2   ...
3   while PathWorkList ≠ ∅ do
4     Select and remove an item  $\langle s_p, d_1 \rangle \rightarrow \langle n, d_2 \rangle$  from PathWorkList;
5     ...
6     switch n do
7       ...
8       case n is the exit node of p do
9         | Insert  $(d_1, p)$  into RetWorklist;
10      end
11      ...
12    end
13  end
14 end

```

■ **Algorithm 3** High-level overview of the two-step fixed point computation with garbage collection. The `foreach` loop in Line 5 denotes the content from `ForwardComputeJumpFunctionsSLRPs` [20] that we have removed from Algorithm 2. The function `RunGarbageCollector` behaves exactly as described by Arzt [1].

```

1 while PathWorkList ≠ ∅ do
2   ForwardComputeJumpFunctionsSLRPs(... );
3   while RetWorklist ≠ ∅ do
4     Remove  $(d_1, p)$  from RetWorklist;
5     foreach call node c that calls p with corresponding return-site r do
6       ...
7     end
8   end
9   RunGarbageCollector();
10 end

```

empty, we have the guarantee that for all currently analyzed procedures (and their transitive callees), the analysis has reached their exit points, making them candidates for garbage collection. Hence, we now have a structure that precisely defines points for placing the GC.

In particular, we now have two candidate locations to place the garbage collection in Algorithm 3: Line 3: Right after the returning from `ForwardComputeJumpFunctionsSLRPs` (i.e., when the `PathWorkList` becomes empty) or Line 9: After the `RetWorklist` becomes empty. In Line 3, the `RetWorklist` is potentially non-empty as it may contain procedures p that have computed a new summary for the propagation of a source data-flow fact d_1 that needs to be propagated back to all callers of p . In Line 9, though, the `RetWorklist` is empty, whereas the `PathWorkList` may be filled with return flows again.

Both insertion points at Line 3 and Line 9 are very similar, however, Line 9 has one small benefit: Having a jump function from a procedure p in the `RetWorklist` prevents all caller procedures of p from being garbage collected. After processing the `RetWorklist` items, only those callers of p have jump functions in the `PathWorkList` for which the new information

from p requires further propagation. All other caller procedures can still be garbage collected (unless there are other callees that prevent the collection). This leads to our preference to place the garbage collection at Line 9. Note, although the worklists are processed until completion in one iteration of the outer loop, there are still potentially many iterations such that the garbage collector is run many times as well.

4.2.1.1 Correctness

Our modifications to the IDE algorithm and the integration of the garbage collection do not violate the correctness and complexity of the IDE algorithm. Splitting the worklist into two smaller worklists, as we have done in Algorithm 2 and Algorithm 3, does not create new worklist items that would not be created in the original, and also does not drop worklist items that would be processed in the original. Only the order, in which the worklist items are processed, may change. This is, because (1) the processing of exit nodes (cf. Line 9) gets delayed through the *Ret Worklist* to Algorithm 3 without modifying the corresponding worklist items, and (2) since the processing order of the worklist items is not defined in the algorithm [20], any modification on the processing order has no influence on the correctness or complexity of the algorithm.

In addition, we use the same *RunGarbageCollector* function from Arzt without modification. Only the garbage collection condition, has slightly changed: Whereas in the original GC, a procedure p 's jump functions can be erased, if the worklist does not contain a node from inside p or its transitive callees, in our extension, this requirement holds for both the *PathWorkList* and the *Ret Worklist*. Since we argue above that both *PathWorkList* and *Ret Worklist* in combination express the same worklist items as the original worklist, the correctness argumentation from Arzt still holds.

4.2.2 Generalizing Garbage Collection for IDE

When a procedure p gets evicted by the original GC from Arzt, all jump functions corresponding to that procedure are removed. However, when performing an analysis that uses IDE's edge functions, one needs to ensure that the value computation (cf. Subsection 2.1) can still be performed correctly. To solve the value computation problem for an ESG node $(n, d) \in N \times D$, the edge functions annotated to all jump functions that lead to node (n, d) have to be evaluated and thus need to be present. For example, removing the intermediate jump function $\langle \Lambda, n_3, a, \lambda\ell.3 \rangle$ in Figure 1 would prevent that the analysis computes the result relation $(n_3, a) \mapsto 3$. This makes garbage collection for IDE's jump functions impossible when the values for all ESG nodes must be computed. Fortunately, many analyses can define for which ICFG nodes $n_i \in N$ analysis-result queries may be raised before starting the solving process. For example, in a typestate analysis, only the API call nodes that are relevant for the analyzed usage pattern may be queried. We call those nodes n_i *interesting*. At *interesting* nodes, we erase no jump functions in the GC to ensure that at those nodes the complete analysis results including edge values will be present.

However, we have to retain additional jump functions: The value-propagation phase (cf. Subsection 2.1) first propagates initial edge values from the entry points to the starting nodes of all reachable procedures. This is done by iteratively querying and evaluating the jump functions at all call sites to map the initial values to the start of all reachable procedures. This initial value-propagation is necessary for the other jump functions to be evaluated, as it determines the input values for these jump functions. Therefore, for the value propagation to work properly, one must also retain the jump functions at all call sites, even if they are

not considered *interesting*, such that the value propagation to the starting points of all procedures can succeed. Hence, when using IDE’s edge functions, the garbage collection must retain more jump functions than just the ones corresponding to *interesting* nodes, making it potentially less effective.

In the evaluation, we demonstrate that the garbage collection is still effective in a real world setting, even in a single-threaded environment and when using IDE without restrictions.

5 Implementation

We implemented the IDE algorithm including the optimizations proposed in Section 4 on top of the PhASAR framework [22]. PhASAR is able to analyze LLVM IR [13] in a fully automated manner and already provides an implementation of IDE, called **IDESolver** [22, 23]. The **IDESolver** is parametrizable with an user-defined description of an IDE analysis problem that shall be solved. After solving the analysis problem, the **IDESolver** can answer queries about which data-flow facts hold at a given ICFG node and which edge value has been computed for a given node–data-flow fact pair $(n, d) \in N \times D$. We chose to provide the same interface in the new solver such that it can be used as a drop-in replacement. Note that the determination of *interesting* nodes for the garbage collector is completely opt-in, so only IDE analyses that use both the garbage collector and edge functions may need to implement it. We call our new solver **IDESolver++**.

The existing solver provides several configuration options that influence how the analysis problem should be solved (e.g., whether the value computation in IDE Phase II should be performed). Our new implementation is configurable as well, but we chose to lift the configuration from runtime to compile-time. This allows to specialize the solver for the selected configuration such that the algorithms and data structures can be selected precisely for the requested needs. For example, if the implementation detects at compile-time that the to-be-solved analysis problem does not need edge functions, the jump functions table will replace its inner map by a set, eliding the storage for associated edge functions that would otherwise all default to the identity function $\lambda x.x$.

In Section 4, we have shown different representations of the table storing the jump functions, and we concluded that this representation is critical for optimal performance of the overall solving process. Therefore, we chose to use open-addressing⁶ hash maps to store the concrete mappings of the structures JF_{ND} and JF_N , as well as JF_{old} . Open-addressing hash maps are particularly performant because of their cache efficiency and small number of dynamic memory allocations. However, their performance degrades with increasing size of the entries to store. The domains N and D are user defined for both solvers (the current **IDESolver** and our **IDESolver++**) making them generic over the program representation to analyze and the type of data-flow facts. Therefore, we do not use these types directly as keys and values in the hash maps to guarantee predictable performance. Instead, we chose to introduce an intermediate layer that maps each used node and data-flow fact to 32-bit integers in the contiguous ranges $[0, \dots, |N| - 1]$ and $[0, \dots, |D| - 1]$. These integers are then used as keys/values in the actual jump-functions table. The sizes of the intermediate maps are negligible compared to the size of the jump-functions table. We reasonably assume that both N and D do not grow larger than $2^{32} - 1$, since these domains are bound by the size of the input program. For the JF_N (and JF_{NE}) approach, the intermediate layer enables one more optimization: The outer map can be replaced by a plain array to further reduce the memory footprint and to improve lookup performance.

⁶ Open-addressing hash tables store all buckets in a contiguous block of memory, using probing for collision resolution.

Since the inner maps are very small in many cases, we chose to use `llvm::SmallDenseMap<K,V,4>` for the inner maps to optimize for the case in which these maps do not exceed a capacity of 4. This optimization is critical, especially for JF_{ND} and JF_{old} , because they store a large number of small inner maps, where their sizes mostly do not exceed the initial capacity (48 entries) of a regular `llvm::DenseMap`. Independent from the selected jump-functions representation, the corresponding outer hash map is pre-allocated with a reasonable size that scales linearly with the size of the input program. Together with the small-size optimization, this pre-allocation reduces the total number of potentially expensive (re-)allocations.

Our implementation is openly available in the supplementary material of this paper and we are already in contact with the maintainers of PhASAR for rapid integration into the open source framework.

6 Empirical Study

To empirically evaluate the optimizations proposed in Section 4, we use our IDE implementation (see Section 5) to analyze 31 real-world C/C++ programs. We start with defining our research questions.

6.1 Research Questions

Jump-Functions Table Structure

In Subsection 4.1, we have argued that the structure of the jump-functions table directly influences the performance of the analysis, especially regarding memory consumption. Hence, we ask:

RQ₁ | *What is the influence of choosing one of the proposed data structures, JF_{ND} , JF_N , and JF_{NE} , in terms of runtime and memory consumption when analyzing real-world C/C++ programs?*

Jump-Functions Garbage Collection

Arzt [1] has shown that a garbage collector for jump functions not only significantly reduces memory usage of the underlying analysis, but reduces runtime as well. As we have applied significant changes (cf. Subsection 4.2) to the garbage collection by extending it to general IDE problems and mitigating its restriction to multi-threaded analyses, we ask:

RQ₂ | *How effective is the jump functions garbage collector in reducing memory usage and running time when analyzing real-world C/C++ applications without the restrictions to a subset of IDE and a multi-threaded implementation?*

6.2 Experiment Setup

To ensure that our experiments are easily reproducible and comprehensible, we detail on our setup in the following. In Subsubsection 6.2.1, we define what kind of analyses we consider during the evaluation, and in Subsubsection 6.2.3 we present how we perform our measurements as well as the required actions to answer the research questions.

6.2.1 Analysis Problems

To test our solver implementation, we choose to evaluate it using three commonly used analysis problems that put a different amount of load to the solver:

- **TSA:** *Typestate analysis*, configured to find invalid usage patterns of `libc`'s file-IO API
- **LCA:** *Linear constant analysis*
- **IIA:** *Instruction-interaction analysis*, to generate git-blame reports [21].

These analysis problems are available within PhASAR, and we use them unchanged. The *typestate analysis* is expected to put low load on the solver as many programs use `libc`'s file-IO only in few small regions of their code. The *linear constant analysis* should put medium load on the solver, as it needs to propagate all potentially constant integer values; however, the implementation in PhASAR currently is not alias aware, so the load on the solver is still less than for the instruction-interaction analysis, which propagates all potential aliases of the generated data-flow facts. Finally, the *instruction-interaction analysis* puts an extreme load on the solver as it needs to exhaustively track *all* of the target program's variables and capture their interactions with the program's instructions [21]. This way, the size of the data-flow domain D approaches $|N|$ allowing us to approximate the worst-case scenario for field-insensitive analyses.

6.2.2 Target Programs

To ensure that our evaluation results reflect real-world analysis usage as closely as possible, we carefully select the set of 31 target programs shown in Table 1. We select the target programs out of 12 different domains to achieve broad coverage. Further, we choose the target programs in various sizes in the range from 1 676 to 849 623 lines of code in LLVM IR to test the IDE solver with different loads. The target programs have varying properties, such as the number of procedures (66 to 35 134), the number of address-taken functions (0 to 2 696), the number of globals (113 to 15 108), the number of call-sites (314 to 176 350), the number of indirect call-sites (0 to 2 155), and the number of basic-blocks (266 to 111 521).

We include the benchmarked programs from the initial PhASAR paper [22] excluding PhASAR itself, because it has grown significantly since 2019, such that expensive analyses, e.g., the IIA, do not work on that large programs anymore. Still, our evaluation results cannot be compared to the results from Schubert et al. [22], since we use different client analysis problems; the taint analysis used by Schubert et al. is of less interest for our work, since it does not require IDE to be solved efficiently. We also include programs from the evaluation of Sattler et al. [21] as they explicitly report performance problems of PhASAR's IDE solver on their benchmark. In contrast to the PhASAR benchmark, the time and memory results for the programs analyzed by Sattler et al. can be compared to our evaluation results, because the implementation and configuration of the IIA has not changed.

6.2.3 Measurement Setup

Each individual experiment is performed separately for each analysis problem. As analysis targets we use 31 real-world C/C++ programs, which we compile to LLVM 14 IR using WLLVM⁷, so that PhASAR's analyses can consume them. To reduce measurement bias, we run each experiment (solver configuration \times analysis problem \times analysis target) three times and report average values. To validate that our experiments indeed show low variance, we compute the standard deviation of the runtime measurements of the three repetitions. We observe an average standard deviation of 2.2s to 8.3s depending on the jump-functions representation. Normalizing that by the total runtime, the average standard deviation lays

⁷ WLLVM: <https://github.com/travitch/whole-program-llvm>

between 0.99% and 1.5% of the measured runtime. As we expect running times in the area of hours instead of seconds, the impact of measurement bias, as well as the variance between repetition is expected to be negligible and therefore, we consider the relative small number of repetitions $k = 3$ as sufficient to achieve reliable results.

We use the UNIX `time` utility to measure the total runtime and peak memory usage for all experiments. We compute speedups for runtime and memory consumption (maximum resident set size) by comparing the statistics of the to-be-evaluated configuration of the **IDESolver++** to the statistics of the respective baseline. Given runtime measurement samples $M_N = \{m_{n_1}, \dots, m_{n_k}\}$ and baseline-measurements $M_B = \{m_{b_1}, \dots, m_{b_k}\}$ with the number of samples $k = 3$, the speedup is defined as

$$S = \frac{1}{k^2} \sum_{(m_n, m_b) \in (M_N \times M_B)} \frac{m_b}{m_n}$$

For memory measurements, we use the inverse $\frac{1}{S}$ of the above formula to compute the relative memory usage in percent. We compare each combination of m_n and m_b , as these samples are unordered. This prevents potential biases due to sample ordering. Note that in contrast to Arzt [1] we can make use of the external tool `time` for measuring memory consumption, because our experiments do not run in the JVM that makes external memory measurements unreliable.

We conducted our evaluation on a compute cluster in an isolated and controlled environment to ensure that our measurements are not influenced by external factors. Each compute node is equipped with an AMD EPYC 72F3 8-Core processor and 250GiB of RAM, running a minimal Debian 10.

In addition, to increase the reproducibility of our results, we automate the evaluation process with the VaRA Tool-Suite⁸.

Baseline. We also evaluate the existing state-of-the-art **IDESolver** that is openly available in PhASAR as shown in Section 3. As a baseline for our further experiments, we use the **IDESolver++** with the deeply nested jump-functions representation JF_{old} , which the **IDESolver** uses as well. In addition, we compare the both solvers in terms of runtime and memory consumption to assess the influence of our implementation in comparison with the current state-of-the art, when *not* applying the optimizations proposed in Section 4. Note that we do not implement the multi-index table for storing jump functions since the **IDESolver++** does not need it, as discussed in Subsubsection 4.1.2. To achieve a fair comparison, we need to configure the **IDESolver**. We set the configuration option `recordEdges` to `false` to avoid storing the ESG edges in a path sensitive way. We record runtime and memory usage, as well as out-of-memory (OOM) and timeout events of both solvers, providing a baseline to compare against in the evaluations of our research questions.

RQ₁. We evaluate four configurations of our **IDESolver++**, one using JF_{ND} , JF_N , JF_{NE} , and JF_{old} as jump-functions table respectively. JF_{old} serves as a baseline for the others. To judge which jump-functions table structure performs best on our target programs, we compute the speedups compared to the baseline and consider the configuration with the highest speedup as best. To verify whether the best configuration is *significantly* best, we perform a *t*-test with significance level $\alpha = 0.05$. The garbage collector is turned off.

⁸ VaRA Tool-Suite: <https://vara.readthedocs.io/en/vara-dev/>

RQ₂. We configure the **IDESolver++** as follows: turning the GC on or off and using JF_{ND} or JF_N . The **IDESolver++** with GC turned off is used as baseline. We exclude JF_{NE} here, because it stores the jump functions in exactly the same way as JF_N , just with one additional table that only contains jump functions which cannot be evicted by the GC at all. So, in total, we have four configurations for this experiment. For the typestate analysis all state transition instructions are considered *interesting*, whereas for the linear constant analysis, all branch conditions are considered *interesting*, which is useful when eliminating dead code, for example. All jump functions at those interesting instructions are ignored by the garbage collector. We exclude the instruction-interaction analysis for RQ_2 as its post-processing needs the results at all instructions [21] rendering the garbage collection useless. To examine the influence of the jump functions garbage collector on the analysis, we compute the speedups of the **IDESolver++** compared to its corresponding versions without GC. We consider the configuration with the highest speedup to perform best.

6.3 Results

We have conducted our experiments on the 31 real-world C/C++ programs listed in Table 1. Although we have already argued on the correctness of our optimizations, we ran an additional, non-measured analysis batch to confirm that the new **IDESolver++** indeed computes the same results as the **IDESolver**. In what follows, we detail on the results of our experiments and answer the before defined research questions.

6.3.1 Baseline

Our evaluation of the baseline shows that in almost all measured configurations the **IDESolver++** is faster and consumes less memory than the **IDESolver**. We measured runtime speedups ranging from $1.16\times$ to $7.2\times$ on average and memory savings from $0.96\times$ to $4.8\times$ compared to the **IDESolver** as shown in Table 3. Due to the variance, the benefits of using our **IDESolver++** may be program dependent. Note that sometimes the **IDESolver++** consumes more memory in the typestate analysis than the **IDESolver**. This is because the **IDESolver++** allocates large buffers in advance to lower the number of re-allocations (cf. Section 5); in addition, the typestate analysis is very sparse; it propagates only a very small number of data-flow facts and therefore does not fill out the pre-allocated buffers which we do not consider as a problem since the total memory usage is negligible.

In contrast to the **IDESolver**, the **IDESolver++** ran out-of-memory very rarely, as is apparent in Figure 4. However, the figure also shows that the number of timeouts is higher for the **IDESolver++** than for the **IDESolver**. That is because analyses that ran out-of-memory in the **IDESolver** were able to run long enough to exceed the given time budget in the **IDESolver++**. All of the experiments that completed with the **IDESolver** were also completed with the **IDESolver++**, showing that the performance does not degrade. In fact, out of the 7 experiments that exceeded the time limit of four hours, three were solved in time with the new solver; out of the five experiments that ran out of memory, one can now be completed within the memory limit of 250GiB. Furthermore, all 7 experiments that required up to 143GiB of RAM can now be solved on an consumer hardware with only 32GiB RAM.

There are several aspects that contribute to the improvements in this baseline experiment. The most notable ones are: The elision of the multi-index storage for jump functions (see Section 4.1.2), the batch-processing (see Algorithm 1) of data-flow fact propagations, and the switch from the `std::unordered_map` to `l1vm::SmallDenseMap` (see Section 5).

Table 3 The average speedups/memory savings of the IDESolver++ with JF_{old} compared to PhASAR’s IDESolver together with their standard deviations

Analysis	Memory	Runtime
IIA	4.811 ± 1.192	7.227 ± 2.042
LCA	1.729 ± 0.365	4.683 ± 2.150
Typestate	0.968 ± 0.050	1.162 ± 0.143

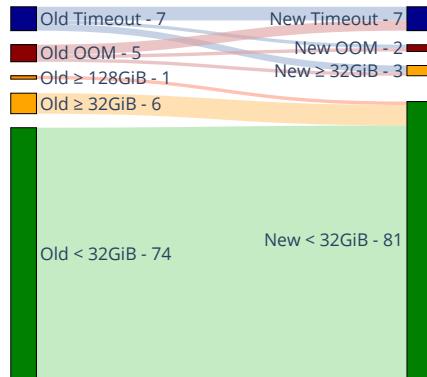

Figure 4 A sankey-plot showing how the number of (target program × analysis type) that finish with out-of-memory (OOM), timeout, or completed changes when switching from PhASAR’s IDESolver (Old) to our IDESolver++ (New) with JF_{old} keeping the time-limit of four hours and the memory limit of 250GiB.

Table 4 Results of our per-analysis comparison between the jump-function representations within our IDESolver++. We report the mean speedup and its standard deviation for both runtime and memory. Cells highlighted with green background indicate the JF with highest runtime speedup or memory savings for that analysis. In case, the highest speedup is <1 or the difference to the other jump-functions representations is not significant, we omit the highlight.

	JF1		JF2		JF3	
	Memory	Runtime	Memory	Runtime	Memory	Runtime
IIA	1.270 ± 0.231	0.927 ± 0.059	1.382 ± 0.230	0.949 ± 0.071	1.371 ± 0.221	0.957 ± 0.096
LCA	1.126 ± 0.097	0.939 ± 0.102	1.406 ± 0.267	1.064 ± 0.061	1.400 ± 0.261	1.063 ± 0.061
Typestate	1.059 ± 0.053	0.996 ± 0.023	1.057 ± 0.042	1.013 ± 0.035	1.057 ± 0.042	1.005 ± 0.022

Hence, we can already conclude that based on the high speedups for both runtime and memory as well as avoiding out-of-memory events, it is crucial to implement IDE in a performance-oriented way and just changing the implementation of the same underlying IDE algorithm can enable analyses that were not feasible before.

6.3.2 RQ₁: Jump-Functions Table Structure

We evaluated all three data structures JF_{ND}, JF_N, and JF_{NE}. We found that they behave differently depending on the target program and analysis. As expected, the instruction-interaction analysis puts a high load onto the solver, whereas the typestate analysis is very sparse and therefore completes within seconds.

Figure 5 shows both the runtime speedups and the memory savings of the different jump-functions representations compared to the deeply nested jump-functions representation JF_{old}. Both the runtime speedups and memory savings differ depending on the client analysis and have high variance over the target programs. In the (left) runtime speedup plot we can

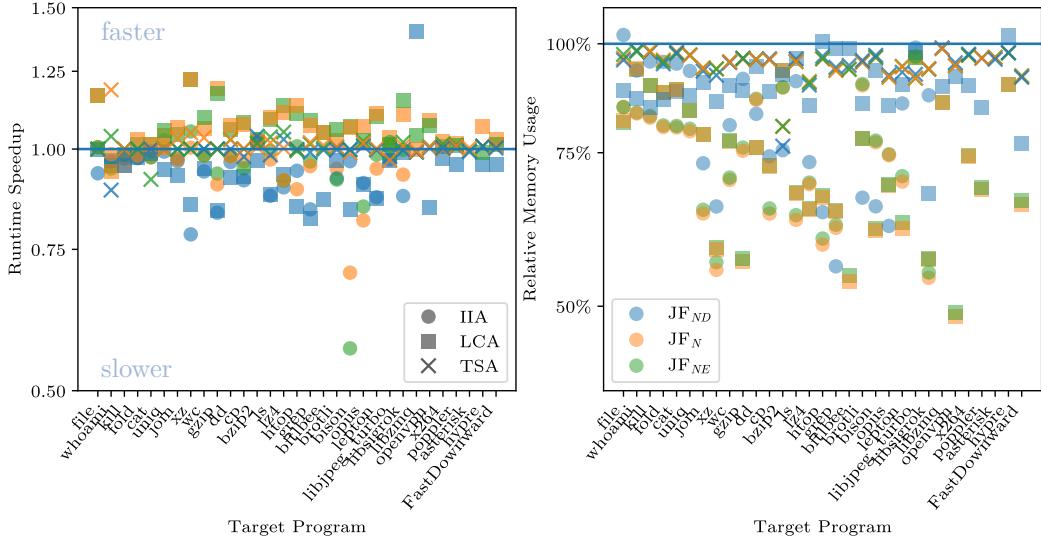

Figure 5 Scatter plots showing the IDESolver++ with the proposed jump-functions representations compared to the IDESolver++ using the nested representation inherited from PhASAR’s current IDESolver. The left plot shows the runtime speedup (higher is better), whereas the right plot shows the relative memory usage (smaller is better). The target programs are sorted in ascending order based on their number of LLVM-IR instructions. The IDESolver++ was configured to use JF_{ND} (blue), JF_N (orange), and JF_{NE} (green). The both horizontal lines are set at 1 meaning no speedup. We use a log-scale to account for the non-linear distribution of speedups.

see that the speedups of the analyses are approximately centered around 1 with a small advantage of JF_N and JF_{NE} over JF_{ND} for the LCA. In the (right) relative memory usage plot, it becomes visible that the IIA and LCA consume less memory with any of the proposed jump-functions representations than with JF_{old}. However, the variance across the analyzed target programs is high. For the TSA, the relative memory consumption is close to 94% for all jump-functions representations. The target programs in the plots of Figure 5 are sorted in ascending order by their number of LLVM-IR instructions. We provide variants of these plots with different program orderings on our supplementary website (see visualizations). Still, the orderings did not show observable correlations between the speedups and any of the tested program characteristics.

So, there is no clear overall “best” jump-functions table structure, and project- and analysis specific tradeoffs have to be made. However, by taking an analysis-centric view, we can determine the “best” jump-functions representation per analysis as shown in Table 4. For the IIA, JF_N has highest average memory improvement with 1.382×(consuming 72% of the memory from JF_{old}), but the significance test shows that the difference to JF_{ND} and JF_{NE} is not significant, so in terms of memory, they share the first place. In terms of running time, JF_{old} performed significantly best. For the LCA, JF_N is best in terms of both runtime and memory improvements, consuming only 71% of the memory from JF_{old} while being 6.4% faster; the difference to JF_{NE} is not significant, so we consider both JF_N and JF_{NE} best for the LCA. While for memory improvement, JF_{ND} is with using 97% of the memory slightly, but significantly better than JF_{old}, for runtime speedup, the difference between JF_{ND} and JF_{old} is insignificant. Finally, for the typestate analysis, the jump-functions representations performed similarly; yet the memory improvement of JF_{ND}, JF_N, and JF_{NE} over JF_{old} is significant, consuming around 94% of the memory from JF_{old}.

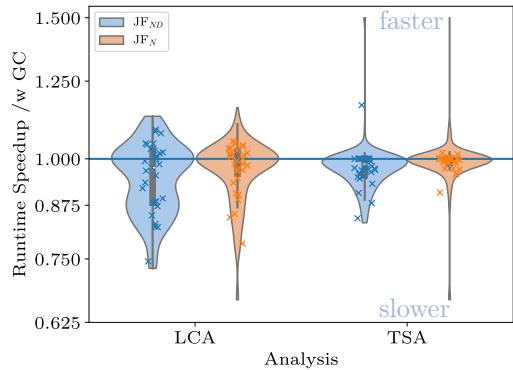

Figure 6a. A violin plot showing the runtime speedups of the IDESolver++ with garbage collection compared to their versions without GC. The solver was configured to use JF_{ND} (blue) and JF_N (orange). Note, that the y-axis is in log-scale to account for the non-linear distribution of speedups < 1 (slowdowns).

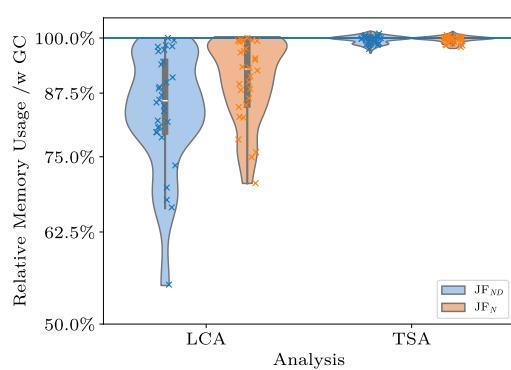

Figure 6b. A violin plot showing the relative memory usage of the IDESolver++ with GC compared to its versions without GC. The solver was configured to use JF_{ND} (blue) and JF_N (orange). We use a log-scale for the relative memory usages here.

■ **Figure 6** Violin plots showing the impact of enabling garbage collection on runtime and memory usage of the IDESolver++.

To answer *RQ₁*: The performance of the jump-functions representations highly depends on the performed analysis. However, JF_N and JF_{NE} have shown significantly best memory usage for the LCA and perform well for the IIA and TSA; this makes them a generally reasonable default choice. We also conclude that picking the right data structure oftentimes is *no* tradeoff between runtime speedup and memory savings; the same data structure can improve runtime and memory usage at the same time.

6.3.3 RQ₂: Jump-Functions Garbage Collection

The results of evaluating the jump functions garbage collector with JF_N are shown in Figure 6a and Figure 6b. For the LCA we see memory savings, where the analysis consumed, on average, 12% less memory ($\pm 10\%$). Furthermore, Figure 6b shows higher memory savings with JF_{ND} than with JF_N . For the TSA, the analysis with GC saved around 0.4% memory, which is significant, but we consider it negligible in most cases. This is expected because the TSA is very sparse and therefore does not have much to erase during garbage collection. Some analysis runs consumed even more memory than with disabled garbage collection. This is because of the additional book keeping meta-data that the garbage collector requires. In summary, the generalization to IDE indeed makes the GC less effective, but still it can drastically reduce the memory footprint of IDE analyses.

As expected, enabling jump functions garbage collection has non-negligible runtime-performance impact. The reason for this is that – in contrast to the experiments of Arzt [1] – the GC runs in the same thread as the analysis and therefore blocks the analysis process while performing the garbage collection. However, the mean speedup is close to 1 with 96.6% ($\pm 8.6\%$) for LCA and 98.3% ($\pm 6.3\%$) for TSA. Hence, the average runtime cost is still low.

Enabling the GC in single-threaded mode is a tradeoff between runtime and memory, as the GC reduces the memory consumption of IDE at the cost of increased runtime.

To answer *RQ₂*: Constraining the jump functions garbage collector to work in a single-threaded scenario results in a reduction of the memory consumption of the linear constant analysis of 12%, with only minimal runtime overhead. However, the effectiveness of the GC compared to the original GC from Arzt [1] is reduced, making it impractical for smaller analyses, and for those that do not propagate many data-flow facts.

6.4 Threads to Validity

Internal Validity

Runtime measurement on modern computing systems is a challenging task due to automatic clock boost and throttling as well as context switches enforced by the operating system. This makes reliable runtime measurements hard. We therefore ran our experiments three times and report averages to compensate for this noise. In addition, we ran each experiment in isolation on equivalent machines, ensuring that no other task is running in parallel. Our experiments each utilize only one thread to minimize the influence of the OS scheduler on the measurements.

We evaluated our experiments on a fixed set of target programs, on which we verified that the **IDESolver++** produces the same results as the **IDESolver**. We cannot rule out that there are programs where the solvers produce different results because of bugs in the implementations of either of them. To mitigate this risk, we performed our evaluation on a large set of real-world programs and configured the IDE solvers with three different client analysis problems.

External Validity

The performance of the analysis solvers may be different depending on the target program, that is, there may be programs that we did not benchmark where the analysis solvers behave differently. To mitigate this threat, we selected a diverse set of target programs from various domains and with different sizes and complexities. Furthermore, we configured the analysis solvers with three differently complex analysis problems to have greatest possible variation. This gives us for the first time a comprehensive study on a substantial number of real-world C/C++ programs.

6.5 Discussion

In Section 6, we presented the results of our evaluation, some of them require interpretation.

We have observed that JF_N in many cases has a lower memory consumption than JF_{ND} . This can be explained by the distribution of jump functions: For many analyses an extra experiment run with statistics instrumentation shows that the average size of the inner maps in JF_{ND} is < 4 , but still with a high number of total jump functions. Hence, JF_{ND} pays the memory overhead of a hash map for the majority of jump functions, whereas JF_N and JF_{NE} oftentimes store more than 1000 elements in their inner maps which can lead to more efficient use of the provided memory.

On the other hand, depending on the access patterns of the jump-functions table, JF_{ND} can lead to faster jump functions access. For the IIA, we see drastic performance benefits of JF_{ND} and JF_{old} compared to JF_N and JF_{NE} when analyzing BISON. This can be explained by the handling of aliasing in the IIA. All aliases of a data-flow fact are propagated individually

in the IIA. Therefore, for memory-indirection statements, such as `store a to b`, for all aliases of the stored pointer a all aliases of the target pointer b must be generated, which are independent from each other. This leads to the same jump functions to be accessed multiple times, which may be faster if the inner maps do not incur memory indirections because they are small enough for small-size optimization.

Combining the measurements from our baseline (cf. Figure 3) with our specific optimizations from Section 4, we achieve the following overall mean speedups in the IDESolver++ compared to PhASAR’s current IDESolver: Memory improvements of $6.9\times$ for IIA, and $2.7\times$ for LCA; runtime speedups of $6.9\times$ for IIA, and $4.9\times$ for LCA. For the typestate analysis, there is no overall mean speedup, but also no mean slowdown.

7 Related Work

Performance problems of IDE implementations are a known issue. He et al. [9] perform sparsification on the ESG by propagating data-flow facts not along ICFG edges, but on their corresponding def-use chains. Arzt and Bodden [3] automatically generate IDE summaries for libraries, which prevents re-analyzing commonly used libraries and lowers the size of the analyzed target programs. Arzt and Bodden [2] improve re-analysis of already analyzed programs by incrementally analyzing only the changes compared to the previously analyzed version. These approaches let any existing implementation of IDE scale better in the circumstances that they optimize. Nonetheless, they can still further profit from an improved solver that scales better in the first place.

Weiss et al. [29] use a database system to store their internal data structures partially on disk effectively increasing the amount of available memory. However, they focus on the specific problem of error-code propagation and do not generalize to arbitrary IDE analyses. Hsu et al. [10] propose a modified IFDS algorithm that no longer needs to store the ESG explicitly and computes the reachability based on Depth-First Tree Intervals instead. While this approach works well for IFDS problems, it cannot be applied to IDE problems directly as composing edge functions requires to store the jump functions in some way.

He et al. [8] improve the garbage collection presented by Arzt [1] by increasing the GC’s granularity from method-level to data-flow fact level. However, it suffers from the same restrictions of required multi-threading and also only applies to the same subset of IDE as the original garbage collector [1] that we generalize in this paper.

Apart from IDE, there are other approaches to precise interprocedural static data-flow analysis, such as weighted pushdown systems (WPDS) [12, 18]. As WPDS has the same runtime- and memory complexities as IDE, similar optimizations as the ones presented in this paper may be possible for WPDS as well. Other approaches, such as Boomerang [25] reduce their resource requirements by conducting demand-driven analyses, only computing the data-flow information for specific program locations. While demand-driven analyses work well for pointer analysis where a client analysis requests the demand, exhaustive taint analyses, e.g., a use-after-free analysis would need to issue a demand for each potential sink statement effectively degenerating the demand-driven analysis to a whole-program analysis with similar performance issues.

Yu et al. [31] tackle the performance problem by bringing data-flow analysis to the GPU and optimizing the algorithm, as well as the data-layout for GPU processing. As the CPU and GPU are particularly different hardware components, optimizations for GPU programs usually do not apply to CPU programs, and vice versa.

8 Conclusion

Current state-of-the-art IDE implementations do not scale well to large programs preventing the analysis of many interesting data-flow problems that can be used for bug- and vulnerability detection, as well as other important fields in software engineering. Based on years of experience with implementing and using IDE-based program analyses, we identified two different optimizations of the IDE algorithm. We found that choosing an efficient representation for the jump-functions table structure within the solver implementation has great influence on the performance of the algorithm. Still, it requires further research to select the right data structure for an analysis, or to even automate this process. Yet, we learned that an implementation of IDE has to be designed with performance in mind from the beginning to achieve a scalable implementation. Furthermore, we extended the jump functions garbage collection from Arzt to general IDE problems and removed the restriction to a multi-threaded solver implementation. We evaluated that it still reduces the memory footprint of the IDE analyses, though being less effective than the original.

Our experiments on 31 real-world C/C++ programs show runtime and memory speedups of up to $7\times$ on average compared to the existing IDE implementation in PhASAR and enable the analysis of more target programs than before. We found that especially extremely heavy analyses such as the instruction interaction analysis presented by Sattler et al. [21] can now be run on medium-to large programs that was not possible previously, even with larger server hardware. Still, some analyses require too much memory for being executed on an ordinary developer machine.

Abstract

Analyzing the similarity of two code fragments has many applications, including code clone, vulnerability and plagiarism detection. Most existing approaches for similarity analysis work on source code. However, in scenarios like plagiarism detection, copyright violation detection or Software Bill of Materials creation source code is often not available and thus similarity analysis has to be performed on binary formats. Java bytecode is a binary format executable by the Java Virtual Machine and obtained from the compilation of Java source code. Performing similarity detection on bytecode is challenging because different compilers can compile the same source code to syntactically vastly different bytecode.

In this work we assess to what extent one can nonetheless enable similarity detection by *bytecode normalization*, a procedure to transform Java bytecode into a representation that is identical for the same original source code, irrespective of the Java compiler and Java version used during compilation. Our manual study revealed 16 *classes of compilation differences* that various compilation environments may induce. Based on these findings, we implemented bytecode normalization in a tool jNORM. It uses Jimple as intermediate representation, applies common code optimizations and transforms all classes of compilation difference to a normalized form, thus achieving a representation of the bytecode that is identical despite different compilation environments.

Our evaluation, performed on more than 300 popular Java projects, shows that solely the act of incrementing a compiler version may cause differences in 46% of all resulting bytecode files. By applying bytecode normalization, one can remove more than 99% of these differences, thus acting as a crucial enabler for subsequent applications of bytecode similarity analysis.

1 Introduction

In the past, researchers have developed many approaches for code similarity analysis on Java applications [50, 35, 52, 31, 60, 47]. These techniques target a wide variety of applications, like code clone detection, plagiarism detection, copyright infringement investigation, program comprehension, vulnerability detection and many more [49, 37]. Most developed techniques operate on source code. However, an application's source code is not always available, since applications are typically distributed in binary form. Especially in scenarios where external dependencies are included into a software product, often only the binary form is included without the corresponding source code. In case of Java, applications are distributed as JAR-archives that contain the *bytecode* of the application. Instead of compiling the source code directly to executable machine code, Java compilers generate an intermediate representation called *bytecode*, which is translated into machine code during execution time by the Just-in-time (JIT) compiler within the Java Virtual Machine (JVM). With the European Union's Cyber Resilience Act [11] coming into force soon and the US's Executive Order on Improving the Nation's Cybersecurity [6] already being effective, the creation of Software Bill of Materials (SBOM) has become mandatory. However, creating a faithful SBOM for Java applications is a difficult undertaking due to current tool's reliance on metadata [5, 13]. To reliably create such SBOMs an approach needs to be established that is able to find all used components based on the similarity of bytecode, since source code is generally not available.

There are only few approaches that have been developed for similarity analysis based on bytecode [4, 36, 58]. This may be due to the increased complexity when trying to compare bytecode instead of source code. As Dann et al. [12] and Kononenko et al. [38] have shown, the comparison of bytecode is more complex than the comparison of source code, since equal source code is compiled into different bytecode, depending on the compiler, version and configuration used. While the generated bytecode is semantically equivalent, its syntactic structure may vastly differ. To overcome this difficulty we investigate the utility of *bytecode normalization* to create a representation that is *independent* of the environment that has been used for compilation. This independent representation can subsequently be used by bytecode-based code clone, plagiarism or vulnerability detectors without the need for consideration of compilation environments, significantly simplifying their task. Our approach to achieve bytecode normalization, which builds upon Dann et al.'s approach [12], is a procedure that

1. translates the bytecode into Jimple, the primary intermediate representation of the Soot [55] bytecode optimization framework, which reduces the more than 200 available bytecode-instructions to only 15 different Jimple instructions,
2. as a baseline first applies common optimizations like constant propagation, dead code removal and unconditional branch folding to further reduce differences, and then specifically, and lastly
3. transforms *compilation differences* induced by different compilation environments.

We uncovered the set of compilation differences by systematically comparing bytecode of popular Java libraries generated by different vendors, versions and configurations of Oracle's Java Development Kit's (JDK) and OpenJDK's compiler (javac). During this initial study, we found a total of 16 classes of compilation differences.

We implemented bytecode normalization in a tool JNORM, and evaluated it on more than 300 of the most popular Java projects on GitHub by compiling the same source code within various compilation environments with different compiler vendors, versions and target levels. The evaluation shows that even a single increase of the compiler version may result in up to 46% of all generated bytecode files containing compilation differences. By applying JNORM's

bytecode normalization one can reduce these differences by more than 99%. Thus, bytecode normalization can function as an important enabler for bytecode similarity analysis in all cases in which source code is not available.

To summarize, this paper makes the following original contributions:

- It investigates the usage of different Java compilers and settings in real-world projects.
- It presents a comprehensive set of 16 classes of compilation differences that are induced when using different vendors, versions or target level configurations of the JDK's and OpenJDK's Java compiler.
- It presents an approach to bytecode normalization, implemented in a tool `JNORM`, to virtually completely remove the differences introduced by compiling the same source code within different compilation environments.
- It evaluates `JNORM` on a large set of real-world Java applications collected from GitHub.

The remainder of this paper is structured as following. Section 2 introduces terms and concepts related to similarity analysis, Java compilation and normalization. Afterwards, Section 3 presents the concept of Java bytecode normalization implemented in `JNORM` and an overview of the uncovered compilation difference classes. Section 4 presents an evaluation of `JNORM` on a set of real-world Java projects. Related work is presented in Section 5. We discuss possible threats to validity in Section 6 and conclude in Section 7.

`JNORM`, its source code, more detailed evaluation results and a study on the usage of Java compilers and target levels are publicly available at:

<https://doi.org/10.5281/zenodo.12625104>

2 Background

This section introduces concepts that are related to code similarity analysis and the compilation of Java applications.

2.1 Code Similarity Analysis

Code similarity analysis is a technique that seeks to determine the similarity of two or more code fragments. The calculation of the similarity of code fragments has a large number of uses, like code clone, plagiarism, licensing violation, malware or vulnerability detection [49, 37].

Depending on the desired application area different techniques are employed. Text- [50, 4] or token-based [35, 52] techniques try to find similarities within the textual information of the code fragments. Tree-based techniques [31] try to additionally leverage syntactic information of the code for the similarity analysis. Some techniques even try to find semantic similarities within code fragments [39]. These techniques are typically graph-based and offer low potential for scalability [49]. Recently machine learning based approaches [60, 51], which typically train a classifier that decides how similar code fragments are, have become popular. In terms of efficiency and scalability, text- and token-based techniques, which can solely focus on syntactic features, are much preferred.

Typically the similarity analysis is performed on a source code level. However, the source code of a compiled binary is not always available or trustworthy. In such scenarios, e.g. plagiarism detection or SBOM generation, the similarity analysis has to be performed on the binary itself. However, the resulting binary code is highly dependent on the environment it has been compiled in, i.e. different compiler versions or settings produce different code, even when compiling the same source code [12]. This characteristic makes binary similarity analysis a much more complex task.

2.2 Java compilers

In contrast to other compiled programming languages like C or Go, Java applications are not directly compiled into machine-executable code, but into Java *bytecode*. This bytecode is executed by the Java virtual machine (JVM), which comes with a just-in-time (JIT) compiler that compiles the bytecode into executable machine code at runtime. Because of this, the Java bytecode has the following characteristics:

1. **Platform independence:** The JVM architecture aims at platform independence. The generated bytecode is independent from the platform it is intended to run on [46].
2. **Unoptimized bytecode:** Optimizations are performed during runtime by the JIT compiler, therefore compiled bytecode is typically not optimized [24].

Because of these characteristics, the amount of variance across generated bytecode is not as high, when compared to machine-code, since there are no different optimization levels or differences due to the targeted platform.

There exist multiple different Java compilers like e.g. Oracle’s JDK or OpenJDK’s compiler [45], Eclipse’s JDT core compiler [28], IBM’s Jikes compiler [32], or the GNU Compiler for Java (GCJ) [19]. The JDK’s and OpenJDK’s compilers can be invoked programmatically or through the command-line application *javac* that comes pre-shipped with each JDK. Given the same source code as input, in many cases these compilers produce *different* Java bytecode.

In general, Java compilers support source codes that adhere to different versions of the language specification and can generate bytecode for different JVM versions lower than the compiler’s version. This backwards compatibility can be used by setting the compiler’s *target level*. For example, bytecode compiled with a JDK11 compiler with target level set to 8 can be executed by a JVM only supporting up to Java 8. The set of available target levels for a compiler is usually limited to a subset of earlier versions.

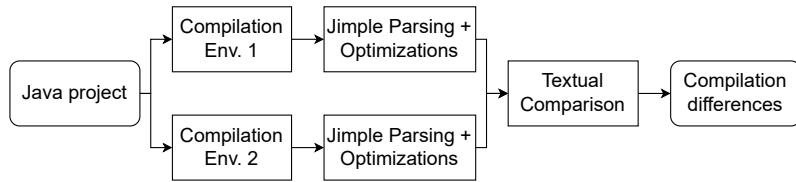

2.3 Jimple

Jimple is an intermediate representation (IR) of Java bytecode that was designed for providing a format that allows for simplified analysis, optimization and code transformations. Jimple maps the more than 200 Java bytecode instructions to only 15 different Jimple instructions in a *three-address* based representation. Three-address based representation means, that each instruction generally contains at most three different operands, e.g., one used for the left-hand side of an assignment and two used for binary operations on the right-hand side. This restriction greatly simplifies the processing of individual IR statements, which is why three-address IRs are nowadays commonplace. During the transformation Jimple retains all the type information present in the bytecode.

Jimple is the primary IR of the most popular Java bytecode optimization and analysis framework SOOT [55]. Alongside various code optimization options, SOOT provides an API to conveniently transform Jimple instructions. SOOT can automatically convert Java bytecode to Jimple (and vice-versa).

3 Java Bytecode Normalization

As we show next, Java bytecode normalization allows for the removal of differences in Java bytecode that are solely introduced by the usage of different compilation environments. In the following we describe how we detected the compilation differences in the first place, as well as the details of our bytecode normalization approach and its implementation in jNORM.

■ **Figure 1** Setup to determine compilation differences.

3.1 Investigation of Compilation Differences

Before the development of our bytecode normalization approach jNORM, we performed a study to investigate the differences induced by different compilation environments. Figure 1 shows the setup we used to determine compilation differences. For each comparison, we supplied the source code of various versions of the popular Java libraries Apache commons-io, Apache commons-lang, Jackson-databind, SLF4J and Google Guava, to two different environments for compilation. Afterwards, we converted the resulting bytecodes to Jimple and applied code optimizations, provided by the SOOT framework, to reduce dissimilarities. Finally, we performed a textual comparison on the optimized Jimple representations to determine the remaining compilation differences. Two files were considered different, and manually inspected by the authors, as soon as one character differed in the textual comparison.

Our compilation environments included the javac compilers shipped with JDKs 5–8, 11, and 17. Moreover, this version-range covers all Long-Term-Support (LTS) versions of the Java ecosystem until August 2023. A usage study of Java compilers and target levels in Java projects, which revealed these to be the by far most relevant compilers and versions, is available within an electronic appendix in our provided artifact.

We consider three types of parameters, JDK vendor, JDK version, and Java target level. We used Oracle’s JDK, as well as OpenJDKs distributed by Amazon Corretto and Eclipse Adoptium.

In total, our setup revealed 16 compilation difference classes, present in the investigated projects, which are listed in Tables 1a and 1b. Table 1a shows the difference classes produced by changing the JDK version, while Table 1b shows the difference classes produced when adjusting the Java target level. We did not find any vendor-related difference classes in our initial experiments.

Furthermore, we inspected the official JDK release notes [27] related to newly released compiler versions. However, this inspection did not reveal any so far uncovered difference classes. Our evaluation performed on more than 300 of the most popular Java projects (see Sections 4.3 and 4.4) also revealed no additional difference classes.

In the following we describe jNORM’s approach to bytecode normalization and how it transforms the identified compilation difference classes into a representation that is common across all investigated compilation environments.

3.2 Overview of jNorm

Figure 2 depicts an overview of jNORM. First, jNORM parses a Java bytecode file (.class file) into Jimple format, which is specifically designed for efficient optimizations and transformations. Note that jNORM also has the capability to process multiple bytecode files at once, and therefore full Java projects, but because each file is normalized independently of others we will explain bytecode normalization of single files. To reduce the initial set of differences for the following steps of the normalization process, jNORM applies different types of common

Table 1 Difference classes on JDK version and Target level change.

(a) JDK version change.

ID	JDK	Compilation Difference Class
N1	5 → 6 & 7 → 8	Synthetically generated methods
N2	5 → 6	Arithmetic
N3	6 → 7	CharSequence toString invocation
N4	7 → 8	Empty try-catch-finally block
N5	7 → 8	String constant concatenation
N6	8 → 11	Method reference operator
N7	8 → 11	Buffer method invocation
N8	8 → 11	Try-with-resources
N9	8 → 11	Duplicate checkcasts
N10	11 → 17	Enums

(b) Target level change.

ID	Target	Compilation Difference Class
N11	6 → 7	Outer class object creation
N12	8 → 11	Dynamic string concatenation
N13	8 → 11	Nest-based access control
N14	8 → 11	Invocation of private methods
N15	8 → 11	Inner class instantiation
N16	multiple ^a	Insertion or removal of typechecks

^a This compilation difference class occurs across multiple JDK and target level changes.

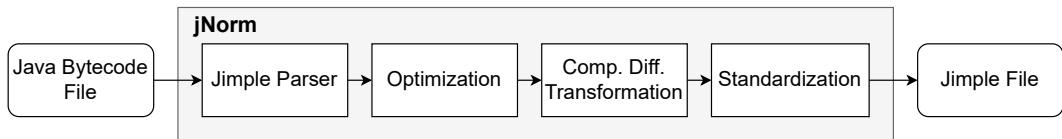

Figure 2 Overview of jNORM.

optimizations to the Jimple representation of the input bytecode file. Afterwards, in the Compilation Difference Transformation step (see Figure 2), jNORM handles the remaining set of compilation differences by performing certain transformations on the optimized Jimple representation. These transformations are targeted towards specific constructs that we found to be compiled differently based on the used compilation environment. jNORM detects these constructs within the target program and transforms them into a normalized representation. The applied transformations interfere with the naming scheme of local variables inside the target programs, which cause the introduction of new dissimilarities. jNORM handles these dissimilarities by standardizing (see Figure 2) the order and naming scheme of variables. After the normalization process is finished, jNORM outputs the normalized Jimple representation.

3.3 Jimple Parsing and Optimization

The first step of Java bytecode normalization consists of parsing the targeted bytecode file into a Jimple representation. This allows for a convenient application of common program optimizations provided by SOOT. We apply the following optimizations to each method [54]:

- **Copy Propagation:** Usages of variables in statements are replaced by their values, e.g. in a statement like `x = y + 3`, the reference to variable `y` is replaced by the value stored in `y`.
- **Constant Propagation and Folding:** Expressions that entirely consist of compile-time constants (e.g. `2 * 3`) are replaced by the constant result.
- **Dead Assignment Elimination:** Assignment statements to local variables, whose value is not subsequently used, are removed.
- **Conditional Branch Folding:** The expressions inside if-conditions are statically evaluated. If the expressions evaluate to constants, the unreachable conditional branch statements are removed.

- **Unconditional Branch Folding:** Unnecessary `goto` statements are removed.
 - **Unreachable Code Elimination:** Unreachable code is removed.
 - **Null Check Elimination:** Null-check statements, where the checked variable is known not to be null, are removed.
 - **Unused Local Elimination:** Unused local variables within a method are removed.
- These optimizations already contribute to a decrease of dissimilarities introduced during compilation [12]. However, after applying the optimizations, many important compilation differences still remain, which are targeted in the next step.

3.4 Compilation Difference Transformation

Through our investigation (see Section 3.1) we identified 16 compilation difference classes summarized in Tables 1a and 1b. In the following we describe the identified classes and the transformations applied by JNORM in detail.

The transformations that JNORM performs are not arbitrarily chosen. Each transformation produces a version that is generated by at least one compiler within our dataset. Furthermore, the decision whether to transform a compilation difference class to the older or the newer version is also not arbitrary. Typically one of the two versions contains more information than the other (e.g. a more specific return type in the newer version or the amount of string concatenation calls before their combination into a single call). As we cannot simply add information that is unavailable when only having access to the bytecode, we have to transform the difference class to the version that contains less information, therefore stripping some information from the generated bytecode. However, this information cannot be used for similarity analysis, since, based on the used compilation environment, it is not guaranteed to be present in the bytecode.

Note that we do not aim at generating an executable version of the bytecode with all semantics preserved, but at preserving information that is possibly important for a similarity analysis. Similarity analysis approaches that additionally require an executable version of the analyzed application, can use the original bytecode that has not been normalized, in addition to the normalized version.

N1: Synthetically generated methods

In many cases the JDK compiler synthetically generates methods into classes. Often this is used to generate bridge-methods that enable access to private members. Such synthetically generated methods are marked by the compiler with a specific `synthetic` flag [34]. Depending on the used JDK, these methods are not always generated in certain cases, e.g. whenever a method of a class uses a `Comparator` to create a specific ordering of objects, starting from JDK6 the compiler automatically generates a corresponding `sort` method into the class. Thus, such synthetic methods introduce differences and cannot be reliably used for a code comparison.

Transformation: JNORM removes such synthetic methods from the Jimple representation, as they cannot be modified within the source code anyway.

N2: Arithmetic

In some cases, integer subtractions are replaced with additions of negative numbers inside the bytecode produced by JDK6 and higher. A statement like `i1 = i1 - 5`, generated by JDK5, is replaced by a conversion of the positive number to a negative one (`i1 = (int) -5`) and a subsequent addition with the negative number like `i2 = i2 + i1`, by JDK6 and higher.

■ Listing 1 `toString()` invocation (Jimple)

```

1 java.lang.CharSequence r1;
2 java.lang.String r2;
3
4 // JDK6:
5 r2 = virtualinvoke r1.<java.lang.Object: java.lang.String toString()>();
6
7 // JDK7:
8 r2 = interfaceinvoke r1.<java.lang.CharSequence: java.lang.String toString()>();

```

Transformation: Whenever JNORM identifies an addition involving negative integers, it converts it into a subtraction.

N3: CharSequence `toString` invocation

The JDK7 compiler changed the way the `toString` method is handled in the bytecode when invoked on an object of type `CharSequence`. As it can be observed in Listing 1 (subtle differences are highlighted within the listings), the invoke type `interfaceinvoke` replaced `virtualinvoke`, and the more specific type `java.lang.CharSequence` replaced the method return type `java.lang.Object`.

Transformation: Whenever JNORM identifies a call to a `toString` method with a `java.lang.CharSequence` return type, it converts the method call to its previous, more generic, version.

N4: Empty try-catch-finally block

In most cases a try-catch-finally block comes with one or more catch blocks that react to some types of thrown exceptions. However, catch blocks can be empty or even missing completely. A try-catch-finally block with empty (or even missing) catch blocks is a syntactically valid Java construct, used to execute some instructions, no matter what happens in the try block. Prior to JDK8, the JDK compiler produces a redundant exception catching block¹ in the bytecode, if a catch block is empty or missing.

Transformation: If JNORM identifies such redundant exception catching blocks, it removes them from the Jimple representation of the bytecode.

N5: String constant concatenation

When using the JDK8 or higher compiler, string concatenation optimizations are introduced. Whenever multiple string constants are concatenated, compilers prior to JDK8 would use multiple calls to the `StringBuilder.append` method. A simple concatenation like

```
String helloWorld = "Hello " + "World!";
```

would result in two calls to the `StringBuilder.append` method, one receiving “Hello” and the other receiving “World!” as argument. However, as of JDK8, the compiler concatenates these two strings at compile time and produces a single call to `StringBuilder.append`. This holds true only for subsequent string constants: whenever a substring assigned to a variable is involved in the concatenation, multiple `StringBuilder.append` calls are used.

¹ In bytecode and Jimple there exists no notion of catch blocks. We use this terminology in synonym with exception traps.

■ **Listing 2** Method reference operator usage (Jimple)

```

1 org.apache.commons.io.IOFileFilter r0;
2
3 // JDK8:
4 virtualinvoke r0.<java.lang.Object: java.lang.Class getClass()>();
5
6 // JDK11:
7 staticinvoke <java.util.Objects:
8     java.lang.Object requireNonNull(java.lang.Object)>(r0);

```

■ **Listing 3** Buffer method invocation (Jimple)

```

1 java.nio.ByteBuffer r0;
2
3 // JDK8:
4 virtualinvoke r0.<java.nio.ByteBuffer: java.nio.Buffer flip()>();
5
6 // JDK11:
7 virtualinvoke r0.<java.nio.ByteBuffer: java.nio.ByteBuffer flip()>();

```

Transformation: When jNORM identifies subsequent calls to the `StringBuilder.append` method with string constants as arguments that are not referenced by variables, it combines them into a single call.

N6: Method reference operator

With the release of JDK8, the method reference operator (`::`) was introduced to the Java programming language. It allows one to refer to a method with the help of its declaring class or object name and is especially useful in combination with streams. Listing 2 shows how the operator usage is handled during compilation. Before performing the actual method call, if the operator is referring to a method of an object, a null check is performed at runtime. This is done to ensure that the object, the referred method belongs to, actually exists and is not `null`. The usual way to perform null checks in JDK8 and lower is to call the method `getClass` on the object to check. This mechanism was replaced in newer JDKs by invoking the static `requireNonNull` method.

Transformation: For normalization, jNORM transforms all occurrences back to the old null-checking mechanism.

N7: Buffer method invocation

Starting from JDK11, the return type of all subclasses of `java.nio.Buffer` was further specified. Instead of returning the type `java.nio.Buffer` (cf. Listing 3), newer JDKs further specify the return type. Listing 3 shows that methods of the class `java.nio.ByteBuffer`, compiled with JDK11, return `ByteBuffer` instead of `Buffer`. This holds true for every subclass of `java.nio.Buffer` and any method returning a `Buffer` object.

Transformation: When jNORM finds the invocation of a method of a `java.nio.Buffer` subclass with `Buffer` as return type, it transforms the return type to the more specific type.

N8: Try-with-resources

The try-with-resources statement allows to declare resources that are used within the statement, which are guaranteed to be closed at the end, no matter if an exception is thrown.

Whenever a try-with-resources statement is used in the source code, the JDK compiler produces multiple exception handlers that wrap each other in the bytecode, since the bytecode does not provide a separate instruction for such a statement. In some cases, prior to JDK11, these wrapped exception handlers are redundant, since they do not cover any application code but only automatically generated exception handling code. These redundant exception handlers are not created as of JDK11.

Transformation: Whenever jNORM identifies an exception handler that only covers automatically generated exception handling code, it removes the exception handler and its corresponding code from the declaring function.

N9: Duplicate checkcasts

Due to a bug [18] fixed in JDK11, earlier JDK compilers may insert the same `checkcast` instruction twice, one after the other.

Transformation: jNORM removes redundant typechecks for normalization, if it identifies such duplicates.

N10: Enums

Enums in Java are special types that can only take on certain predefined values. When an enum is created, the JDK compiler creates a separate class for each enum and defines the possible values inside the `clinit` function, which acts as a static initializer. In contrast to a constructor, which is called when an object of a class is initialized, the `clinit` function is called when the class itself is initialized. Prior to JDK17, the initialization of the possible enum values is performed directly inside the `clinit` method, while in JDK17 the definition is moved to its own function, which is called from `clinit`.

Transformation: If jNORM detects that the enum values are initialized within the `clinit` method, it moves the initializations into its separate method and calls this method from `clinit`.

N11: Outer class object creation

Changing the target level from Java 6 to Java 7 changes the generated bytecode, when an inner class creates an object of another sibling inner class within their shared outer class as shown in the following listing:

```
SiblingInnerClass sic = getOuterClass().new SiblingInnerClass();
```

In this case the method `getOuterClass` returns a reference to the outer class shared by both inner classes, the one that contains the above statement and the one that is created by the statement. Whenever this is the case, the compiler inserts a check to verify, that the method `getOuterClass` does not return `null`. This is done in the same way, as described for difference class N6, where the previous way of performing a null-check via the `getClass` method is replaced by a call to the `requireNonNull` method.

Transformation: jNORM transforms all occurrences back to the old null-checking mechanism, as it does for difference class N6.

■ Listing 4 String concatenation (Jimple)

```

1 int i0;
2 java.lang.StringBuilder $r0, $r1, $r2, $r3;
3 java.lang.String[] r5;
4
5 // Target Level 8:
6 $r0 = new java.lang.StringBuilder;
7 specialinvoke $r0.<StringBuilder: void <init>()>();
8 $r1 = virtualinvoke $r0.<StringBuilder:
9     StringBuilder append(java.lang.String)>("Amount: ");
10 $r2 = virtualinvoke $r1.<StringBuilder:
11     StringBuilder append(int)>(i0);
12 $r3 = virtualinvoke $r2.<StringBuilder:
13     StringBuilder append(java.lang.String)>(" Pieces");
14 virtualinvoke $r3.<StringBuilder: java.lang.String toString()>();
15
16 // Target Level 11:
17 dynamicinvoke "makeConcatWithConstants" <java.lang.String (int)>(i0)
18     <java.lang.invoke.StringConcatFactory:
19         java.lang.invoke.CallSite makeConcatWithConstants(
20             java.lang.invoke.MethodHandles$Lookup,
21             java.lang.String, java.lang.invoke.MethodType,
22             java.lang.String, java.lang.Object[]
23         )>("Amount: \u0001 Pieces");

```

N12: Dynamic string concatenation

In Java 11 and higher the old string concatenation approach of repeatedly calling the `StringBuilder.append` method (see N5), is replaced by a single `invokedynamic` instruction, which defers the resolution of a method call to runtime. This change was introduced to optimize the performance of string concatenations [25]. Listing 4 showcases the differences of string concatenation compiled for target levels 8 and 11. Previously, for each part of the string concatenation, one call of the `StringBuilder.append` method was required. However, in the new version, a dynamic approach that looks similar to template-based string building is generated. A single dynamic call of the `makeConcatWithConstants` method is performed, where string constants are concatenated into a single constant, while dynamic values are expressed by placeholders (see `\u0001` in line 23 in Listing 4) which are replaced by the resolved value during runtime.

Transformation: JNORM transforms the old string concatenation procedure into a template-based concatenation using `invokedynamic`.

N13: Nest-based access control

With the release of Java 11, a new concept for accessing members of inner classes, called nest-based access control [43], was introduced to the language specification. When inner classes are defined within a class, the JDK compiler compiles each inner class into its own file. The JVM treats each class as a separate entity and therefore disallows access to private members from methods outside of the class. However, the Java language specification *does* allow such access to private members of inner classes if they are originating *from the outer class* and vice versa. Prior to the release of Java 11, such access was handled by the compiler generating public bridge methods in the inner class for each private member, that the outer class can use to circumvent calling a private method. Starting from Java version 11, this

indirect access via generated bridge methods is not necessary anymore. A new property has been introduced that marks inner classes as *nestmates* of their outer class, which tells the JVM that access to private members is explicitly allowed between the marked classes. The JVM then automatically puts appropriate access-control checks into place. This change was introduced due to transparency, simplicity and security reasons.

Transformation: If jNORM finds classes that use bridge-methods to access private members of their respective inner classes, it transforms them to the nest-based access pattern created when specifying target level 11.

N14: Invocation of private methods

On top of adding nest-based access control, Java 11 comes with a new way to invoke private methods, even within the same class. Prior to Java 11, all private methods were invoked via the `invokespecial` instruction. With Java 11, to be consistent with the rules of the nest-based access control specification, certain private-method invocations were changed to use `invokevirtual` instructions [43].

Transformation: jNORM transforms private method invocations to use `invokevirtual` instead of `invokespecial`.

N15: Inner class instantiation

Going from Java 8 to Java 11, the instantiation of inner classes was changed. In some cases, in Java 8 and earlier, when an inner class is instantiated within the outer class, the JDK compiler generates an additional anonymous class that is empty. This behavior serves no apparent purpose and was removed in Java 11.

Transformation: If jNORM finds empty anonymous classes, it removes them.

N16: Insertion or removal of typechecks (aggressive transformation)

To check the type of an object, the bytecode instruction `checkcast` is used. Among other things, it is used when the developer performs a typecast on an object, so that the JVM can verify whether the specified type is suitable for the object. However, when changing the JDK version or target level, the compiler's behavior regarding typechecks changes. In contrast to the other compilation difference classes, this difference class cannot be isolated to a single version change, as it happens to different extents at various JDK version or target level changes. In some cases the compiler inserts `checkcast` instructions even though the developer did not write a typecast, or it does not place a `checkcast` instruction for typecasts placed by the developer. Whether the compiler places a `checkcast` instruction or not often depends on the used compilation environment.

Transformation: By default jNORM does not transform such typechecks, as we were not able to detect a pattern that indicates whether a typecheck should be removed or inserted, by just having access to the bytecode. Still, jNORM offers an *aggressive normalization mode* where it removes all `checkcast` instructions from the normalized Jimple representation of the bytecode. Such transformation removes information that can be used for similarity analysis and possibly changes the application's semantics rather than just adopting a format produced in a different compilation environment. In some cases, e.g. when the change between two bytecode fragments only consists of typecheck insertions or removals, this loss of information makes the normalized fragments indistinguishable.

<pre> 1 i1 = i1 - 1; 2 i2 = i1 + 10; 3 i3 = i2 + 10; </pre>	<pre> 1 i1 = (int) -1; 2 i2 = i1 + i1; 3 i3 = i2 + 10; </pre>	<pre> 1 i1 = i1 - 1; 2 i3 = i1 + 10; </pre>
(a) JDK5 (not normalized)	(b) JDK6 (not normalized)	(c) JDK6 (normalized)

Figure 3 Application of standardization (Jimple).

We leave a more thorough investigation of the patterns that indicate typecheck placements in the bytecode as future work.

3.5 Standardization

Since the names of local variables are removed by default after compiling Java source code into bytecode (bytecode uses an operand stack instead of local variables), all local variables within the Jimple representation are named by concatenating their inferred type with an ascending integer number. After applying transformations that create, remove, or reorder local variables, such as the Arithmetic or Try-with-resources transformations, the ordering of local variable definitions and their naming scheme might become inconsistent. Because of this, we remove unused local variables and reorder definitions of used local variables based on their usage order, which stays consistent during all optimizations and transformations. Afterwards, we rename the local variables based on their types and usage order. This ensures a standardized naming scheme across all methods, even after applying transformations.

Figure 3 shows why standardization is necessary in some cases. Listing 3a shows subtraction generated by the JDK5 compiler, while Listing 3b shows subtraction output by the JDK6 compiler. After applying normalization to the code fragment in Listing 3b (see N2: Arithmetic), we obtain the code shown in Listing 3c. Since we removed the intermediate variable `i2`, the logical naming following the variable deletion does not match up anymore to the version that did not require any normalization. Therefore we need to apply standardization and rename every following variable usage, to achieve a representation that is equal to the code fragment that did not require normalization.

4 Evaluation

In the following we evaluate JNORM’s normalization performance. To do so, we answer the following research questions.

RQ1: Does the JDK vendor influence the bytecode generation?

RQ2: How does JNORM perform on changing JDK versions?

RQ3: How does JNORM perform on changing Java target levels?

RQ4: To which degree can bytecode normalization support similarity analysis tools?

RQ5: How prevalent are the individual compilation difference transformations of JNORM?

The first three research questions focus on JNORM’s normalization performance within different compilation environments. Research question 4 investigates to which extent JNORM can support similarity analysis tools. The final research question gives an overview about the most common compilation difference classes. We used similar experimental setups for each of the research questions.

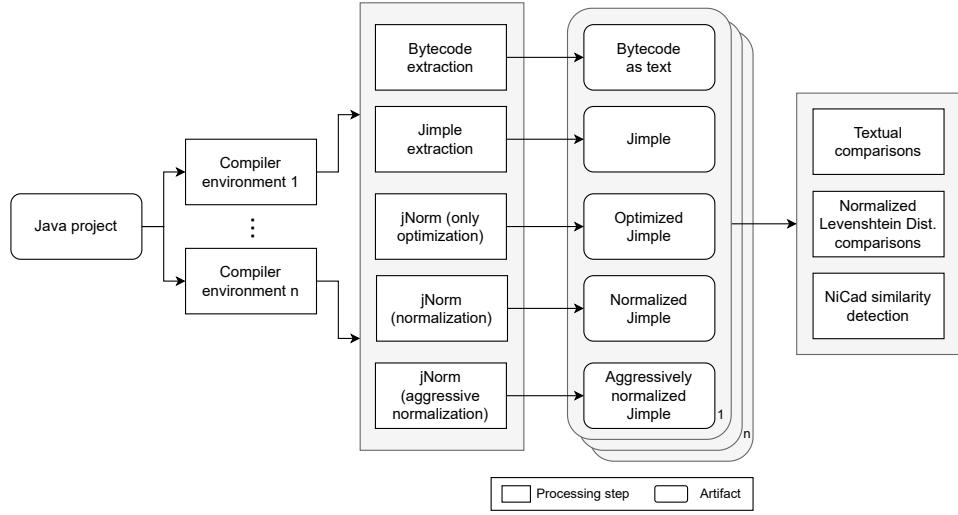

Figure 4 Overview of our experimental setup.

4.1 Experimental Setup

To evaluate JNORM’s normalization performance, we use the approach depicted in Figure 4.

We selected real-world Java projects based on the following process: At first, we used the GitHub search API to obtain the 1,000 projects with the most stars that have Java listed as their main language as of August 2023. We excluded two projects that, alongside Java files, also contained other JVM-based programming languages like Groovy or Clojure, as the compiled classes would interfere with further evaluation steps. Then we filtered out every project that does not use Maven as build tool, as Maven’s static configuration files in XML format, unlike Gradle, allow for an automated change of the compilation setup without knowing the project’s build structure in detail. After this step we were left with 322 Maven projects. Finally, we excluded two projects that, when compiled twice within the same environment, would produce different results, because of code generation at compilation time. This is typically due to files being generated for testing purposes or due to parser code being generated from a grammar, which in some cases produces random identifiers. This left us with a set of 320 Java projects, including tutorial projects, popular libraries, frameworks and real-world applications.

We cloned each project’s git repository. As automatic compilation is a known problem for Java projects [22], to increase the chances of a successful compilation in the next step, we then moved to the latest release tag (if available). As depicted in Figure 4, we compiled each of the projects within different compilation environments. We chose the compilation environments based on the setting we were interested in for the respective research questions.

To evaluate the normalization performance of JNORM, we applied different procedures to the compiled projects, as shown in Figure 4. The “Bytecode extraction” component in the figure uses ASM 9.3 [3] to extract the textual representation of the bytecode from the compiled class files (omitting all debug information). Furthermore, we additionally extracted the plain Jimple representation of the compiled classes in textual form without applying any optimizations or transformations. The plain bytecode and Jimple can be used as a baseline to establish the amount of differences induced by different compilation environments. To establish how the different normalization steps of JNORM contribute to the removal of compilation differences, we let JNORM run in different modes. “JNORM (only optimization)” only applies the Jimple parsing and optimizations described in Section 3.3. “JNORM (normalization)” applies all the steps described in Section 3 with transformations

■ **Table 2** JDKs considered in our evaluation.

JDK Version	Oracle JDK	AC OpenJDK	EA OpenJDK
7	1.7.0_80	—	—
8	1.8.0_333	8.342.07.4	8u352-b08
11	11.0.16	11.0.16.9.1	11.0.17+8
17	17.0.4.1	17.0.5.8.1	17.0.5+8

N1–N15, but keeps all typechecks in place (default normalization mode). “JNORM (aggressive normalization)” differs from the previous as it also removes all typechecks from the resulting Jimple representation. Applying all procedures, we obtain five sets of files per compilation environment and project:

- Extracted bytecode as text
- Extracted Jimple
- Optimized Jimple
- Normalized Jimple
- Aggressively normalized Jimple

We apply different comparisons to each of the resulting file sets generated within different compilation environments, resulting in multiple comparisons per project. At first we perform a textual head-to-head comparison on the file-, as well as method-level. To do so we compare files with the same fully qualified name and methods with the same signature to each other that were produced within different compilation environments. As soon as there is a single textual difference between the compared files or methods, they are classified as being *different*. If a method is present in one file, but not the other, it is classified as *disjunct*.

In addition to textual head-to-head comparisons, which only allow for a yes/no detection of equality, we calculate the normalized Levenshtein Distance (NLD) [59] between the compared files and methods. The NLD is a measure that is used to calculate the similarity of two text sequences. The Levenshtein Distance counts the number of required character insertions, deletions or substitutions to transform one text sequence into the other. The normalized Levenshtein Distance additionally takes the length of the text sequences into account and produces a similarity value between 0% and 100%, with 100% indicating that every single character needs to be changed and 0% indicating that both text sequences are identical. Lastly, we include the similarity analysis tool NiCad [50] into our comparison process to evaluate to which degree the prior application of bytecode normalization can improve the performance of similarity analysis tools. We use NiCad for our experiment, as it is one of the most popular similarity analysis tools.

Table 2 shows the JDKs considered in our evaluation. We considered all Java Long-Term-Support versions up to August 2023. According to a 2022 survey on the state of the Java ecosystem [44], our JDK selection covers more than 97% of JDK versions used in projects. This gives us an indication for the representativeness of our version selection. Furthermore, we considered the three most popular JDK vendors according to the survey, which include Oracle’s JDK, Amazon Corretto’s (AC) OpenJDK and Eclipse Adoptium’s (EA) OpenJDK, in our evaluation. Note that AC and EA do not distribute OpenJDK versions prior to version 8. Moreover, only a single project within our dataset can be compiled using Oracle’s JDK5 and JDK6, thus we do not consider these two no longer supported JDKs in our evaluation [26].

We executed the compilations and normalizations on a Debian 10 system, configured to use four cores of an Intel Xeon E5-2695 v3 (2.30 GHz) CPU and 32GB of main memory. We used Maven 3.8.6 for the invocation of builds.

4.2 RQ1: Does the JDK vendor influence the bytecode generation?

Before assessing the differences introduced when using different JDK or Java versions, we evaluate if different JDK *vendors* induce differences in the bytecode. Even though most vendors build upon the same OpenJDK source code, there are still some adjustments in regards to e.g. security fixes or performance improvements [1]. This research question aims at determining whether these changes may affect the generated bytecode. To do so, we compiled our full dataset of Java projects using the compilers of the JDK's listed in Table 2. Subsequently we compared all bytecode files generated by the compilers of the investigated vendors, using the same Java and JDK version, against each other.

None of the generated bytecode files contain any difference related to the vendor of the JDK used for compilation. These results indicate that changing the JDK vendor does not influence the bytecode generation of the JDK's compiler.

Based on this result, we consider a single JDK vendor (Oracle) in the remaining research questions.

4.3 RQ2: How does jNorm perform on changing JDK versions?

To investigate jNORM's normalization performance on different JDK versions, we kept all compilation settings at the project's configured default values and only varied the used JDK version within our experimental setup (see Section 4.1). For this experiment we considered versions 7, 8, 11, and 17 of Oracle's JDK.

Table 3 shows the results of our comparisons. The first column shows the pair of JDK versions used to generate the different artifacts we consider (see Section 4.1), e.g., in the first row (sets of) artifacts generated with JDK7 have been compared to (sets of) artifacts obtained from JDK8. The number inside the parentheses indicates the amount of projects we were able to compile with the respective JDKs. As we were not able to compile every project with all JDKs in our experimental setup, the number of compared projects varies based on the successful builds for each JDK. Notice that only few projects could be compiled using JDK7. This is due to features introduced in Java 8 being very popular in modern projects, e.g., default interface functions, streams and lambda expressions. To isolate differences introduced by incremental version increases, we decided to compare a JDK version with the next higher version in our experimental setup. To confirm that we do not miss differences by only comparing incremental version increases, we initially performed a comparison of projects compiled with JDK7 and JDK17 and compared the resulting set to the union of all incremental comparisons. In total we were able to compile ten projects using each version of Oracle's JDK in our experimental setup, comprising 4,621 bytecode files. This analysis showed that the set of differences obtained when comparing JDK7 to JDK17 is equal to the union of the sets of differences obtained when comparing each incremental version increase, i.e., $D_{7 \rightarrow 8} \cup D_{8 \rightarrow 11} \cup D_{11 \rightarrow 17} = D_{7 \rightarrow 17}$ with $D_{i \rightarrow j}$ representing the set of files containing compilation differences when comparing bytecode files yielded by the JDK i and JDK j compilers. This comparison holds true for all five processed sets of artifacts (bytecode, plain, optimized, normalized and aggressively normalized Jimple), showing that a comparison of incremental version increases does not miss compilation differences.

Columns two and three show the accumulated results of the textual comparison on a file-level granularity. The remaining columns show the accumulated comparison results on a method-level granularity. Columns "Files" and "Methods" show the total amount of files and methods we managed to compile with the respective JDKs. The "Diffs" columns

Table 3 Normalization results for different JDK versions². Percentage in brackets indicates the share of files/methods with compilation differences.

	Files	Diffs	Methods	Diffs	NLD	Disj.
JDK7 – JDK8 (29)						
Bytecode	8,060	1,058 (13.13%)	48,052	113 (0.24%)	4.02%	4
Jimple	8,069	93 (1.15%)	48,068	113 (0.24%)	5.78%	4
Optimized	8,069	93 (1.15%)	48,068	113 (0.24%)	5.90%	4
Normalized	8,069	24 (0.30%)	45,654	32 (0.07%)	8.13%	0
Aggressive	8,069	24 (0.30%)	45,654	32 (0.07%)	7.46%	0
JDK8 – JDK11 (98)						
Bytecode	45,625	8,068 (17.68%)	417,906	10,253 (2.45%)	9.00%	2,834
Jimple	60,265	2,959 (4.90%)	461,594	5,594 (1.21%)	9.31%	2,832
Optimized	60,265	2,852 (4.89%)	461,594	5,459 (1.18%)	8.28%	2,832
Normalized	60,265	995 (1.65%)	408,250	1,309 (0.32%)	4.80%	8
Aggressive	60,265	392 (0.65%)	408,250	426 (0.10%)	3.16%	8
JDK11 – JDK17 (91)						
Bytecode	58,623	13,936 (23.77%)	469,536	3,146 (0.67%)	18.94%	2,510
Jimple	80,584	2,566 (3.18%)	535,184	3,033 (0.57%)	17.30%	2,501
Optimized	80,584	2,553 (3.17%)	535,184	3,016 (0.56%)	17.06%	2,501
Normalized	80,584	120 (0.15%)	487,280	141 (0.03%)	4.24%	0
Aggressive	80,584	82 (0.10%)	487,280	95 (0.02%)	3.51%	0

show the total amount of files or methods that contained differences within the textual head-to-head comparison and their respective shares. The “NLD” column shows the average NLD of methods that contain differences, indicating the degree of dissimilarity induced by the compilation into individual methods. Note that only methods that are considered as not equal by the textual comparison are considered for the calculation of the NLD. The “Disj.” (disjunct) column represents the amount of methods that are present within the file generated by one JDK, but not within the file generated by the other JDK, e.g. synthetically generated bridge-methods. Therefore a direct comparison of such methods is not possible. Note that the transformation of bytecode to Jimple in some cases splits classes into multiple files, thus the number of bytecode files may differ from the number of Jimple files. In cases when dynamically invoked features like e.g. lambda functions are used, they are split into a separate file. We considered the by SOOT additionally generated files in our comparison.

One thing that is immediately noticeable is the high amount of differences in bytecode files when considering the file-level granularity, whereas the share of differences is considerably lower at method-level granularity. A detailed investigation into the differing bytecode files revealed this to be due to the presence of nested class information, which in bytecode is contained inside the class, but outside of methods. Depending on the used JDK, different modifiers are used or the order of these definitions varies. One can also observe that by simply converting the bytecode to Jimple, the amount of differences at file-level granularity considerably decreases. Nested class information, in contrast to the bytecode representation, is stored implicitly in the Jimple representation, which causes the disappearance of many dissimilarities. At method-level granularity, the amount of differences between bytecode and Jimple stays fairly similar. This indicates that besides removing some information

² Individual project results are available on <https://doi.org/10.5281/zenodo.12625104>

at class level, the plain conversion to Jimple itself does not significantly contribute to the normalization of method-level bytecode. Additionally it can be seen that the optimization step does not significantly contribute to the normalization by itself either. On the contrary, when looking at the results for the normalized file set, the amount of dissimilarities and disjunct methods heavily decreases. The remaining dissimilarities decrease even further when applying an aggressive normalization. Depending on the considered JDKs, the amount of compilation differences at file-level granularity decreases by up to 99% from the textual comparison of plain bytecode to the aggressively normalized Jimple. At method-level granularity the dissimilarity amount decreases by up to 97%.

We investigated the remaining differences in more detail to determine whether we missed other compilation difference classes. We found that the remaining differences are mostly due to more complex cases of compilation difference classes N4 and N8, which target try-catch blocks. Sometimes when such try-catch blocks are nested in specific ways, jNORM fails to apply the corresponding transformation correctly. Other differences are due to incorrect optimizations applied by the SOOT framework or an incorrect renaming of local variables.

Since we considered a small set of Java projects to establish the compilation difference classes in the first place and the evaluation across a large dataset of real-world Java projects only revealed a small set of edge cases of the already known difference classes not yet handled by jNORM, we believe that our normalization addresses the most common difference classes appearing within projects compiled with the investigated JDK versions. We will address the transformations incorrectly applied by jNORM in future work.

jNORM can remove up to 99% of the file-level differences and up to 97% of the method-level differences, which are induced when compiling the same source code with different versions of the JDK compiler.

4.4 RQ3: How does jNorm perform on changing Java target levels?

The target level that has been used to compile a specific Java class is typically included in the compiled class in form of a *major version* identifier [33]. While in some cases this information can be used to compile the source code to the version specified within the bytecode files, this is not possible when one wants to directly compare two already compiled bytecode files. Thus it is also important to assess jNORM’s performance on differing target levels.

To evaluate jNORM’s normalization performance on different Java target levels, we fixed the used JDK version and adjusted the target level in each project’s build configuration, within our experimental setup (see Section 4.1). All other build settings have been kept at each project’s provided configuration. We consistently used Oracle’s JDK11 in our experiment, as it is the most used JDK version in 2022 [44], which also offers backwards compatibility down to target level 6. To adjust the project’s target level we scanned each project of our dataset for build files (pom.xml). Inside each of the detected build files, we adjusted the *target*, *release*, or *java.version* properties, which are used to declare the desired Java target level [9, 8], to compile the project to our desired target levels. To validate that all projects were compiled with the intended target level, we verified the target level indicator [33] within the resulting bytecode files and removed it subsequently to not interfere with the comparison.

Table 4 shows the results of our experiment. The table has the same structure as Table 3, besides the first column now representing Java target levels instead of JDK versions. As in the previous experiment, we compare one target level to the next higher target level within our experimental setup, to best isolate compilation differences. To confirm that we do not miss differences by only comparing incremental version increases, we perform a comparison

Table 4 Normalization results for different target levels of the JDK11 compiler³. Percentage in brackets indicates the share of files/methods with compilation differences.

	Files	Diffs	Methods	Diffs	NLD	Disj.
T6 – T7 (25)						
Bytecode	13,774	29 (0.21%)	76,102	55 (0.07%)	2.38%	0
Jimple	14,411	29 (0.20%)	77,833	55 (0.07%)	2.36%	0
Optimized	14,411	29 (0.20%)	77,833	55 (0.07%)	2.32%	0
Normalized	14,411	8 (0.06%)	73,102	20 (0.03%)	0.56%	0
Aggressive	14,411	8 (0.06%)	73,102	20 (0.03%)	0.95%	0
T7 – T8 (31)						
Bytecode	4,100	70 (1.71%)	33,109	89 (0.27%)	1.90%	2
Jimple	4,127	33 (0.80%)	33,190	37 (0.11%)	5.05%	2
Optimized	4,127	33 (0.80%)	33,190	37 (0.11%)	4.67%	2
Normalized	4,127	32 (0.78%)	31,338	37 (0.12%)	4.67%	0
Aggressive	4,127	4 (0.10%)	31,338	4 (0.01%)	4.10%	0
T8 – T11 (80)						
Bytecode	28,709	13,260 (46.19%)	293,804	25,301 (8.61%)	18.39%	3,677
Jimple	42,690	9,654 (22.61%)	335,700	25,294 (7.53%)	17.74%	3,677
Optimized	42,690	9,654 (22.61%)	335,700	25,294 (7.53%)	17.58%	3,677
Normalized	42,690	110 (0.26%)	297,541	140 (0.47%)	2.76%	0
Aggressive	42,690	88 (0.21%)	297,541	115 (0.39%)	2.40%	0

of the maximum possible target level distance. Again, the following equation holds for the twelve projects (1,245 bytecode files) that can be compiled to each target level within our experimental setup, when using JDK11 $D_{11.6 \rightarrow 11.7} \cup D_{11.7 \rightarrow 11.8} \cup D_{11.8 \rightarrow 11.11} = D_{11.6 \rightarrow 11.11}$ with $D_{11.i \rightarrow 11.j}$ representing the set of files containing differences when comparing bytecode files yielded by JDK11 set to target levels i and j .

The number within the parentheses inside the first column indicates the amount of projects we were able to compile using JDK11 configured with the respective Java target levels. The total amount of successful builds is lower than the one we obtained in our previous experiment. This is due to the change in the provided build configuration that this experiment requires, which often leads to projects not being able to compile anymore.

One thing that is immediately noticeable in Table 4 is the low amount of compilation differences throughout target levels 6, 7 and 8. Many of these are removed by the (aggressive) normalization. We investigated the remaining differing files and discovered that all remaining differences are due to wrong type inference and incorrect renaming of local variables performed by the SOOT framework. The picture changes when considering a target level change from Java 8 to Java 11, as visible in the third row of Table 4. Almost half of the compared files show differences in a textual head-to-head comparison. This value decreases to around 10% when considering method-level granularity. Furthermore, the NLD is very high, indicating that the compiled methods are significantly dissimilar. This large amount of differences is due to many highly used features being affected by the target level increase. From Java target level 8 to 11 the way that string concatenation, private method calls, and inner classes are handled has been changed. These are features that are frequently used within Java

³ Individual project results are available on <https://doi.org/10.5281/zenodo.12625104>

projects. The conversion to Jimple removes around half of the differences at file-level, but removes only few differences on method-level. The subsequent optimization does not remove any differences in the textual comparison. The normalization, instead, heavily decreases the dissimilarities. After aggressive normalization the amount of dissimilarities decreases by more than 99.3% from the textual comparison of plain bytecode to aggressively normalized Jimple. On a method-level granularity the dissimilarity amount even decreases by 99.6%.

Again we performed a manual inspection of the remaining differing files and methods to uncover possibly missed compilation difference classes. The inspection showed that the remaining differences can mostly be attributed to incorrect optimizations by the SOOT framework and incorrect transformations of dynamic string concatenation and nest-based access control applied by JNORM in specific scenarios (e.g. boolean variables being handled as integer values in the string concatenation). Again, we leave addressing of incorrectly applied transformations by JNORM for future work.

As we already stated in the previous research questions, the absence of previously not uncovered compilation difference classes leads us to believe that we uncovered the most frequent compilation difference classes for projects compiled to the investigated Java target levels. Furthermore, we additionally investigated compilation environments in which we compared changes to the JDK version *and* target level, however, again we did not uncover any further difference classes.

JNORM can remove up to 99.3% of the file-level differences and up to 99.6% of the method-level differences, which are induced when compiling the same source code with different configured Java target levels.

4.5 RQ4: To which degree can bytecode normalization support similarity analysis tools?

In this research question we investigate whether existing similarity analysis tools are already capable of handling compilation differences on their own, without the need of a previous normalization by JNORM. To do so, we used our dataset from the previous research questions, but instead of performing a textual head-to-head comparison, we used the code clone detector NiCad 6.2 [50] to determine its performance without and with normalization applied. NiCad is a flexible and extensible code clone detector that is frequently used in similarity analysis studies. While there are other Java similarity analysis tools available, e.g. CCFinder [35], SourcererCC [52] or JPLAG [47], we decided on NiCad due to it being the most popular similarity analysis tool and its simple extensibility. It supports detection on block- or function-level granularities and different languages (e.g. Java, Rust, C) and applies its own pretty-printing and code normalizations before the similarity analysis. NiCad offers a wide array of possible applications like code clone or plagiarism detection and therefore provides many configurations. We employed NiCad set to function-level granularity with three different configurations (Plagiarism-1, Plagiarism-2 and Default) in our evaluation setup (described in Section 4.1). NiCad does not support Java bytecode nor Jimple out-of-the-box. To perform our experiment, we extended NiCad with the capability to handle Jimple inputs by adjusting and extending the provided Java grammar and normalization/transformation rules. Due to Jimple's syntactic similarity to Java source code, the only adjustments we performed on NiCad consisted of adding Jimple-exclusive statements (identity, invoke, goto, monitor), adjusting try-catch definitions and adjusting if-statements to their Jimple structure.

We decided to perform a plagiarism detection experiment since this is a typical scenario where only bytecode originating from an unknown compilation environment is available, but the corresponding source code is not. To perform the experiment we selected a method pair

Table 5 NiCad performance on method pairs with compilation differences. Percentage indicates the share of method pairs correctly identified as clones.

(a) JDK version comparison.

	Plag-1	Plag-2	Default
J7 – J8 (104)			
Jimple	12.5%	75.0%	99.0%
Optimized	14.4%	66.3%	99.0%
Normalized	78.9%	85.6%	99.0%
Agg. Normalized	81.7%	87.5%	100%
J8 – J11 (4,967)			
Jimple	35.2%	57.1%	90.2%
Optimized	38.6%	59.3%	92.1%
Normalized	82.9%	94.0%	99.9%
Agg. Normalized	97.4%	98.6%	99.9%
J11 – J17 (2,858)			
Jimple	6.4%	9.8%	26.1%
Optimized	6.9%	10.0%	25.9%
Normalized	96.7%	99.3%	99.7%
Agg. Normalized	98.0%	99.4%	99.9%

(b) Target level comparison.

	Plag-1	Plag-2	Default
T6 – T7 (53)			
Jimple	88.7%	94.3%	100%
Optimized	88.7%	94.3%	100%
Normalized	92.5%	98.1%	100%
Agg. Normalized	92.5%	98.1%	100%
T7 – T8 (37)			
Jimple	10.8%	86.5%	100%
Optimized	13.5%	83.8%	100%
Normalized	16.2%	83.8%	100%
Agg. Normalized	91.9%	100%	100%
T8 – T11 (24,095)			
Jimple	24.7%	28.3%	70.8%
Optimized	25.7%	28.0%	70.4%
Normalized	99.7%	99.9%	100%
Agg. Normalized	99.8%	99.9%	100%

that originated from the same source code, but was compiled within different compilation environments, and gave it to NiCad running with different configurations and checked whether it reported the pair as matching or not. Since each method pair originates from the exact same source code, NiCad *should* report it as plagiarism. We considered all methods that were not equal in the textual comparison within our Jimple dataset (see RQ2 4.3 & RQ3 4.4). We executed NiCad on the same set of methods across all other representations (optimized, normalized and aggressively normalized Jimple).

Tables 5a and 5b report the results of our experiment with NiCad. The first column of each table shows the compilation environments that the compared files originated from (J stands for JDK version and T stands for target level) and indicate which normalization steps have been applied before being forwarded to NiCad. The number in parentheses indicates the number of *method pairs* compared by NiCad. Note that, since NiCad was not able to analyze some pairs, the number is slightly lower than the differing methods reported in RQ2 and RQ3. The remaining columns show the detection recall of NiCad using different configurations. The Plagiarism-1 and Plagiarism-2 configurations are explicitly targeting plagiarism detection. The allowed degree of dissimilarity after applying pretty-printing and its own normalizations is specified at 10%. The Plagiarism-2 configuration additionally applies the *blind* renaming scheme, which removes identifier names. The provided Default configuration of NiCad does not target a plagiarism detection scenario but an aggressive code clone detection that allows a dissimilarity of up to 30%. It also applies the additional blind-renaming. Note that we test NiCad in a best-case scenario: First, we provide it with Jimple code, which in contrast to bytecode already contains fewer compilation differences. Second, we evaluate NiCad’s performance on small configuration changes only (e.g. comparing JDK7 to JDK8) and do not combine multiple configuration changes, which would result in even more compilation differences. Finally, as most similarity analysis studies [52] we do not take potential false positives into account. Especially with its aggressive Default configuration, which only requires 70% similarity for a match, NiCad would incorrectly classify method pairs as plagiarism cases, which actually do not originate from the same source code.

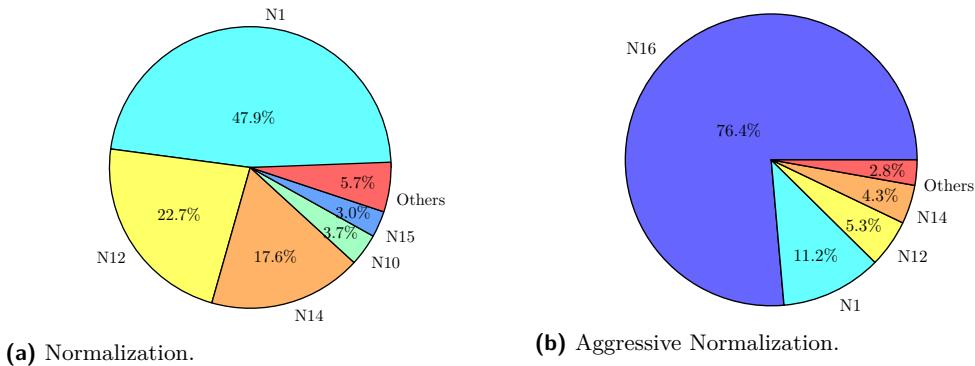

Figure 5 Average prevalence of the individual compilation difference classes.

One can observe that before applying normalization the Plagiarism-1 configuration performs poorly for most JDKs. However, after normalization is applied the performance drastically increases. A similar effect, although not as drastic, can be observed for Plagiarism-2. The aggressive Default configuration of NiCad performs well for compilation environments that do not contain a high degree of dissimilarity. However, for environment changes that actually induce significant differences in methods (J11 - J17 and T8 - T11), indicated by a high NLD between method pairs (see Tables 3 and 4), NiCad continues to perform poorly before normalization, but offers a significantly increased performance when normalizations are applied first via jNORM. Recall, that the Default configuration allows for up to 30% dissimilarity and is still not able to reliably classify method pairs as matching. Note that the provided code did not contain any intentional modifications, e.g. obfuscations, as the removal of such intentional modifications is not part of jNORM's scope. Even without intentional obfuscations, NiCad was not able to detect many of the clones.

NiCad, one of the most popular code clone detectors, is not capable of handling all differences induced by different compilation environments on its own. However, when applying normalization via jNORM first, NiCad's performance increases significantly.

4.6 RQ5: How prevalent are the individual compilation difference transformations of jNorm?

To investigate the prevalence of the compilation difference classes and their individual contribution to the normalization, we tracked each applied transformation within the normalization process of our dataset used throughout RQ2 – RQ4.

Figure 5 shows the average amount of transformations across each JDK and Java version setting. On average jNORM applies 888 transformations during normalization per project. One can see that a few of the established compilation difference classes make up the biggest share of the transformations. For plain normalization, transformation N1, which handles synthetically generated methods, makes up almost half of all transformations. This is due to the large amount of bridge-methods generated for each private method within nested classes. This transformation is followed by transformations N12, which normalizes string concatenations, and N14, which normalizes the invocation of private methods. Both of these are frequently used features within Java applications. The remaining transformations are only sparsely required. For aggressive normalization, transformation N16, which removes all typechecks, makes up by far the biggest share of all transformations. This is due to

the compiler frequently placing typechecks into the bytecode. This is further enhanced by our aggressive approach of removing *all* occurrences of typechecks. Since jNORM applies transformation N16 after all other transformations, the prevalence of the other compilation difference classes is the same as for plain normalization. During aggressive normalization 4,134 transformations are applied on average per project.

Transformations N16 (Insertion or removal of typechecks), N1 (Synthetically generated methods), N12 (Dynamic String concatenation) and N14 (Invocation of private methods) make up 97.2% of all applied transformations and are thus the most prevalent during normalization.

5 Related Work

Many similarity analysis approaches have been proposed, targeting source code, bytecode, or binary code, which typically come with their own set of normalizations.

Bytecode level. Only few approaches have been developed for bytecode similarity analysis. However, there are various scenarios in which Java source code is not available. Whenever this is the case, the comparison has to be performed on the bytecode. SeByte [36] is a similarity detector targeting Java bytecode. It divides the bytecode into tokens and separates them based on their types to employ the Jaccard similarity measure for matching. Baker and Manber [4] leverage a combination of the similarity comparison tools Diff, Siff and Dup to determine the degree of similarity of Java bytecode files. Yu et al. [58] use the Smith-Waterman algorithm to determine the similarity of two bytecode snippets. They extract instruction and method-call sequences from the bytecode and apply the Smith-Waterman algorithm to align the extracted sequences. Ji et al. [30] propose an approach to perform a plagiarism detection on bytecode. They divide the bytecode into sequences and utilize the adaptive local alignment to find potential plagiarisms. Davis and Godfrey [17] propose an approach to find clones that works on Assembler and bytecode. Their approach implements a greedy matching of instruction types and arguments by using an internal weight measure. Chen et al. [7] present an approach that aims at detecting application clones on Android markets. They utilize control flow graphs, to compare apps to each other and find clones in the Dalvik bytecode.

The above mentioned approaches do not explicitly mention how the differences in bytecode resulting from different compilation environments.

Source code level. For source code level similarity analysis many approaches have been developed. NiCad [50, 10] is a textual based code clone detector that targets a variety of programming languages. It uses different means of normalization and is designed to be easily extensible. CCFinder [35] transforms the input source code into a set of tokens and performs the comparisons on this set of tokens. SourcererCC [52] uses a similar token-based detection approach. However, SourcererCC specifically aims at high scalability and is optimized towards a usage on large software repositories. JPlag [47] divides the source code into token strings and applies a greedy string tiling algorithm to find plagiarisms within sets of applications. DECKARD [31] leverages the Abstract Syntax Tree representation of an application’s source code to perform the similarity analysis. StoneDetector [2] uses a more specialized code-representation called dominator trees, a concept often used in compilers, to detect structural clones, which use different syntactical constructs to implement the same

control flow. DeepSim [60] uses a deep learning model to find semantic similarities within code snippets that are syntactically different. Oreo [51] is another code clone detection tool that leverages deep learning. It uses a pre-trained model that utilizes several code metrics to decide whether two code snippets are clones of each other, even if their syntactical similarity is below 70%.

Source code based similarity analysis approaches have become much more permissive to syntactic differences over the years. This allows some tools to perform a similarity analysis across intermediate representations that are syntactically similar to the targeted source code. Selim et al. [53] investigated how the additional supplementation of the Jimple intermediate representation, alongside the source code, of a Java application can help in code clone detection tasks. To do so, they applied the clone detection tools CCFinder and Simian to Jimple code, which is syntactically similar to Java source code.

Ragkhitwetsagul et al. [49] evaluate and compare 30 different code similarity detection techniques, including code clone detectors, plagiarism detectors and compression tools, within different similarity analysis scenarios.

Binary level. As machine code is usually at the hardware level and there is a lot of variety in compilation environments and optimization levels, binary similarity analysis is a complex problem. David et al. [14, 15, 16] propose multiple approaches that decompose the assembly code of the binary into strands, which encode specific semantic behaviors in small units. Before comparing the units, in a similar way as JNORM and SootDiff do to achieve a more normalized representation, they transform the units to LLVM-IR and apply some optimizations and transformations to them, which are specific to LLVM-IR. Luo et al. [40] model the semantics of binaries with a set of symbolic formulas that represent input-output relations and use a theorem solver to determine their similarity. Hemel et al. [23] created the Binary Analysis Tool which uses different comparison strategies, like string matching, compression and a binary delta check to find software license violations within binaries. Many approaches like SAFE [42] and Xu et al.'s approach [57] use machine learning to determine the similarity of binaries. Marcelli et al. [41] investigate and compare multiple machine learning based approaches that try to classify the similarity of binaries. Haq and Caballero [21] present a survey of binary code similarity in which they analyze and systemically categorize 70 different binary similarity analysis approaches developed since 1999.

While most binary similarity analysis techniques cannot be directly applied towards bytecode similarity analysis, they can theoretically at least be adapted to it.

Compiler influence There are few works that investigate the relation of compilers to similarity analysis. Kononenko et al. [38] investigate a compilation's degree of influence on code clone detection. To do so, they compare the detected code clones within Java source code and bytecode compiled from the same source code which results in different sets of detected clones. Ragkhitwetsagul and Krinke [48] investigate how compilation and decompilation can influence the clone detection performance within Java code bases. They suggest that decompilation can aid as a complementary measure to source code based clone detection, but is not sufficient on its own. Dann et al. [12] investigate the impact that different compilation environments have on the resulting bytecode. They propose the bytecode comparison tool SootDiff, which employs an approach similar to JNORM, however only support one of the transformations we defined (string constant concatenation) and only considers Java versions 5 to 8. Xiong et al [56] investigate sources of non-determinism in the Java build process that hinder builds from being reproducible. They uncover 14 patterns that may introduce

non-equivalences in the build and present corresponding mitigation strategies. In the context of `JNORM` many of these sources of non-determinism are addressed by the conversion of bytecode to `Jimple`.

6 Threats to Validity

For our evaluation of `JNORM` we exclusively relied on projects that use Maven as build tool. While other Java build tools such as Gradle [20] exist, Maven is the most popular [29]. Furthermore, we limited our experiments to Java versions 5–8, 11 and 17. Although this version range covers all LTS-versions (up to August 2023) and are also the by far most frequently used Java versions in projects (see electronic appendix), other versions may yield different evaluation results and cause unidentified compilation differences. While we included a large number of Java projects in our evaluation, there may be some rare instances of differences induced by different compilation environments, which we did not uncover across our data set. Moreover, we tried to isolate the detected compilation difference classes to the specific configuration change they are caused by. There may also be other configuration changes that cause the same differences. However, as `JNORM` does not know the used configuration anyway, the differences will still be normalized.

Even though `JNORM`, in its default mode, only transforms constructs from the version produced within one compilation environment to the version produced in another environment, there still may be semantic changes created by the applied transformation. Furthermore, in few cases there are incorrect analyses, transformations and optimizations applied by the `SOOT` framework before the application of `JNORM`'s transformations.

7 Conclusion

In this paper we presented the concept of bytecode normalization for code similarity analysis. Bytecode normalization addresses the problem of comparing the bytecode of Java applications that are compiled in different compilation environments. This is especially necessary when the source code is not available, like in plagiarism, copyright or vulnerability detection and SBOM creation scenarios. By converting bytecode into the intermediate representation `Jimple`, applying common optimizations, transforming remaining compilation differences and applying naming standardization, we create a representation that is always the same no matter the JDK and Java (LTS) version used to compile the source code. To do so, we identified and presented 16 compilation difference classes, which are induced in the bytecode when using different JDK and Java versions.

Based on the concept of bytecode normalization we implemented `JNORM`. Our evaluation on a large set of popular real-world Java projects showed that compiling equal Java source code within different compilation environments leads up to 46% of all generated bytecode files containing differences for single incremental version increases. By using `JNORM` we can reduce the number of compilation differences by more than 99%, for most of the investigated compilation environments. Furthermore, our evaluation of the similarity analyzer `NiCad` showed that the tool was not able to handle all compilation differences on its own, yet an application of bytecode normalization via `JNORM` prior to the similarity analysis significantly improved the tool's performance, showcasing the effectiveness of bytecode normalization.

`JNORM` creates a code representation that is independent of the environment the Java source code has been compiled in and thus lowers the required complexity for subsequent similarity analysis. This could potentially pave the way for further research in the field of bytecode similarity analysis, bringing it closer to the wide range of tools and techniques currently available for analyzing source code similarity.

Abstract

While programmers know that memory representation of data structures can have significant effects on performance, compiler support to *optimize* the layout of those structures is an under-explored field. Prior work has optimized the layout of individual, *non-recursive* structures without considering how collections of those objects in linked or *recursive* data structures are laid out.

This work introduces MAMOSET, a compiler that optimizes the layouts of algebraic datatypes, with a special focus on producing highly optimized, *packed* data layouts where recursive structures can be traversed with minimal pointer chasing. MAMOSET performs an analysis of how a recursive ADT is used across functions to choose a *global* layout that promotes simple, strided access for that ADT in memory. It does so by building and solving a constraint system to minimize an abstract cost model, yielding a predicted efficient layout for the ADT. MAMOSET then builds on top of GIBBON, a prior compiler for packed, mostly-serial representations, to synthesize optimized ADTs. We show experimentally that MAMOSET is able to choose optimal layouts across a series of microbenchmarks and case studies, outperforming both GIBBON's baseline approach, as well as MLTON, a Standard ML compiler that uses traditional pointer-heavy representations.

1 Introduction

Recursive data structures are readily available in most programming languages. Linked lists, search trees, tries and others provide efficient and flexible solutions to a wide class of problems – both in low-level languages with direct memory access (C, C++, Rust, Zig) as well as high-level ones (Java, C#, Python). Additionally, in the purely functional (or *persistent* [20]) setting, recursive, tree-like data structures largely replace array-based ones.

Implementation details of recursive data structures are not necessarily known to application programmers, who can only hope that the library authors and the compiler achieve good performance. Sadly, recursive data structures are a hard optimization target.

High-level languages represent recursive structures with pointers to small objects allocated sparsely on the heap. An algorithm traversing such a *boxed* representation spends much time in pointer chasing, which is a painful operation for modern hardware architectures. Optimizing compilers for these languages and architectures have many strengths but optimizing memory representation of user-defined data structures is not among them. One alternative is resorting to manual memory management to achieve maximum performance, but it has the obvious drawback of leaving convenience and safety behind.

A radically different approach is representing recursive datatypes as dense structures (basically, arrays) with the help of a library or compiler. The GIBBON compiler tries to improve the performance of recursive data structures by embracing dense representations by default [25]. This choice has practical benefits for programmers: they no longer need to take control of low-level data representation and allocation to serialize linked structures; and rather than employing error-prone index arithmetic to access data, they let GIBBON automatically translate idiomatic data structure accesses into operations on the dense representation.

Dense representations are not a panacea, though. They can suffer a complementary problem due to their inflexibility. A particular serialization decision for a data structure made by the compiler can misalign with the behavior of functions accessing that data. Consider a tree laid out in left-to-right pre-order with a program that accesses that tree right-to-left. Rather than scanning straightforwardly through the structure, the program would have to jump back and forth through the buffer to access the necessary data.

One way to counter the inflexibility of dense representations is to introduce some pointers. For instance, GIBBON inserts *shortcut pointers* to allow random access to recursive structures [24]. But this defeats the purpose of a dense representation: not only are accesses no longer nicely strided through memory, but the pointers and pointer chasing of boxed data are back. Indeed, when GIBBON is presented with a program whose access patterns do not match the chosen data layout, the generated code can be *significantly slower* than a program with favorable access patterns.

Are we stuck with pointer chasing when processing recursive data structures? We present MAMMOSET as a counter example. MAMMOSET is our program analysis and transformation approach that spots misalignments of algorithms and data layouts and fixes them where possible. Thus, our slogan is:

Algorithms + Data Layouts = Efficient Programs

MAMMOSET analyzes the data access patterns of a program and synthesizes a data layout that corresponds to that behavior. It then rewrites the datatype and code to produce more efficient code that operates on a dense data representation in a way that matches access patterns. This co-optimization of datatype and code results in improved locality and, in the context of GIBBON, avoidance of shortcut pointers as much as possible.

We implement MAMMOSET as an extension to GIBBON – a compiler based on dense representations of datatypes. That way, MAMMOSET can be either a transparent compiler optimization, or semi-automated tool for exploring different layouts during the programmer’s optimization work. Our approach has general applicability because of the minimal and common nature of the core language: the core language of MAMMOSET is a simple first-order, monomorphic, strict, purely functional language. Thanks to the succinct core language, we manage to isolate MAMMOSET from GIBBON-specific, complicated (backend) mechanics of converting a program to operate on dense rather than boxed data.

Overall, in this paper:

- We provide a static analysis capturing the temporal access patterns of a function towards a datatype it processes. As a result of the analysis, we generate a *field access graph* that summarizes these patterns.
- We define a cost model that, together with the field access graph, enables formulating the field-ordering optimization problem as an integer linear program. We apply a linear solver to the problem and obtain optimal positions of fields in the datatype definition relative to the cost model.
- We extend the GIBBON compiler to synthesize new datatypes based on the solution to the optimization problem, and transform the program to use these new, optimized types, adjusting the code where necessary.
- Using a series of benchmarks, we show that our implementation, MAMOSET, can provide speedups of 1.14 to 54 times over the best prior work on dense representations, GIBBON. MAMOSET outperforms MLTON on these same benchmarks by a factor of 1.6 to 38.

2 Dense Representation: The Good, The Bad, and The Pointers

This section gives a refresher on dense representations of algebraic datatypes (Section 2.1) and, using an example, illustrates the performance challenges of picking a layout for a datatype’s dense representation (Section 2.2).

2.1 Overview

Algebraic datatypes (ADTs) are a powerful language-based technology. ADTs can express many complex data structures while, nevertheless, providing a pleasantly high level of abstraction for application programmers. The high-level specification of ADTs leaves space to experiment with low-level implementation strategies. Hence, we use ADTs and a purely functional setting for our exploration of performance implications of data layout.

In a conventional implementation of algebraic datatypes, accessing a value of a given ADT requires dereferencing a pointer to a heap object, then reading the header word, to get to the payload. Accessing the desired data may require multiple further pointer dereferences, as objects may contain pointers to other objects, requiring the unraveling of multiple layers of nesting. The whole process is often described as *pointer chasing*, a fitting name, especially when the work per payload element is low.

In a dense representation of ADTs, as implemented in GIBBON, the data constructor stores one byte for the constructor’s *tag*, followed immediately by its fields, in the hope of avoiding pointer chasing. Wherever possible, the tag value occurs inline in a bytestream that hosts multiple values. As a result, values tend to reside compactly in the heap using contiguous blocks of memory. This representation avoids or reduces pointer chasing and admits efficient linear traversals favored by modern hardware via prefetching and caching.

2.2 Running Example

The efficiency of traversals on dense representations of data structures largely depends on how well access patterns and layout match each other. Consider a datatype (already monomorphized) describing a sequence of posts in a blog¹:

¹ Throughout the paper we use a subset of Haskell syntax, which corresponds to the input language of the GIBBON compiler.

38:4 Optimizing Layout of Recursive Datatypes with Marmoset

```

emphKeyword :: String → BlogList → BlogList
emphKeyword keyword blogs = case blogs of
    Nil → Nil
    Blog content hashTags blogs' →
        case search keyword hashTags of
            True → let content' = emphContent content keyword
                    blogs'' = emphKeyword keyword blogs'
                    in Blog content' hashTags blogs''
            False → let blogs'' = emphKeyword keyword blogs'
                      in Blog content hashTags blogs''

```

Figure 1 Blog traversal motivating example.

```

data BlogList = Nil | Blog Content HashTags BlogList

```

A non-empty blog value stores a content field (a string representing the body of the blog post), a list of hash tags summarizing keywords of the blog post, and a pointer to the rest of the list.² The datatype has one point of recursion and several variable-length fields in the definition. To extend on this, Section 5.3 contains an example of tree-shaped data (two points of recursion, in particular) with a fixed-length field. The most general case of multiple points of recursion and variable-length fields is also handled by MAMOSET.

The most favorable traversal for the `Blog` datatype is the same as the order in which the fields appear in the datatype definition. In this case, GIBBON can assign the dense and pointer-free layout as shown in Figure 2a. Solid blue arrows connecting adjacent fields represent unconditional sequential accesses – i.e., reading a range of bytes in a buffer, and then reading the next consecutive range. Such a traversal will reap the benefits of locality.

On the other hand, consider a traversal with less efficient access patterns (Figure 1). The algorithm scans blog entries for a given keyword in `hashTags`. If the hash tags of a particular blog entry contain the keyword, the algorithm puts an emphasis on every occurrence of the keyword in the content field. In terms of access patterns, if we found a match in the hash tags field, subsequent accesses to the fields happen in order, as depicted in Figure 2b. Otherwise, the traversal skips over the content field, as depicted in Figure 2c.

Here we use red lines to represent accesses that must *skip over* some data between the current position in the buffer and the target data. Data may be constructed recursively and will not necessarily have a statically-known size, so finding the end of a piece of unneeded data requires scanning through that data in order to reach the target data. This extra traversal (parsing data just to find the end of it) requires an arbitrarily large amount of work because the `content` field has a variable, dynamically-allocated size.

Extra traversals that perform useful no work, like skipping over the `content` field above, can degrade the asymptotic efficiency of programs. One way to avoid such traversals is to use pointers. For instance, when GIBBON detects that it has to skip over intervening data, it changes the definition of the constructor by inserting *shortcut pointers*, which provide an exact memory address to skip to in constant time. For our example program, GIBBON introduces one shortcut pointer for the `HashTags` field, and another one for the tail of the list.

² In practice, you may want to reuse a standard list type, e.g.:

```

type BlogList = [Blog]
data Blog = Blog Content HashTags

```

but a typical compiler (including GIBBON) would specialize the parametric list type with the `Blog` type to arrive at an equivalent of the definition shown in the main text above.

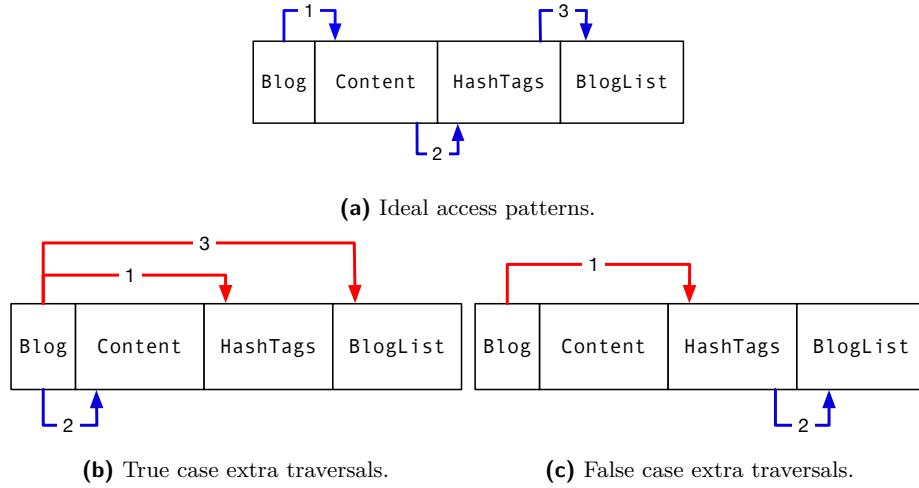

Figure 2 Showing a dense pointer-free layout with ideal accesses on top. Numbers represent the access order. Out of order accesses (red), incur costly extra traversals over fields in the middle.

The pointers provide direct accesses to the respective fields when needed and restore the constant-time asymptotic complexity for certain operations. This results in the access patterns shown in Figure 3a and 3c. Red dashed lines represent pointer-based constant-time field accesses. Otherwise, the access patterns are similar to what we had before.

The pointer-based approach in our example has two weaknesses. First, this approach is susceptible to the usual problems with pointer chasing. Second, just like with the initial solution, we access fields in an order that does not match the layout: the hash tags field is always accessed first but lives next to the content field.

MARMOSET, described in the following section, automates finding the weaknesses of the pointer-based approach and improving data layout and code accordingly. For instance, performance in our example can be improved by swapping the ordering between the `Content` and `HashTags` fields. Given this reordering, the hash tags are available directly at the start of the value, which lines up with the algorithm better, as the algorithm always accesses this field first. Additionally, our program’s `True` case (the keyword gets a hit within the hash tags) is more efficient because after traversing the content to highlight the keyword it stops at the next blog entry ready for the algorithm to make the recursive call. This improved data layout results in the more-streamlined access patterns shown in Figures 3b and 3d.

3 Design

MARMOSET infers efficient layouts for dense representations of recursive datatypes. MARMOSET’s key idea is that the best data layout should match the way a program accesses these data. Section 2 shows how this idea reduces to finding an ordering of fields in data constructors. The ordering must align with the order a function accesses those fields, in which case the optimization improves performance of the function.

To find a better layout for a datatype in the single-function case, MARMOSET first analyzes possible executions of the function and their potential for field accesses. In particular, MARMOSET takes into account (a) the various paths through a function, each of which may access fields in a different order, and (b) dependencies between operations in the function, as in the absence of dependencies, the function can be rewritten to access fields in the

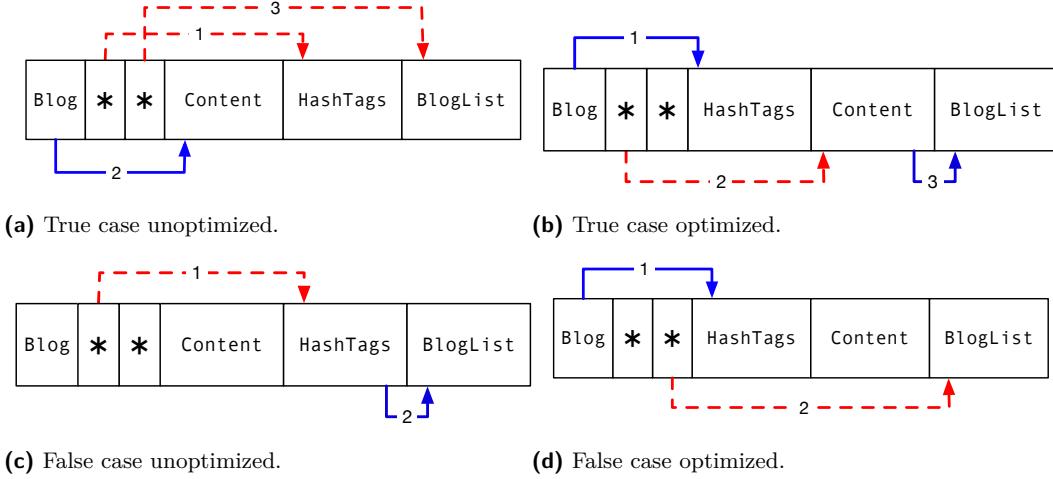

Figure 3 Showing the unoptimized representation with pointers to allow random access and the optimized layout with favorable access patterns.

original order, and that order will work best. MAMMOSSET thus constructs a control-flow graph (Section 3.2) and collects data-flow information (Section 3.3) to build a *field access graph*, a representation of the various possible orders in which a function might access fields (Section 3.4 and Section 3.5).

Once data accesses in a function are summarized in the field access graph, MAMMOSSET proceeds with synthesizing a data layout. MAMMOSSET incorporates knowledge about the benefits of sequential, strided access and the drawbacks of pointer chasing and backtracking to define an abstract cost model. The cost model allows to formulate an integer linear program whose optimal solution corresponds to a layout that minimizes the cost according to that model (Section 3.6).

The remainder of this section walks through this design in detail, and discusses how to extend the system to handle multiple functions that use a datatype (Section 3.7).

3.1 MAMMOSSET’s Language

MAMMOSSET operates on the language λ_M shown in our extended version [22]. λ_M is a first-order, monomorphic, call-by-value functional language with algebraic datatypes and pattern matching. Programs consist of a series of datatype definitions, function definitions, and a main expression. λ_M ’s expressions use A-normal form [12]. The notation \bar{x} denotes a vector $[x_1, \dots, x_n]$ and \bar{x}_i the item at position i . λ_M is an intermediate representation (IR) used towards the front end in the Gibbon compiler. The monomorphizer and specializer lower a program written in a polymorphic, higher-order subset of Haskell³ to λ_M , and then location inference is used to convert it to the *location calculus* (LoCal) code next [24]. It is easier to update the layout of types in λ_M compared to LoCal, as in λ_M the layout is implicitly determined by the ordering of fields, whereas the later LoCal IR makes the layout explicit using locations and regions (essentially, buffers and pointer arithmetic).

³ With strict evaluation semantics using `-XStrict`.

3.2 Control-Flow Analysis

Algorithm 1 Control-Flow Graph Psuedocode.

```

1: Input
2:   exp: An expression in subset of  $\lambda_M$ 
3:   weight: The likelihood of exp executing (i.e., exp's inbound edge)
4: Output
5:   A tuple of list of cfg nodes and the node id.
6: function CONTROLFLOWGRAPH(exp, weight)
7:   let nodeId = genFreshId()
8:   switch exp do
9:     case LetE (v, ty, rhs) bod
10:      let (nodes, succId) = CONTROLFLOWGRAPH(bod, weight)
11:      let newNode = (nodeId, (LetRHS (v, ty, rhs), weight), [succId])
12:      return (nodes ++ newNode, nodeId)
13:   end case
14:   case CaseE scrt cases
15:     let (nodes, successors) = CFGCASE(weight/length(cases), cases)
16:     let newNode = (nodeId, (scrt, weight), successors)
17:     return (nodes ++ [newNode], nodeId)
18:   end case
19:   case VarE v
20:     let newNode = (nodeId, (v, weight), [])
21:     return ([newNode], nodeId)
22:   end case
23: end switch
24: end function

```

We construct a control-flow graph with sub-expressions, and let-bound RHS's (right hand sides) of λ_M as the nodes. Algorithm 1 shows the psuedocode for generating the control-flow graph. Because the syntax is flattened into A-normal form, there is no need to traverse within the RHS of a let expression. Edges between the nodes represent paths between expressions. The edges consist of *weights* (Line 11) that represent the likelihood of a particular path being taken. An edge between two nodes indicates the order of the evaluation of the program. A node corresponding to a `let`-binding (Line 9) contains the bound expression and has one outgoing edge to a node corresponding to the body expression. A `case` expression (Line 14) splits the control flow n -ways, where n is the number of pattern matches. Outgoing edges of a node for a `case` expression have weights associated with them that correspond to the likelihood of taking a particular branch in the program. Control flow terminates on a leaf λ_M expression: a variable reference, a data constructor or a function application.

Figure 4a shows the control-flow graph for the running example (Figure 1). Each node corresponds to a sub-expression of the function `emphKeyword`. The first `case` expression splits the control flow into two branches, corresponding to whether the input list of blogs is empty or not. The branch corresponding to the empty input list is assigned a probability α , and the other branch is assigned a probability $1 - \alpha$. The next node corresponds to the pattern match `Blog content hashTags blogs'`. Another two-way branch follows, corresponding to whether `keyword` occurs in the `content` of this blog or not. We assign the probabilities σ and $1 - \sigma$ to these branches respectively. Note that as a result, the corresponding edges in the CFG have weights $(1 - \alpha) * \sigma$ and $(1 - \alpha) * (1 - \sigma)$, as the likelihood of *reaching* that condition is $(1 - \alpha)$. Each of these branches terminate by creating a new blog entry with its content potentially updated. In the current model, α and σ are 0.5: they are uniformly distributed.

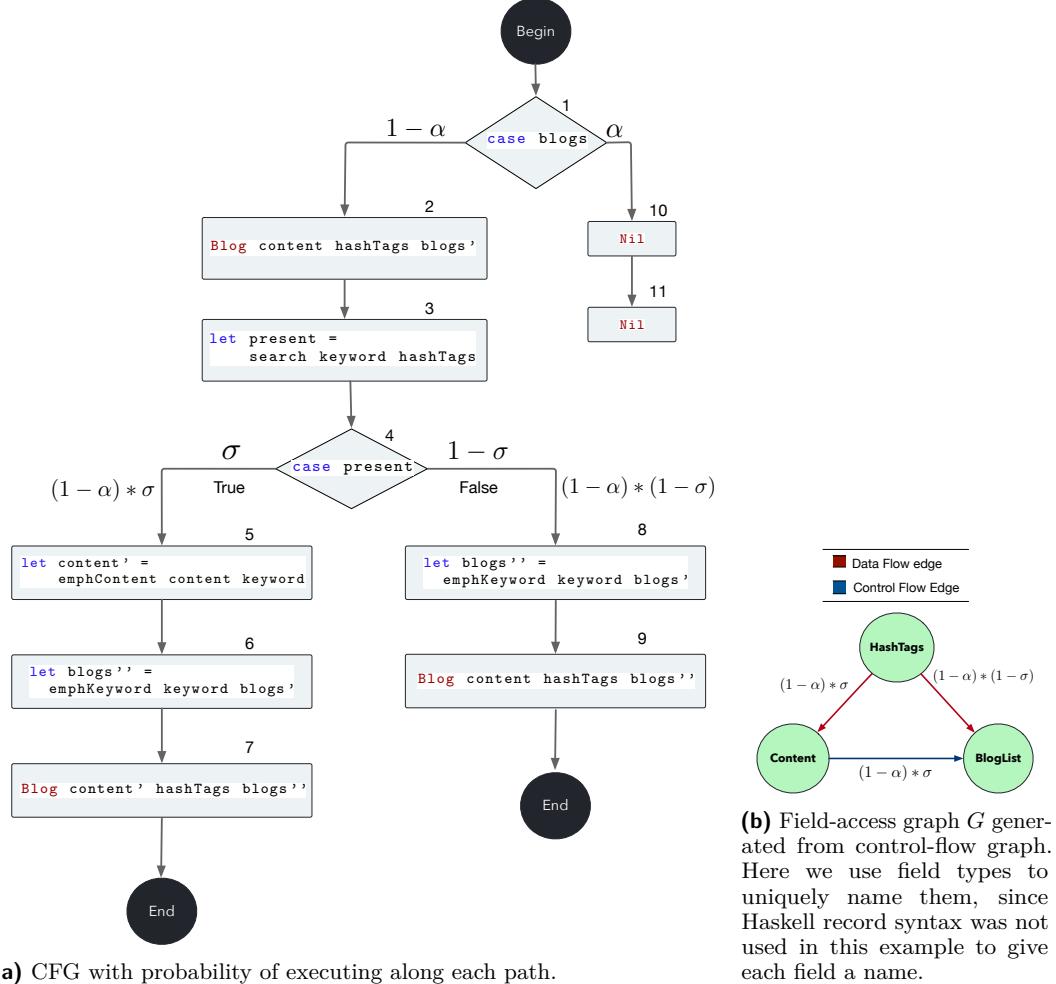

Figure 4 Control-flow and corresponding field access graphs generated for the running example.

One intuition for why realistic branch weights are not essential to MARMOSET’s optimization is that accurate weights only matter if there is a trade off between control-flow paths that are best served by different layouts. The base cases (e.g. empty list) typically contribute *no* ordering constraints, and in our experience, traversals tend to have a preferred order per function, rather than tradeoffs intra-function, which would reward having accurate, profile-driven branch probabilities. Hence, for now, we use uniform weights even when looking at the intra-function optimization.

3.3 Data Flow Analysis

We implement a straightforward analysis (use-def chain, and def-use chain) for `let` expressions to capture dependencies between `let` expressions. We use this dependence information to form dataflow edges in the field access graph (Section 3.5) and to subsequently optimize the layout and code of the traversal for performance. For *independent* `let` expressions in the function we are optimizing, we can transform the function body to have these let expressions in a different order. (Independent implies that there are no data dependencies between such `let` expressions. Changing the order of independent `let` expressions will not affect the

```

foo :: List → List
foo lst = case lst of
  Nil → Nil
  Cons x rst →
    let x' = x ^ 100
    rst' = foo rst
    in Cons x' rst'

```

(a) Function `foo` with `List`.

```

foo' :: List' → List'
foo' lst = case lst of
  Nil' → Nil'
  Cons' rst x →
    let rst' = foo' rst
    x' = x ^ 100
    in Cons' rst' x'

```

(b) Function `foo'` with `List'`.**Figure 5** Two different traversals on a list.

correctness of code, modulo exceptions.) However, we do such a transformation only when we deem it to be more cost efficient. In order to determine when re-ordering `let` expressions is more cost efficient, we classify fields based on specific attributes next.

3.4 Field Attributes For Code Motion

When trying to find the best layout, we may treat the code as immutable, but allowing ourselves to move the code around (i.e. change the order of accesses to the fields) unlocks more possibilities for optimizing layout. Not all code motions are valid due to data dependencies in the traversal. For instance, in a sequence of two `let` binders, the second one may reference the binding introduced in the first one: in this case, the two binders cannot be reordered.

To decide which code motions are allowed, we classify each field with one or more of the attributes: *recursive*, *scalar*, *self-recursive*, or *inlineable*. Some of these attributes are derived from the ADT definition and some from the code using the ADT. A *scalar* field refers to a datatype only made up of either other primitive types, such as `Int`. A *recursive* field refers to a datatype defined recursively. A *self-recursive* field is a recursive field that directly refers back to the datatype being defined (such as a `List` directly referencing itself). Finally, we call a field *inlineable* if the function being optimized makes a recursive call into this field (i.e. taking the field value as an argument). Hence, an *inlineable* field is necessarily a recursive field. As we show in the example below, the *inlineable* attribute is especially important when choosing whether or not to do code motion.

A single field can have multiple attributes. For instance, a function `traverse` doing a pre-order traversal on a `Tree` makes recursive calls on both the left and right children. The left and right children are recursive and self-recursive. Therefore, when looking at the scope of `traverse`, the left and right children have the attributes *recursive*, *self-recursive* and *inlineable*.

Example. Consider the example of a list traversal shown in Figure 5a. Here the function `foo` does some work on the `Int` field (it raises the `Int` to the power of 100) and then recurs on the tail of the list. Since MARMOSET compiles to dense representations, a `List`'s representation in memory stores the `Cons` tag (one byte) followed by the `Int` (8 bytes) followed by the next `Cons` tag and so on. Hence, the `Cons` tag and the `Int` field are interleaved together in memory. The function `foo` becomes a stream processor that consumes one stream in memory and produces a dense output buffer of the same type.

Alternatively, another layout of a list follows from the following definition:

```
data List' = Nil' | Cons' List' Int
```

In memory, the list has all `Cons'` tags next to each other (a unary encoding of array length!) and the `Int` elements all next to each other. In such a scenario, the performance of our traversal `foo` on the `List'` can improve traversal performance due to locality when accessing

38:10 Optimizing Layout of Recursive Datatypes with Marmoset

elements stored side-by-side⁴. However, this only works if we can subsequently change the function that traverses the list to do recursion on the tail of the list first and then call the exponentiation function on the `Int` field after the recursive call. If there are no data dependencies between the recursive call and the exponentiation function, then this is straightforward. We show `foo'` with the required code motion transformation to function `foo` accompanied with the change in the data representation from `List` to `List'` as shown in Figure 5b.

To optimize the layout, the tail of the list is assigned the attribute of `inlineable`. This attribute is used by the solver to determine a least-cost ordering to the `List` datatype in the scope of function `foo`. Whenever such code motion is possible, MAMOSET will place the `inlineable` field first and use code-motion to change the body of the function to perform recursion first if data flow dependencies allow such a transformation.

Structure of arrays. The transformation of `List/foo` to `List'/foo'` is similar to changing the representation of the `List` datatype to a *structure of arrays*, which causes the same types of values to be next to each other in memory. In particular, we switch from alternating constructor tags and integer values in memory to an array of constructor tags followed by an array of integers.

Note that the traversals `foo` and `foo'` have access patterns that are completely aligned with the data layout of `List` and `List'` respectively. The resulting speedup is solely a consequence of the *structure of arrays* effect. This is an added benefit to the runtime in addition to ensuring that the access patterns of a traversal are aligned with the data layout of the datatype it traverses.

3.5 Field Access Pattern Analysis

After constructing the CFG and DFG for a function definition, we utilize them to inspect the type of each of the function's input parameters – one data constructor at a time – and construct a *field-access graph* for it. Algorithm 2 shows the pseudocode for generating the field-access graph. This graph represents the temporal ordering of accesses among its fields.

The fields of the data constructor form the nodes of this graph. A directed edge from field f_i to field f_j is added if f_i is accessed immediately before f_j . Lines 13 to 24 in Algorithm 2 show how we keep track of the last accessed field and form an edge if possible. A directed edge can be of two different types. In addition, each edge has a associated weight which indicates the likelihood of accessing f_i before f_j , which is computed using the CFG. An edge can either be a data-flow edge or a control-flow edge (Lines 18 and 20). In Figure 4b, the red edge is a data flow edge and the blue edge is a control flow edge.

Data-Flow Edge indicates an access resulting from a data flow dependence between the fields f_i and f_j . In our source language, a data flow edge is induced by a `case` expression. A data flow edge implies that the code that represents the access is rigid in structure and changing it can make our transformation invalid.

Control-Flow Edge indicates an access that is not data-flow dependent. It is caused by the control flow of the program. Such an edge does not induce strict constraints on the code that induces the edge. The code is malleable in case of such accesses. This gives way to an

⁴ However, this effect can disappear if the elements are very large or the amount of work done per element becomes high, such that the percent of time loading the data is amortized.

Algorithm 2 Recursive function for generating the field access graph.

```

1: Input
2:   cur: current CFG node from which to start processing
3:   dcon: data constructor for which we are searching the best layout
4:   edges: field-access graph built so far
5:   lastAccessedVar: last accessed variable name, initially None
6:   dfgMap: set of data-flow edges between variables
7: Output
8:   Field access graph represented as a list of edges
9: function FIELDACCESSGRAPH(cur, dcon, edges, lastAccessedVar, dfgMap)
10:  let ((expr, weight), successors) = cur
11:  let mutable lastAccessedVarMut = lastAccessedVar
12:  let mutable edges' = edges
13:  for var : ORDEREDFREEVARIABLES(expr) do
14:    if !BOUNDPATTERNMATCHONDCON(var, dcon) then
15:      continue
16:    end if
17:    if lastAccessedVarMut != None then
18:      mutate edges' = ADDEdge(edges', ((lastAccessedVar, var), weight), ControlFlowTag)
19:      if LOOKUP((lastAccessedVar, var), dfgMap) then
20:        mutate edges' = ADDEdge(edges', ((lastAccessedVar, var), weight), DataFlowTag)
21:      end if
22:    end if
23:    mutate lastAccessedVarMut = var
24:  end for
25:  for succ : successors do
26:    let edges'' = FIELDACCESSGRAPH(succ, dcon, edges', lastAccessedVarMut, dfgMap)
27:    mutate edges' = MERGE(edges', edges'')
28:  end for
29:  return edges'
30: end function

```

optimization search space via code motion of `let` expressions. The optimization search space involves transformation of the source code, i.e, changing the access patterns at the source code level.

The field-access graph G is a directed graph, which consists of edges of the two types between fields of a datatype and can have cycles. The directed nature of the edges enforces a temporal relation between the corresponding fields. More concretely, assume that an edge e that connects two vertices representing fields fe_a (source of e) and fe_b (target of e). We interpret e as an evidence that field fe_a is accessed before field fe_b . The weight w for the edge e is the probability that this access will happen based on statically analyzing a function.

In our analysis, for a unique path through the traversal, we only account for the *first* access to any two fields. If two fields are accessed in a different order later on, the assumption is that the start address of the fields is likely to be in cache and hence it does not incur an expensive fetch call to memory. In fact, we tested our hypothesis by artificially making an example where say field f_a is accessed first, field f_b is accessed after f_a after which we constructed multiple artificial access edges from f_b to f_a , which might seem to suggest placing f_b before f_a . However, once the cache got warmed up and the start addresses of f_a and f_b are already in cache, the layout did not matter as much. This suggests that prioritizing for the first access edge between two unique fields along a unique path is sufficient for our analysis.

Two fields can be accessed in a different order along different paths through a traversal. This results in two edges between the fields. (The edges are in reversed order.) We allow at most two edges between any two vertices with the constraint that they have to be in the opposite direction and come from different paths in the traversal. If two fields are accessed in the same order along different paths in the traversal, we simply add the probabilities and merge the edges since they are in the same direction.

In order to construct G , we topologically sort the control-flow graph of a function and traverse it in the depth-first fashion via recursion on the successors of the current cfg node (Lines 25 to 28). As shown in line 14, we check if a variable is an alias to a field in the data constructor for which we are constructing the field-access graph G . As we process each node (i.e. a primitive expression such as a single function call), we update the graph for any direct or indirect references to input fields that we can detect. We ignore new variable bindings that refer to newly allocated rather than input data – they are not tracked in the access graph. We traverse the control-flow graph once, but we maintain the last-accessed information at each CFG node, so when we process a field access at an expression, we consult what was previously-accessed at the unique predecessor of the current CFG node. Figure 4b shows the generated access graph from the control-flow graph in Figure 4a. It also shows the probability along each edge obtained from the control-flow graph.

As we are traversing the nodes of the control-flow graph and generating directed edges in G , we use the likelihood of accessing that cfg node as the weight parameter (Line 10).

3.6 Finding a Layout

We use the field-access graph G to encode the problem of finding a better layout as an Integer Linear Program (ILP). Solving the problem yields a cost-optimal field order for the given pair of a data constructor and a function.

3.6.1 ILP Constraints

In our encoding, each field in the data constructor is represented by a variable, f_0, f_1, \dots . As a part of the result, each variable will be assigned a unique integer in the interval $[0, n - 1]$, where n is the number of fields. Intuitively, each variable represents an index in the sequence of fields.

The ILP uses several forms of constraints, including two forms of *hard* constraints:

$$\forall_{0 \leq i < n} \quad 0 \leq f_i < n \tag{1}$$

$$\forall_{0 \leq i < j < n} \quad f_i \neq f_j \tag{2}$$

The constraints of form 1 ensure that each field is mapped to a valid index, while the constraints of form 2 ensure that each field has a unique index. Constraints of either form must hold because each field must be in a valid location.

Hard constraints define valid field orderings but not all such reorderings improve efficiency, MAMOSET's main goal. To fulfil the goal, beside the hard constraints we introduce *soft* ones. Soft constraints come from the field access analysis. For example, assume that based on the access pattern of a function, we would *prefer* that field a goes before field b . We turn such a wish into a constraint. If the constraint cannot be satisfied, it will not break the correctness. In other words, such constraints can be broken, and that is why we call them soft.

3.6.2 Cost Model

MARMOSET encodes these soft constraints in the form of an abstract cost model that assigns a cost to a given layout (assignment of fields to positions) based on how efficient it is expected to be given the field-access graph.

To understand the intuition behind the cost model, note that the existence of an edge from field f_i to field f_j in the field-access graph means that there exists at least one path in the control-flow graph where f_i is accessed and f_j is the next field of the data constructor that is accessed. In other words, the existence of such an edge implies a preference *for that control-flow path* for field f_i to be immediately before field f_j in the layout so that the program can continue a linear scan through the packed buffer. Failing that, it would be preferable for f_j to be “ahead” of f_i in the layout so the program does not have to backtrack in the buffer. We can thus consider the costs of the different layout possibilities of f_i and f_j :

C_{succ} (f_j immediately after f_i): This is the best case scenario: the program traverses f_i and then uses f_j .

C_{after} (f_j after f_i in the buffer): If f_j is after f_i , but not *immediately* after, then the code can proceed without backtracking through the buffer, but the intervening data means that either a shortcut pointer or a extra traversal must be used to reach f_j , adding overhead.

C_{pred} (f_j immediately before f_i): Here, f_j is *earlier* than f_i in the buffer. Thus, the program will have already skipped past f_j , and some backtracking will be necessary to reach it. This incurs *two* sources of overhead: skipping past f_j in the first place, and then backtracking to reach it again.

C_{before} (f_j before f_i in the buffer): If, instead, f_j is farther back in the buffer than f_i , then the cost of skipping back and forth is greater: in addition to the costs of pointer dereferencing, because the fields are far apart in the buffer, it is less likely f_j will have remained in cache (due to poorer spatial locality).

We note a few things. First, the *exact* values of each of these costs are hard to predict. The exact penalty a program would pay for jumping ahead or backtracking depends on a variety of factors such as cache sizes, number of registers, cache line sizes, etc.

However, we use our best intuition to statically predict these costs based on the previously generated access graph. Note the existence of two types of edges in our access graph. An edge can either be a data-flow edge or a control-flow edge. For a data flow edge, the code is rigid. Hence the only axis we have available for transformation is the datatype itself. For a data flow edge, the costs are showed in Eq 3. Here, we must respect the access patterns in the original code which lead to the costs in Eq 3.

$$C_{succ} < C_{after} < C_{pred} < C_{before} \quad (3)$$

Note that a control-flow edge signifies that the direction of access for an edge is transformable. We could reverse the access in the code without breaking the correctness of the code. We need to make a more *fine-grained* choice. This choice involves looking at the attributes of the fields and making a judgement about the costs given we know the attributes of the fields. As shown in Sec 3.4 we would like to have the field with an *inlineable* attribute placed first. Hence, in our cost model, if f_i is inlineable, then we follow the same costs in Eq 3. However, if f_j is inlineable and f_i is not, we would like f_j to be placed before f_i . For such a layout to endure, the costs should change to Eq 4. For other permutations of the attributes, we use costs that prioritize placing the inlineable field/s first.

$$C_{pred} < C_{before} < C_{succ} < C_{after} \quad (4)$$

3.6.3 Assigning Costs to Edges

MARMOSET uses the field-access graph and the cost model to construct an objective function for the ILP problem. Each edge in the access graph represents one pair of field accesses with a preferred order. Thus, for each edge $e = (i, j)$, MARMOSET can use the indices of the fields f_i and f_j to assign a cost, c_e , to that pair of accesses following the rules below.

- If f_j is right after f_i , then assign cost C_{succ} , i.e.: $(f_j - f_i) = 1 \implies c_e = C_{succ}$.
- If f_j is farther ahead of f_i , then assign cost C_{after} , i.e.: $(f_j - f_i) > 1 \implies c_e = C_{after}$.
- If f_j is immediately before f_i , then assign cost C_{pred} , i.e.: $(f_j - f_i) = -1 \implies c_e = C_{pred}$.
- And if f_j is farther before f_i , then assign cost C_{before} , i.e.: $(f_j - f_i) < -1 \implies c_e = C_{before}$.

The cost of each edge, c_e must be multiplied by the *likelihood* of that edge being exercised, p_e , which is also captured by edge weights in the field-access graph. Combining these gives us a total estimated cost for any particular field layout:

$$C = \sum_{e \in E} c_e \cdot p_e \quad (5)$$

This is the cost that our ILP attempts to minimize, subject to the hard constraints 1 and 2.

3.6.4 Greedy layout ordering

Finding an optimal layout using an external solver hurts compile times. To solve this tradeoff, we propose a simple algorithm that traverses the field access graph in a *greedy* fashion. The algorithm starts from the root node of the graph, which corresponds to the field accessed first in the function, and greedily visits the child nodes based on the edge weights. We fix the edge order for a control-flow edge as the original order and do not look at field attributes. However, after the greedy algorithm picks a layout we match the let expressions to the layout order to make sure the code matches the layout order. The greedy algorithm is potentially sub-optimal when it comes to finding the best performing layout; however, the compile time is fast.

3.7 Finding a global layout

A data constructor can be used across multiple functions, therefore, we need to find a layout order that is optimal globally. To do so, we take constraints for each function and data constructor pair and combine them uniformly, that is, a uniform weight for each function. We then feed the combined constraints to the solver to get a globally optimal layout for that data constructor. The global optimization finds a globally optimal layout for all data constructors in the program. Once the new global layout is chosen for a data constructor, we re-write the entire program such that each data constructor uses the optimized order of fields. In the evaluation, we use the global optimization. However, we only show the data constructor that constitutes the major part of the program.

3.8 Finding a layout for functions with conflicting access patterns

Consider the datatype definition `D` with two fields `A`, `B`:

```
data D = D A B
```

If two functions, `f1` and `f2`, access the fields of `D` in the opposite orders, we get conflicting access patterns for `D`. For instance, assume `f1` accesses `A` first and then `B`, while `f2` accesses

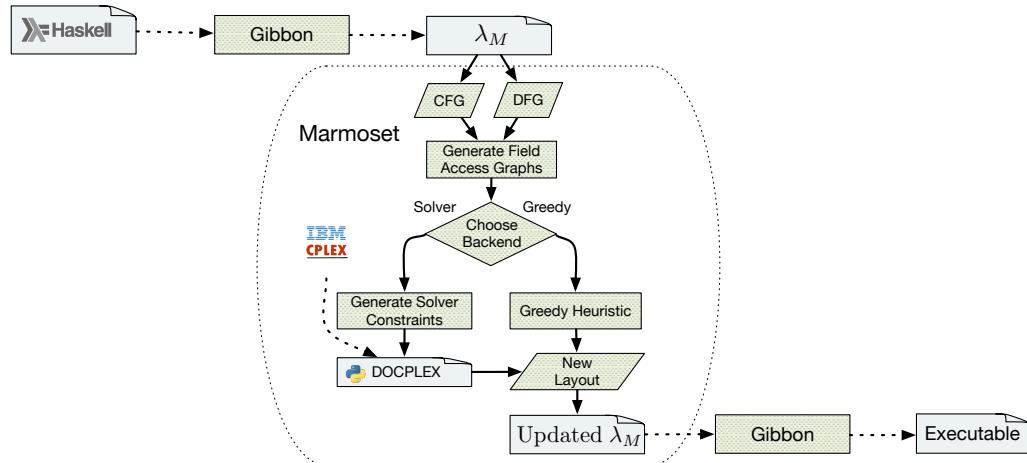

Figure 6 The overall pipeline of MAMOSET.

B first and then A. After combining edges across the two functions, we get two edges in opposition to each other. Since we use uniform weights for all functions, the edges will also have a uniform weight. As a result, placing A before B or vice versa are equally good in our cost model, and MAMOSET defers to the solver to get one of the two layouts.

With the two equally good layouts, MAMOSET’s solver (the default mode) chooses the layout favoring the function it picked first. For instance, if `f1` is defined earlier in the program, the order favoring `f1` will be picked. In the greedy mode, since both A and B are root nodes, MAMOSET will pick the first root node in the list of root nodes, which is, again, dependent on the ordering of functions in the source code.

4 Implementation

We implement MAMOSET in the open-source Gibbon compiler⁵. Figure 6 gives an overview of the overall pipeline. Gibbon is a whole-program micropass compiler that compiles a polymorphic, higher-order subset of (strict) Haskell.

The Gibbon front-end uses standard whole-program compilation and monomorphization techniques [7] to lower input programs into a first-order, monomorphic IR (λ_M). Gibbon performs location inference on this IR to convert it into a LoCal program, which has regions and locations, essentially, buffers and pointer arithmetic. Then a big middle section of the compiler is a series of LoCal \rightarrow LoCal compiler passes that perform various transformations. Finally, it generates C code. Our extension operates towards the front-end of the compiler, on λ_M . We closely follow the design described in Section 3 to construct the control-flow graph and field-access graph, and use the standard Haskell graph library⁶ in our implementation.

To solve the constraints, we use IBM’s DOCPLEX (Decision Optimization CPLEX), because its API allows high level modelling such as logical expressions like implications, negations, logical AND etc. with relatively low overhead. Unfortunately, there isn’t a readily available Haskell library that can interface with DOCPLEX. Thus, we use it via its library bindings available for Python. Specifically, we generate a Python program that feeds the constraints to DOCPLEX and outputs an optimum field ordering to the standard output, which MAMOSET reads and parses, and then reorders the fields accordingly.

5 Evaluation

We evaluate MAMMOSET on three applications. First is a pair of microbenchmarks (Section 5.2) – a list length function and a logical expression evaluator – that help us explore performance penalties imposed by a sub-optimal data layout. Second is a small library of operations with binary trees (Section 5.3). Third is a blog management software based on the [BlogList](#) example from the Sections 2–3 (Section 5.4). Besides the run times, we take a closer look at how MAMMOSET affects cache behavior (Section 5.5) and compile times (Section 5.6). Finally, we discuss evaluation and its scale (Section 5.7).

We detail the impact of various datatype layouts on the performance. As the baseline, we use GIBBON, the most closely related prior work. We also compare MAMMOSET with MLTON (Section 5.4.2). For each benchmark, we run 99 iterations and report the run-time mean and the 95% confidence interval.

5.1 Experimental Setup

We run our benchmarks on a server-class machine with 64 CPUs, each with two threads. The CPU model is AMD Ryzen Threadripper 3990X with 2.2 GHz clock speed. The L1 cache size is 32 KB, L2 cache size is 512 KB and L3 cache size is 16 MB. We use GIBBON’s default C backend and call GCC 10.2.0 with `-O3` to generate binaries.

5.2 Micro Benchmarks

ListLength. This benchmark computes the length of a linked-list and demonstrates the cost of de-referencing memory addresses that are not present in the cache. It uses the linked list datatype:

```
data List = Nil | Cons Content List
```

If each element of the list is constructed using `Cons`, the traversal has to de-reference a pointer – to *jump over* the content – each time to access the tail of the list. This is an expensive operation, especially if the target memory address is not present in the cache. In contrast, if the `Content` and `List` fields were swapped, then to compute the length, the program only has to traverse n bytes for a list of length n – one byte per `Cons` tag – which is extremely efficient. Essentially, MAMMOSET transforms program to use the following datatype, while preserving its behavior:

```
data List' = Nil' | Cons' List' Content
```

In our experiment, the linked list is made of 3M elements and each element contains an instance of the *Pandoc Inline* datatype that occupies roughly 5KB. As seen in table 1⁷, the performance of the list constructed using the original `List` is $\sim 42 \times$ worse than the performance with the MAMMOSET-optimized, flipped layout. Not only does `List` have poor data locality and cache behavior, but it also has to execute more instructions to de-reference the pointer. Both M_{greedy} and M_{solver} choose the flipped layout `List'`.

LogicEval. This microbenchmark implements a short-circuiting logical expressions evaluator and runs it over synthetically generated, balanced syntax-trees with the height of 30. The intermediate nodes can be one of `Not`, `Or`, or `And`, selected at random, and the leaves hold boolean values. The syntax-tree datatype is defined as follows:

```
data Exp = Val Bool | Not Exp | Or Exp Exp | And Exp Exp
```

⁷ The performance of `List'` layout compiled with GIBBON differs from MAMMOSET as code motion to reorder let expressions results in different code. In addition to a noisy server.

Table 1 Run-time mean and 95% confidence interval (ub, lb) for different layouts (seconds). The last two columns show the run time for the layouts chosen by M_{greedy} and M_{solver} . The numbers in blue correspond to the lowest running time and the numbers in red correspond to the highest running time. Legend: l – left subtree, r – right subtree of the tree.

Benchmark name	GIBBON		MAMMOSET	
	List	List'	M_{greedy}	M_{solver}
ListLength	62.34 (62.26, 62.41)	1.51 (1.44, 1.59)	1.49 (1.41, 1.56)	1.50 (1.42, 1.58)
	lr	rl	M_{greedy}	M_{solver}
LogicEval	4.45 (4.42, 4.48)	6.60 (6.59, 6.61)	3.56 (3.53, 3.58)	3.55 (3.55, 3.55)
Rightmost	384.4 (368.4, 400.3)	314.5 (303.7, 325.3)	306.9 (295.6, 318.2)	303.1 (292.6, 313.6)

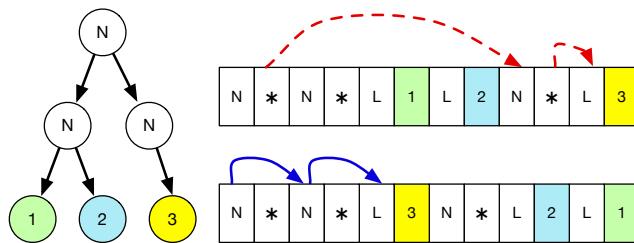

Figure 7 Rightmost: access patterns for, left-to-right (top) and right-to-left (bottom) serializations.

We measure the performance of the evaluator for different orders of the left and right subtrees. Since the short circuiting evaluates from left to right order of the `Exp`, changing the order of the left and right subtrees would affect the performance of the traversal. As can be seen in Table 1, the layout where the left subtree is serialized before the right subtree results in better performance compared to the tree where the right subtree is serialized before the left one. This is as expected since in the latter case, the traversal has to jump over the right subtree serialized before the left one in order to evaluate it first and then depending on the result of the left subtree possibly jump back to evaluate the right subtree. This results in poor spatial locality and hence worse performance. M_{greedy} and M_{solver} are able to identify the layout transformations that would give the best performance, which matches the case where the left subtree is serialized before the right subtree (Table 1⁸).

5.3 Binary Tree Benchmarks

We evaluate MAMMOSET on a few binary tree benchmarks: adding one to all values in a tree, exponentiation on integers stored in internal nodes, copying a tree and getting the right-most leaf value in the tree. For the first three benchmarks, the tree representation we use is:

```
data Tree = Leaf | Node Int Tree Tree
```

⁸ The layout chosen by M_{greedy} and M_{solver} is same as lr, the performance differs from the lr layout compiled with GIBBON as MAMMOSET does code motion which results in different code.

Table 2 Run-time mean and 95% confidence interval (ub, lb) for different layouts and traversal orders in the binary tree benchmarks (seconds). MISALGN_{pre} – post-order traversal on the pre-order layout of the tree. MISALGN_{post} – pre-order traversal on the post-order layout of the tree. ALGN_{pre} – pre-order traversal on the pre-order layout of the tree. ALGN_{in} – in-order traversal on an in-order layout of the tree. ALGN_{post} – post-order traversal on the post-order layout of the tree.

Benchmark name	GIBBON					MAMMOSET	
	MISALGN _{pre}	MISALGN _{post}	ALGN _{pre}	ALGN _{in}	ALGN _{post}	M _{greedy}	M _{solver}
AddOneTree	45.51 (45.35, 45.66)	memory error	1.29 (1.29, 1.29)	1.30 (1.30, 1.30)	1.29 (1.29, 1.29)	1.29 (1.29, 1.29)	1.28 (1.28, 1.28)
ExpTree	45.52 (45.34, 45.70)	memory error	1.31 (1.31, 1.31)	1.31 (1.31, 1.31)	1.29 (1.29, 1.29)	1.31 (1.31, 1.31)	1.29 (1.29, 1.29)
CopyTree	45.52 (45.37, 45.67)	memory error	1.29 (1.29, 1.29)	1.30 (1.30, 1.30)	1.28 (1.28, 1.28)	1.29 (1.29, 1.29)	1.28 (1.28, 1.28)

For right-most, the tree representation we use is:

```
data Tree = Leaf Int | Node Tree Tree
```

AddOneTree. This benchmark takes a full binary tree and increments the values stored in the internal nodes of the tree. We show the performance of an aligned preorder, inorder and postorder traversal in addition to a misaligned preorder and postorder traversal of the tree. Aligned traversals are ones where the data representation exactly matches the traversal order, for instance, a preorder traversal on a preorder representation of the tree. A misaligned traversal order is where the access patterns of the traversal don't match the data layout of the tree. For instance, a postorder traversal on a tree serialized in preorder. Table 2 shows the performance numbers. M_{solver} picks the aligned postorder traversal order which is best performing. It makes the recursive calls to the left and right children of the tree first and increments the values stored in the internal nodes once the recursive calls return. The tree representation is also changed to a postorder representation with the Int placed after the left and right children of the tree. This is in part due to the structure of arrays effect, as the Int are placed closer to each other. M_{greedy} on the other hand picks the aligned preorder traversal because of its greedy strategy which prioritizes placing the Int before the left and right subtree. The tree depth is set to 27. At this input size, the MISALGN_{post} traversal failed due to memory errors, and MISALGN_{pre} runs ~35× slower than aligned versions because of the skewed access patterns of the traversal.

ExpTree. This traversal does exponentiation on the values stored in the internal nodes of the tree. It is more computationally intensive than incrementing the value. We raise the Int to a power of 10 on a tree of depth 27. Table 2 shows the performance of the different layout and traversal orders. M_{solver} picks the ALGN_{post} representation which is the best performing, whereas M_{greedy} picks the ALGN_{pre} representation.

CopyTree. Copy-tree takes a full binary tree and makes a fresh copy of the tree in a new memory location. We use a tree of depth 27 in our evaluation. Table 2 shows the performance of different layout and traversal orders. We see that ALGN_{post} traversal performs the best. Indeed, M_{solver} picks the ALGN_{post} representation, whereas, M_{greedy} chooses the ALGN_{pre} representation.

Rightmost. This traversal does recursion on the right child of the tree and returns the Int value stored in the right-most leaf of the tree. Figure 7 shows an example of a tree with two different serializations of the tree: left-to-right (top) and right-to-left (bottom).

Table 3 Run-time mean and 95% confidence interval (ub, lb) for different layouts in the blog software benchmarks (seconds). Several possible permutations of layout are shown. Layout names abbreviations: h – Header, t – HashTags, b – Blogs, i – TagID, c – Content, a – Author, d – Date.

Bench.	GIBBON							MAMMOSET	
name	hiadctb	ctbhiad	tbchiad	tcbhiad	btchiad	bchiadt	cbiadht	M_{greedy}	M_{solver}
FilterBlogs									
	0.22 (0.22, 0.22)	0.22 (0.22, 0.22)	0.08 (0.08, 0.08)	0.27 (0.26, 0.27)	0.28 (0.28, 0.28)	0.29 (0.29, 0.30)	0.21 (0.21, 0.21)	0.07 (0.07, 0.07)	0.06 (0.06, 0.06)
EmphContent									
	0.67 (0.67, 0.67)	0.65 (0.65, 0.65)	1.60 (1.60, 1.60)	0.66 (0.66, 0.66)	1.63 (1.63, 1.63)	1.61 (1.61, 1.61)	0.47 (0.47, 0.47)	0.47 (0.47, 0.47)	0.64 (0.64, 0.64)
TagSearch									
	1.99 (1.99, 1.99)	1.98 (1.98, 1.98)	3.29 (3.29, 3.30)	1.68 (1.68, 1.68)	3.31 (3.31, 3.31)	3.30 (3.30, 3.30)	1.82 (1.82, 1.82)	1.76 (1.76, 1.76)	1.74 (1.74, 1.74)

The right-to-left serialization is more efficient because the constant-step movements (blue arrows) are usually more favorable than variable-step ones (red arrows) on modern hardware. Both M_{solver} and M_{greedy} pick the right-to-left serialization, and Table 1 shows that this choice performs better in the benchmark.

5.4 Blog Software Case Study

The Blog software case study serves as an example of a realistic benchmark, representing a sample of components from a blog management web service. The main data structure is a linked list of blogs where each blog contains fields such as header, ID, author information, content, hashtags and date. The fields are a mix of recursive and non-recursive datatypes. For instance, `Content` is a recursive type (the Pandoc `Block` type), but `Author` is a single string wrapped in a data constructor.⁹ One possible permutation of fields in the blog is:

```
data Blogs = Empty | HIADCTB Header Id Author Date Content HashTags Blogs
```

We evaluate MAMMOSET’s performance using three different traversals over a list of blogs. Overall, the traversals accept a keyword and a list of blogs; in the blogs, the traversals inspect either of the three fields: `Content`, `HashTags`, and the tail of the linked-list, `Blogs`. (Since `Blogs`, `Content`, and `HashTags` are recursive fields, changing their layout should represent greater differences in performance.) The fields used by an individual traversal are referred as *active fields* and the rest are referred as *passive fields*, and we specify these per-traversal below.

In Table 3, we report the performance of the six possible layouts obtained by permuting the order of the three recursive fields, and two additional layouts (Columns 1 and 2). The column names indicate the order of fields used; for example, the column `hiadctb` reports numbers for the layout with fields ordered as: `Header`, `Id`, `Author`, `Date`, `Content`, `HashTags`, and `Blogs`. All run times are gathered with GIBBON, and last two columns show the run times for code compiled using MAMMOSET’s greedy and solver-based optimization, respectively.

⁹ At times, we have to wrap scalars in data constructors to make them packed fields. GIBBON does not always support mixing scalar and packed fields due to compiler bugs.

FilterBlogs filters the list of blogs and only retains those which contain the given keyword in the `HashTags` field. The *active fields* for this traversal are `HashTags` and `Blogs`. Theoretically, the performance of this traversal is optimized when the `HashTags` field is serialized before `Blogs` on account of the first access to `HashTags` in the traversal. This is confirmed in practice with the layout ***tbchiad*** being the fastest. MAMOSET chooses the layout with `HashTags` serialized first and followed by `Blogs`; the order of other fields remains unchanged compared to the source program, but this has no effect on performance since they are *passive fields*. Table 3 also shows that layout chosen by MAMOSET performs similar to the layout ***tbchiad***. Both M_{solver} and M_{greedy} pick the layout ***tbhiadc*** when compiled from the initial layout ***hiadctb***.

EmphContent searches the content of each blog for the keyword and emphasizes all its occurrences there (if any). The active fields in this traversal are `Content` and `Blogs`. Based on the access pattern (`Content` accessed before `Blogs`), the layout with the best performance should place `Content` first followed by `Blogs`. In practice, the layout with the best performance is ***cbiadht***. In contrast, M_{solver} prioritizes the placement of `Blogs` before `Content`, but it also changes the traversal to recurse on the blogs first and then emphasize content. The passive fields are placed afterwards. The layout chosen by M_{solver} is ***bchiadt***, whereas the layout chosen by M_{greedy} is ***cbhiadt*** when compiled from the initial layout ***hiadctb***. The performance of M_{greedy} and M_{solver} differ because datatypes other than `Blogs` differ in their layout choices.

TagSearch looks for the presence of the keyword in the `HashTags` field, and if the keyword is present, the traversal emphasizes the keyword in the `Content`. The layout with the best performance is ***tcbhiad*** because of the access pattern, which inspects `HashTags` followed by `Content` followed by `Blogs`. M_{solver} chooses the layout ***tbchiad*** – which places `HashTags` followed by `Blogs` followed by `Content` – and changes the traversal to recurse on `Blogs` first and later emphasize `Content` in the `then` branch. On the other hand, M_{greedy} chooses ***tcbhiad*** when compiled from the initial layout ***hiadctb***.

5.4.1 Globally optimizing multiple functions

We use MAMOSET to globally optimize the three blog traversals we discussed above such that we pick one layout for all traversals that minimizes the overall runtime. Table 4 shows the runtime for a layout we compiled using GIBBON (***hiadctb***), M_{solver} (***tbchiad***) and M_{greedy} (***tbchiad***). We see that M_{greedy} and M_{solver} do a good job in reducing the traversal time globally. All the three traversals are run in a pipelined fashion sequentially. Although, M_{solver} does worse with `TagSearch` when run in a pipelined manner, it is actually better performing with M_{solver} when run alone as seen in table 3. Note that M_{solver} changes more than one data constructor based on the `inlineable` attribute that M_{greedy} does not. For instance, M_{solver} uses a packed `Inline` list in the `Content` with the tail serialized before `Inline`. Whereas, M_{greedy} uses a conventional packed list. In a pipelined execution of the traversals, although this helps reduce the runtime in the case of the content search traversal, it inadvertently increases the runtime in case of the tag search traversal due to a cache effect that can benefit from runtime information.

5.4.2 Comparison of MAMOSET against MLTON

We compare MAMOSET’s performance to MLTON, which compiles programs written in Standard ML, a strict language, to executables that are small with fast runtime performance.

Table 4 Run-time mean and 95% confidence interval (ub, lb) for the blog software benchmarks when MAMROSET optimizes the data layout globally (seconds). The input parameters are different from the single-function optimization case.

Figure 8 shows the speedup of MAMROSET over MLTON. As shown, the performance of MAMROSET is better than MLTON by significant margins for all the layouts and traversals. Since ADTs in MLTON are *boxed* – even though native integers or native arrays are *unboxed* – such a behavior is expected because it adds more instructions (pointer de-referencing) and results in worse spatial locality.

5.5 Cache behavior

The results from earlier sections demonstrate that MAMROSET’s layout choices improve run-time performance. This section investigates *why* performance improves. The basic premise of MAMROSET’s approach to layout optimization is to concentrate on minimizing how often a traversal needs to backtrack or skip ahead while processing a buffer. By minimizing this jumping around, we expect to see improvements from two possible sources. First, we expect to see an improvement in instruction counts, as an optimized layout should do less pointer

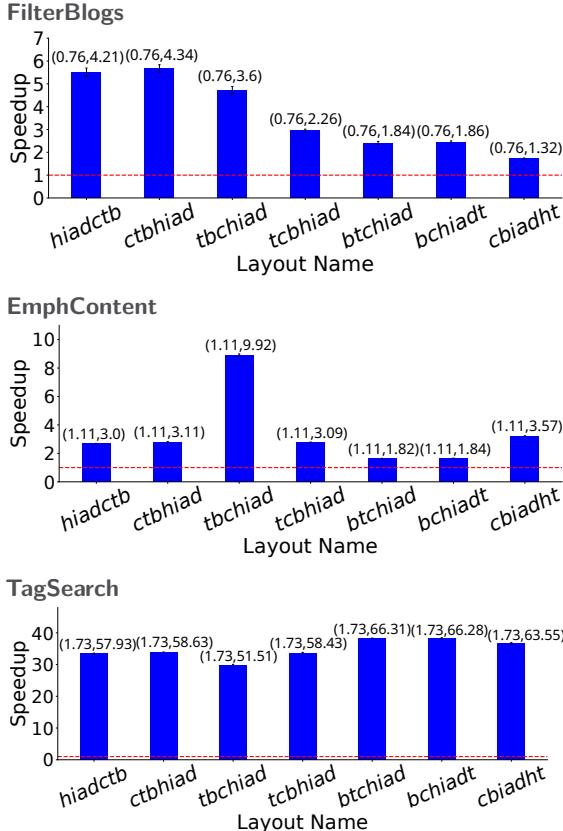

Figure 8 Performance comparison of M_{solver} with MLTON. The pair of numbers on top of each bar shows the median runtime in seconds of M_{solver} followed by the corresponding layout when compiled with MLTON.

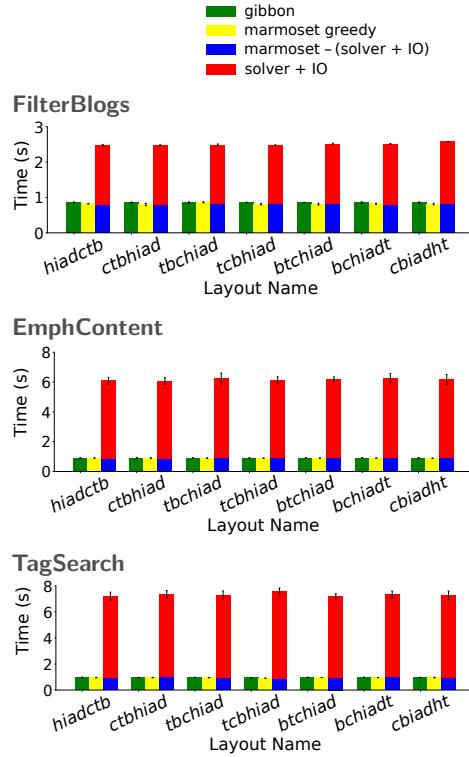

Figure 9 Average compile times (99 runs) in seconds for different layouts and traversal combinations when compiled with GIBBON and when optimized by M_{greedy} and M_{solver} .

chasing. Second, we expect to see an improvement in L2 and L3 cache utilization: both fewer misses (due to improved spatial locality and prefetching) and fewer accesses (due to improved locality in higher level caches).

Table 5 shows that our main hypothesis is borne out and the optimal layout has fewer L2 data cache misses¹⁰: a better layout promotes better locality. Interestingly, we do not observe a similar effect for instruction count. While different layouts differ in instruction counts, the difference is slight. We suspect this light effect of a better layout may be due to GIBBON’s current implementation, which often dereferences pointers even if a direct access in the buffer would suffice.

5.6 Tradeoffs between Marmoset’s solver and greedy optimization

To understand the difference between the layout chosen by M_{solver} and M_{greedy} we now take a closer look at the tag search traversal shown in Table 3. Here, both versions choose two different layouts with different performance implications. M_{solver} chooses the layout **tbchiad**

¹⁰ Since PAPI, the processor counters framework, does not completely support latest AMD processors yet, we were unable to obtain L3 cache misses, only the L2 DCM counter was available.

whereas M_{greedy} chooses the layout ***tcbhiad***. The mechanics of why can be explained using our running example (Figure 1) which is essentially a simplified version of the traversal shown in the evaluation. Figure 4b shows the access graph for this traversal. M_{solver} generates constraints outlined in Section 3.6 that lead to the layout ***tbchiad***. On the other hand, M_{greedy} starts at the root node of the graph and greedily chooses the next child to traverse. The order in which nodes of the graph are visited fixes the order of fields in the data constructor. In this case, the root node is `HashTags` which makes it the first field in the greedy layout, next, the greedy heuristic picks the `Content` field making it the second field and finally followed by the `BlogList` field.

In Figure 9 (p. 22), we show the compile times for different layout and traversal combinations when compiled with GIBBON, M_{greedy} and M_{solver} respectively as a measure of relative costs. The compile times for M_{solver} include the time to generate the control flow graph, the field access graph, the solver time and the time to re-order the datatype in the code. The solver times are in the order of the number of fields in a data constructor and not the program size. Hence, the solver adds relatively low overhead. Since the compiler does an IO call to the python solver, there is room for improvement in the future to lower these times. For instance, we could directly perform *FFI* calls to the CPLEX solver by lowering the constraints to C code. This would be faster and safer than the current implementation. In addition, during the global optimization, we call the solver on each data constructor as of the moment, we could further optimize this by sending constraints for all data constructors at once and doing just one solver call.

Although the cost of MAMOSET’s solver based optimization is higher than the greedy approach, it is a complementary approach which may help the user find a better layout at the cost of compile time. On the other hand, if the user wishes to optimize for the compile time, they should use the greedy heuristic.

5.7 Discussion: Scale of Evaluation

MAMOSET’s approach for finding the best layout for densely presented data is language agnostic, but the evaluation has to be language specific. Hence, we implemented the approach inside a most-developed (to our knowledge) compiler supporting dense representations of recursive datatypes, the Gibbon compiler. Our evaluation is heavily influenced by this.

At the time of writing, the scale of evaluation is limited by a number of Gibbon-related restrictions. Gibbon is meant as a tree traversal accelerator [25] and its original suite of benchmarks served as a basis and inspiration for evaluation of MAMOSET. “Big” end-to-end projects (e.g. compilers, web servers, etc.) have not been implemented in Gibbon and, therefore, are out of reach for us. If someone attempted to implement such a project using Gibbon, they would have to extend the compiler to support many realistic features: modules, FFI, general I/O, networking. Alternatively, one could integrate Gibbon into an existing realistic compiler as an optimization pass or a plugin. For instance, the Gibbon repository has some preliminary work for integrating as a GHC plugin¹¹, but it is far from completion. In any case, the corresponding effort is simply too big. Overall, the current MAMOSET evaluation shows that our approach is viable.

6 Future Work

MARMOSET could allow the user to provide optional constraints on the layout (either relative or absolute) through pragmas. A relative constraint would allow the user to specify if a field A comes immediately after field B. An absolute constraint would specify an exact index in the layout for a field. Such pragmas may be useful if the user requires a specific configuration of a data type for external reasons or has information about performance bottlenecks.

Although the performance optimization is currently statically driven, there are many avenues for future improvement. For instance, we can get better edges weights for the access graphs using dynamic profiling techniques. The profiling can be quite detailed, for instance, which branch in a function is more likely, which function takes the most time overall in a global setting (the optimization would bias the layout towards that function), how does a particular global layout affect the performance in case of a pipeline of functions.

We could also look at a scenario where we optimize each function locally and use “shim” functions that copy one layout to another (the one required by the next function in the pipeline). Although the cost of copying may be high, it warrants further investigation. Areas of improvement purely on the implementation side include optimizing whether MARMOSET dereferences a pointer to get to a field or uses the end-witness information as mentioned in section 2. Lesser pointer dereferencing can lower instruction counts and impact performance positively. We would also like to optimize the solver times as mentioned in 5.6.

We envision that the *structure of arrays* effect that we discovered may help with optimizations such as vectorization, where the performance can benefit significantly if the same datatype is close together in memory. Regardless, through the case studies, we see that MARMOSET shows promise in optimizing the layout of datatypes and may open up the optimization space for other complex optimizations such as vectorization.

7 Related Work

7.1 Cache-conscious data

Chilimbi and Larus [6] base on an object-oriented language with a generational garbage collector, which they extend with a heuristic for copying objects to the TO space. Their heuristic uses a special-purpose graph data structure, the *object affinity graph*, to identify when groups of objects are accessed by the program close together in time. When a given group of objects have high affinity in the object affinity graph, the collector is more likely to place them close together in the TO space. As such, a goal of their work and ours is to achieve higher data-access locality by carefully grouping together objects in the heap. However, a key difference from our work is that their approach bases its placement decisions on an object-affinity graph that is generated from profiling data, which is typically collected online by some compiler-inserted instrumentation. The placement decisions made by our approach are based on data collected by static analysis of the program. Such an approach has the advantage of not depending on the output of dynamic profiling, and therefore avoids the implementation challenges of dynamic profiling. A disadvantage of not using dynamic profiling is that the approach cannot adapt to changing access patterns that are highly input specific. We leave open for future work the possibility of getting the best of both approaches.

Chilimbi et al. [4] introduce the idea of hot/cold splitting of a data structure, where elements are categorized as being “hot” if accessed frequently and “cold” if accessed infrequently. This information is obtained by profiling the program. Cold fields are placed into a new object via an indirection and hot fields remain unchanged. In their approach, at runtime, there is a cache-conscious garbage collector [6] that co-locates the modified object instances.

This paper also suggests placing fields with high temporal affinity within the same cache block. For this they recommend `bbcach`, a field recommender for a data structure. `bbcach` forms a field affinity graph which combines static information about the source location of structure field accesses with dynamic information about the temporal ordering of accesses and their access frequency.

Chilimbi et al. [5] propose two techniques to solve the problem of poor reference locality. `ccmorp`. This works on tree-like data structures, and it relies on the programmer making a calculated guess about the safety of the operation on the tree-like data structure. It performs two major optimizations: clustering and coloring. Clustering takes a tree-like data structure and attempts to pack likely to be accessed elements in the structure within the same cache block. There are various ways to pack a subtree, including clustering k nodes in a subtree together, depth first clustering, etc. Coloring attempts to map simultaneously accessed data elements to non-conflicting regions of the cache.

`ccmalloc`. This is a memory allocator similar to `malloc` which takes an additional parameter that points to an existing data structure element which is likely accessed simultaneously. This requires programmer knowledge and effort in recognizing and then modifying the code with such a data element. `ccmalloc` tries to allocate the new data element as close to the existing data as possible, with the initial attempt being to allocate in the same cache block. It tries to put likely accessed elements on the same page in an attempt to improve TLB performance.

Franco et al. [13, 14] suggest that the layout of a data structure should be defined once at the point of initialization, and all further code that interacts with the structure should be “layout agnostic”. Ideally, this means that performance improvements involving layout changes can be made without requiring changes to program logic. To achieve this, classes are extended to support different layouts, and types carry layout information – code that operates on objects may be polymorphic over the layout details.

7.2 Data layout description and binary formats

Chen et al. [3] propose a data layout description framework *Dargent*, which allows programmers to specify the data layout of an ADT. It is built on top of the Cogent language [19], which is a first order polymorphic functional programming language. Dargent targets C code and provides proofs of formal correctness of the compiled C code with respect to the layout descriptions. Rather than having a compiler attempting to determine an efficient layout, their focus is on allowing the programmer to specify a particular layout they want and have confidence in the resulting C code.

Significant prior work went into generation of verified efficient code for interacting with binary data formats (parsing and validating). For example, EverParse [21] is a framework for generating verified parsers and formatters for binary data formats, and it has been used to formally verify zero-copy parsers for authenticated message formats. With Narcissus [9], encoders and decoders for binary formats could be verified and extracted, allowing researchers to certify the packet processing for a full internet protocol stack. Other work [23] has also explored the automatic generation of verified parsers and pretty printers given a specification of a binary data format, as well as the formal verification of a compiler for a subset of the Protocol Buffer serialization format [26].

Back [1] demonstrates how a domain-specific language for describing binary data formats could be useful for generating validators and for easier scripting and manipulation of the data from a high-level language like Java. [18] introduce *Packet Types* for programming with network protocol messages and provide language-level support for features commonly found in protocol formats like variable-sized and optional fields.

Hawkins et al. [15] introduce RELC, a framework for synthesizing low-level C++ code from a high-level relational representation of the code. The user describes and writes code that represents data at a high level as relations. Using a decomposition of the data that outlines memory representation, RELC synthesizes correct and efficient low-level code.

Baudon et al. [2] introduce the RIBBIT DSL, which allows programmers to describe the layout of ADTs that are monomorphic and immutable. RIBBIT provides a dual view on ADTs that allows both a high-level description of the ADT that the client code follows and a user-defined memory representation of the ADT for a fine-grained encoding of the layout. Precise control over memory layout allows RIBBIT authors to develop optimization algorithms over the ADTs, such as struct packing, bit stealing, pointer tagging, unboxing, etc. Although this approach enables improvements to layout of ADTs, it is different from MAMOSET's: RIBBIT focuses on *manually* defining low-level memory representation of the ADT whereas MAMOSET *automatically* optimizes the high-level layout (ordering of fields in the definition ADT) relying on GIBBON for efficient packing of the fields. While RIBBIT invites the programmer to encode their best guess about the optimal layout, MAMOSET comes up with such layout by analysing access patterns in the source code.

7.3 Memory layouts

Early work on specifications of memory layouts was explored in various studies of PADS, a language for describing ad hoc data-file formats [10, 11, 17].

Lattner and Adve [16] introduce a technique for improving the memory layout of the heap of a given C program. Their approach is to use the results of a custom static analysis to enable *pool allocation* of heap objects. Such automatic pool allocation bears some resemblance to our approach, where we use region-based allocation in tandem with region inference, and thanks to static analysis can group fields of a given struct into the same pool, thereby improving locality in certain circumstances.

Floorplan [8] is a declarative language for specifying high-level memory layouts, implemented as a compiler which generates Rust code. The language has forms for specifying sizes, alignments, and other features of chunks of memory in the heap, with the idea that any correct state of the heap can be derived from the Floorplan specification. It was successfully used to eliminate 55 out of 63 unsafe lines of code (all of the unsafe code relating to memory safety) of the immix garbage collector.

8 Conclusions

This paper introduces MAMOSET, which builds on GIBBON to generate efficient orders for algebraic datatypes. We show that a straightforward control-flow and data-flow analysis allows MAMOSET to identify opportunities to place fields of a data constructor near each other in memory to promote efficient consecutive access to those fields. Because a given function might use many fields in many different ways, MAMOSET adopts an approach of formulating the data layout problem as an ILP, with a cost model that assigns an abstract cost to a chosen layout. Armed with the ILP problem formulation, an off-the-shelf ILP solver allows MAMOSET to generate minimal-(abstract)-cost layout for algebraic datatypes. MAMOSET then uses the best layout to synthesize a new ADT and the GIBBON compiler toolchain to lower the code into an efficient program that operates over packed datatypes with minimal pointer chasing.

We show, across a number of benchmarks, that MAMOSET is able to effectively and consistently find the optimal data layout for a given combination of traversal function and ADT. In our experiments, MAMOSET-optimized layouts outperform not only GIBBON's default layouts but also the popular SML compiler MLTON.

Abstract

Refinement types have been extensively used in class-based languages to specify and verify fine-grained logical specifications. Despite the advances in practical aspects such as applicability and usability, two fundamental issues persist. First, the soundness of existing class-based refinement type systems is inadequately explored, casting doubts on their reliability. Second, the expressiveness of existing systems is limited, restricting the depiction of semantic properties related to object-oriented constructs. This work tackles these issues through a systematic framework. We formalize a declarative class-based refinement type calculus (named RFJ), that is expressive and concise. We rigorously develop the soundness meta-theory of this calculus, followed by its mechanization in Coq. Finally, to ensure the calculus's verifiability, we propose an algorithmic verification approach based on a fragment of first-order logic (named LFJ), and implement this approach as a type checker.

1 Introduction

Refinement types have been widely used in class-based languages [47, 67, 10, 56, 26, 33, 36] to enhance the capabilities of traditional type systems, allowing for more precise safety guarantees. These types extend basic data types (e.g., integer type, boolean type, and class types) with logical constraints that specify detailed conditions on the data. For example, $\{\nu : C \mid \nu.f > 0\}$ characterizes instances of type C with the property that their f field exceeds zero. The logical constraint (e.g., $\nu.f > 0$) is often called the *refinement* of the type.

Despite the advancements in various practical aspects (briefly surveyed in Section 8), a comprehensive examination of the fundamental aspects of class-based refinement types remains elusive. The primary reason stems from the intricate logical interpretation associated with refinements, which determines their meanings. In existing class-based refinement type systems, the logical interpretations are often defined via the Satisfiability Modulo Theories (SMT) relation [9, 35], since they are typically analyzed algorithmically via SMT solvers. Although this interpretation is closer to the actual algorithmic interpretation, it brings two crucial problems. Firstly, the **soundness** of the type system is difficult to define and argue formally, since it depends on the SMT relation, which is both complex and intricate to define properly. This complexity has led to a paucity of mechanized soundness proofs in previous systems, putting their reliability in doubt. Secondly, the **expressiveness** of the refinement types is limited by the need to adhere to decidable theory combinations (e.g., QF-EUFLIA [9]), which impedes the representation of semantic properties relevant to user-defined classes and methods.

To address those fundamental issues, this work makes three consecutive contributions.

1. Formalization. To formalize a foundational calculus, this paper introduces Refinement Featherweight Java (RFJ), an FJ-like [30] calculus with expressive refinements capable of stating arbitrary properties about user-defined elements. Our basic methodology is to construct a declarative, SMT-independent logical interpretation within the language, which greatly increases the expressiveness and benefits the meta-theoretical development. Apart from that, RFJ is equipped with several features important for refinement-type-based verification, yet mostly absent from previous systems, such as interfaces for decomposing proof obligations among subclasses (c.f., Section 2.2), general selfification – a typing mechanism [66, 51] (detailed in Section 2.1) that seamlessly integrates accurate term information into refinements, and flexible method overriding through co/contra-variance [11]. Besides those critical features, RFJ closely mirrors FJ, avoiding the usage of non-standard judgments (e.g., object constraint systems [47, 67]) and non-standard constructs (e.g., ANF [10], existential types [67]). Thus, we believe RFJ can be an ideal base to explore further extensions.

2. Mechanization. The soundness properties of RFJ are rigorously established and mechanized in Coq. Although leveraging an in-language logical interpretation reduces the proof difficulty, the proof is still challenging and requires non-standard techniques. For example, we make a novel use of big-step semantics to obtain a convenient induction principle for proving the preservation lemma under arbitrary type substitution. We introduce a novel approach to establish the logical soundness property (one major soundness property of RFJ), as the standard logical relation technique [62] is ineffective for first-order languages like RFJ [55].

3. Verification. The expressive refinements provided by RFJ fall out of the scope of existing SMT theories, casting ambiguity on the system’s algorithmic verifiability. We address this concern by proposing an algorithmic verification approach based on a fragment of order-sorted first-order logic (OS-FOL) [57]. We name this fragment as LFJ, and define a type-directed translation from RFJ to the LFJ. We define an intended model of LFJ and map the RFJ refinement subtyping problem to the LFJ validity problem under this model. We devise an axiomatization of the intended model covering the semantics of RFJ programs. The axiomatization can be used by SMT solvers to perform algorithmic verification. Thus, the expressive refinements of RFJ are not only meta-theoretical constructs: they are amenable to algorithmic analysis within SMT solvers. Additionally, we develop a refinement type

checker that leverages Z3 [19] for checking the validity of LFJ formulas. The type checker is evaluated against a small yet representative benchmark derived from a Java textbook [23] and prior systems [65].

In the remainder of this paper, we detail our contributions. Section 2 provides an overview. Sections 3, 4, and 5 each describe one of the three contributions. Section 6 discusses the mechanization and implementation. Sections 7, 8, and 9 review related work and conclude.

The accompanying code of this paper, including the meta-theory mechanization and type checker implementation, is available as the supplementary material of this paper.

2 Overview

This section serves as an overview of the whole paper. We start with an example program to demonstrate the expressiveness and features of RFJ. Then, we discuss the actual verification through LFJ. Finally, we turn back to the meta-theory of RFJ and the challenges of developing the meta-theory. The sequence of discussion – starting with verification before addressing meta-theoretical concerns – is intentionally chosen to contrast with the presentation order in subsequent sections, aiming to enhance comprehension by familiarizing readers with the system through its verification aspects first.

2.1 RFJ by Example

```

1  class Pizza{
2      {v:int|v>0} price(){return 1;}
3      Pizza remA(){return new Pizza();}
4      Pizza sell (this.price()>5){return this;}
5  class Crust extends Pizza{
6      {v:int|v>0} price(){return 1;}
7      Pizza remA(){return new Crust();}
8      Pizza sell (){return this;}
9  class Cheese extends Pizza{
10     p:Pizza
11     {v:int|v>0} price(){return let pp = this.p.price() in pp + 1;}
12     Pizza remA(){return new Cheese(this.p.remA());}
13  class Anchovy extends Pizza{
14     p:Pizza
15     {v:int|v>0 && v>=this.p.price()} price(){return let pp = this.p.price() in pp;}
16     Pizza remA(){return this.p.remA();}
17  class MagicAnchovy extends Anchovy{
18     {v:int|v>0 && v>this.p.price()} price(){return let pp = this.p.price() in pp + 1;}
19  class Main{
20     int assertSingleCheesePizza(x: {v:Pizza|v = new Cheese(new Crust())}){
21         return 0;
22     int testRemA(){
23         return let p1 = new Anchovy(new Cheese(new Crust())) in
24             this.assertSingleCheesePizza(p1.remA());}

```

Figure 1 An example RFJ program. In refinements, v stands for ν .

In this section, we illustrate RFJ using a program extended from a textbook example [23] (we add some methods to make it more interesting). The program models various pizzas and three operations on them: computing the price of a pizza (the `price` method), removing all anchovies from a pizza (the `remA` method), and selling a pizza (the `sell` method).

Simple Verification. Our initial focus is a basic property: the price of any pizza must be positive. To enforce this property, we refine the return types of `price` methods with a refinement $\nu > 0$, where ν denotes the value being refined. RFJ’s refinement subtyping mechanism guarantees that the `price` methods indeed return positive values. Pick `Pizza.price` for an example, RFJ enforces the following subtyping constraint for the return type:

$$\textit{this} : \{\nu : \textit{Pizza} | \textit{true}\} \vdash \{\nu : \textit{int} | \nu = 1\} <: \{\nu : \textit{int} | \nu > 0\} \quad (1)$$

In refinement type systems like RFJ, such subtyping constraints have logical interpretations. In particular, Constraint (1) requires all ν *satisfying* $\nu = 1$ must also *satisfy* $\nu > 0$, which holds under RFJ logical interpretation (formally defined in Section 3.3). Note that the subtyping constraint is checked within a specific type environment $\textit{this} : \{\nu : \textit{Pizza} | \textit{true}\}$, which contains the types of all visible variables. Those variables may be referred to by the refinement types, as demonstrated in the following example.

Method Override. RFJ supports overriding methods in subclasses. For example, `Cheese.price` overrides `Pizza.price` to provide a different price computation. To preserve the logical property, the return type must still be validated, yielding the following constraint:

$$\textit{this} : \{\nu : \textit{Cheese} | \textit{true}\}, \textit{pp} : \{\nu : \textit{int} | \nu > 0\} \vdash \{\nu : \textit{int} | \nu = \textit{pp} + 1\} <: \{\nu : \textit{int} | \nu > 0\} \quad (2)$$

The `pp` item in the environment is introduced by the let binding. Since `pp` is bound to `this.p.price()`, RFJ sets its type as the type of `this.p.price()`, which is $\{\nu : \textit{int} | \nu > 0\}$.

Refinement for `this` and Override with Co/contra-variance. In RFJ, every method has an implicit `this` parameter with the same type as the enclosing class of this method (e.g., in `Cheese.price()`, `this` has `Cheese` type). We have seen `this` appearing in previous subtyping constraints, but with a trivial refinement `true`. `this` can also be given a non-trivial refinement to ensure that methods are invoked on objects satisfying specific criteria. For instance, `Pizza.sell` includes a refinement of `this` (marked `cyan`), specifying that only the pizza whose `price` is greater than 5 can be sold.

Meanwhile, suppose that a `Crust` can also be sold regardless of its price. This can be achieved by **overriding** the method `sell` in `Crust`, as the example shows. In the overriding method, the refinement of `this` is `true` and thus omitted, making it a supertype of the previous refinement `this.price > 5`, obeying **contra-variance** of parameter types².

Now, consider a property for `Anchovy.price()`: the price is not only positive, but also not less than that of `this.p`. This extra property is marked `olive` in the program. The property makes the new return type a subtype of the old, obeying return type **co-variance**.

General selfification. Checking `Anchovy.price()`'s return type yields this constraint:

$$\textit{this} : \textit{Anchovy}, \textit{pp} : \{\textit{int} | \nu > 0\} \vdash \{\textit{int} | \nu = \textit{pp}\} <: \{\textit{int} | \nu > 0 \& \& \nu \geq \textit{this.p.price}()\} \quad (3)$$

Here, we omit the refinement binder ν and the refinement when it is trivial (i.e., `true`). However, this constraint can not be proved currently, essentially due to the loss of the `this.p.price()` term information in the type of `pp`. Luckily, RFJ's general selfification³ mechanism addresses this by ensuring the persistence of such information. In a nutshell, it works by equating the term being typed to the refinement of its type, giving $\textit{this.p.price}() : \{\nu : \textit{int} | \nu > 0 \& \& \nu = \textit{this.p.price}()\}$, which is also the type of `pp`. The strengthened type of `pp` lets the constraint be proved. With the same technique, we can prove the validity of `MagicAnchovy.price`, which further overrides `Anchovy.price`.

² Strictly speaking, for the type of `this`, we use co-variance for the base type and contra-variance for the refinement, c.f. Section 3.1.

³ We name it *general* to distinguish from the cases like [34], where selfification is only used for variables.

Referring to Methods. Next, we turn to the `remA` methods for removing all anchovies from a pizza. Consider the method `testRemA`, where we assess the correctness of the `remA` implementations. For the assertion in Line 24, RFJ enforces the subtyping constraint below:

$$p1 : \{An|\nu = An(Ch(Cr()))\} \vdash \{Pi|\nu = p1.\text{remA}()\} <: \{Pi|\nu = Ch(Cr())\} \quad (4)$$

We omit `this` from the type environment, which does not affect the meaning of this subtyping constraint. Meanwhile, we abbreviate class names to their initial two letters (e.g., `Ch` represents *Cheese*), and omit the `new` keyword (e.g., `An(Ch(Cr()))` represents *new An(new Ch(new Cr()))*), in order to save space. Proving Constraint (4) demands intricate reasoning about the program’s semantics, particularly the semantics of the `remA` methods. This contrasts with the previous example, where no specific knowledge about the `price` methods is required. In our meta-theoretical calculus, since the logical interpretation is built upon the program semantics, Constraint (4) does not pose a significant challenge. Nevertheless, facilitating its efficient handling within SMT solvers requires a theory about RFJ program semantics, which is discussed in detail in Section 2.2.

Proving with Interfaces. Finally, we consider a more interesting property concerning `price` and `remA`: the price of a pizza should not increase after removing all anchovies. We can express this by appending the following method to `Pizza`: `{bool|this.price()>=this.remA().price()}` `remA_noinc_price(){return true;}`, yielding the subtyping constraint below:

$$this : Pizza \vdash \{bool|\nu = true\} <: \{bool|this.price() \geq this.\text{remA}().\text{price}()\} \quad (5)$$

This property holds in our meta-theoretical calculus. However, it breaks the proof modularity and is not verifiable in the algorithmic verification, even with the theory extended with RFJ program semantics. The mitigation of this challenge is facilitated by another key feature of RFJ: interfaces. We discuss that in detail in the following section.

2.2 Algorithmic Verification

In conventional refinement type systems, subtyping constraints are typically discharged by SMT solvers, which facilitate automated reasoning and significantly reduce implementation efforts. We adapt this methodology by providing a logical encoding of RFJ into a dedicated order-sorted first-order logic, named LFJ. A detailed exposition of LFJ is provided in Section 5. Here, we offer a concise overview of it, drawing upon the examples discussed in Section 2.1.

EUFLIA. After being encoded into LFJ, the subtyping constraints (1), (2), and (3) fall into the theory of Equality, Uninterpreted Functions, and Linear Integer Arithmetic (EUFLIA), a domain widely supported by contemporary SMT solvers [9, 4, 19]. LFJ incorporates EUFLIA for verifying those constraints.

Reasoning about Program Semantics. We have illustrated in Section 2.1 that the verification of Constraint (4) requires knowledge about program semantics. We encode the knowledge with several axioms, which are discussed formally in Section 5.3. Currently, We illustrate them utilizing Constraint (4), which is translated to the LFJ formula shown below:

$$\forall p1 : An, \nu : Pi. p1 = An_{cr}(Ch_{cr}(Cr_{cr}())) \wedge \nu = An_{remA}(p1) \Rightarrow \nu = Ch_{cr}(Cr_{cr}())$$

Here, the An_{cr} , Ch_{cr} , Cr_{cr} functions represent the constructors for the classes `An`, `Ch`, and `Cr`, respectively. An_{remA} represents the *conditional function* composed of the possible *implementations* of `Anchovy.remA`. The characterization of `Anchovy.remA` is shown below:

$$An_{remA}(this) = \begin{cases} Pi_{remA}(An_p(this)) & \text{if } this = An_{cr}(\dots) \\ Pi_{remA}(An_p(this)) & \text{if } this = Ma_{cr}(\dots) \end{cases}$$

This characterization redirects the function application to the implementation, depending on the *class* of *this* (although the implementations are the same). Since the two classes both use `Anchovy.remA`, all the implementations are the logic translation of the method body of `Anchovy.remA`. Here, An_p denotes the access function of the field `p` of the class `An`, while Pi_{remA} is the conditional function for `Pizza.remA`.

Because we know $p1$ is $An_{cr}(Ch_{cr}(Cr_{cr}(\dots)))$, we choose the first branch and deduce $\nu = Pi_{remA}(An_p(An_{cr}(Ch_{cr}(Cr_{cr}(\dots)))))$, which can be then handled by an axiom for An_p :

$$\forall p : Pi. An_p(An_{cr}(p)) = p$$

With this axiom, we can deduce $\nu = Pi_{remA}(Ch_{cr}(Cr_{cr}(\dots)))$. This time, we need to utilize the semantics of Pi_{remA} , and choose the branch for $this = Ch_{cr}(\dots)$, i.e., $Pi_{remA}(this) = Ch_{cr}(Pi_{remA}(Ch_p(this)))$, which lets us deduce $\nu = Ch_{cr}(Pi_{remA}(Ch_p((Ch_{cr}(Cr_{cr}(\dots))))))$. Following the routine we just outlined, we can deduce $\nu = Ch_{cr}(Cr_{cr}(\dots))$ eventually.

Verifying with Interfaces. Even with the knowledge of program semantics, Constraint (5) still can not be verified. In particular, it would be translated to $\forall this : Pi. Pi_{price}(this) \geq Pi_{price}(Pi_{remA}(this))$, whose verification requires induction. In several previous refinement type systems for functional languages [66], induction is supported but is based on pattern matching and recursive functions. In object-oriented languages, pattern-matching constructs are typically not included. Thus, in this paper, we propose to utilize *interface*, a feature that is included in most object-oriented languages, to perform induction. To use interface-based induction in our case, we reimplement `Pizza` as an interface, which decomposes the proof obligation into subclasses implementing `Pizza`. To illustrate, we pick the proof of Constraint (5) for `Anchovy` as an example, shown in Figure 2.

The first thing to note is that, the method body of `Anchovy.remA_noinc_price` is not trivial (e.g., `return true`). This means that an SMT solver would not prove this property automatically. Before we explain the method body, we first give a brief informal proof to help understanding. The assumptions to facilitate the proof are listed below. Once the assumptions are within the proof context, the formula we want ($this.price() \geq this.remA().price()$) can be easily deduced within EUFLIA.

$this.price() \geq this.p.price()$	$(p_1) : \text{a property of Anchovy.price}$
$this.p.price() \geq this.p.remA().price()$	$(p_2) : \text{the induction hypothesis of this.p}$
$this.remA() = this.p.remA()$	$(p_3) : \text{a property of Anchovy.remA}$

The first assumption (property) is about `Anchovy.price`, and we have proved it in Section 2.1, so we can just refer to it as a lemma. In principle, even if we have not proved it, the solver can still automatically prove the property with the given program semantics and use it to prove the formula we want. However, leaving such a property to the solver often increases the searching time for proving the formula. Thus, we prove it as a separate property and introduce it ($p1$ in the body of `remA_noinc_price()`) to the proof context so that the solver can use it directly. The second property is the induction hypothesis of `this.p`

```

25   interface Pizza{
26     {int|v>0} price()
27     Pizza remA()
28     Pizza sell (this.price()>5)
29     {v:bool|this.price()>=this.remA().price()} remA_noinc_price() }
30   class Anchovy implements Pizza{
31     p:Pizza
32     {v:int|v>0 && v>=this.p.price()} price(){return let pp = this.p.price() in pp;}
33     Pizza remA(){return this.p.remA();}
34     {v:bool|this.price()>=this.remA().price()} remA_noinc_price(){
35       return let p1 = this.price() in
36       let p2 = this.p.remA_noinc_price() in true;}}

```

Figure 2 Proving `remA_noinc_price` for `Anchovy`.

($this.p.price() \geq this.p.remA().price()$), and we can utilize it by referring to the method `remA_noinc_price` of `this.p`. The third property asserts that for every `this:Anchovy`, it holds that `this.remA()=this.p.remA()`. This is obvious since no matter whether `this` is an `Anchovy` or a `MagicAnchovy`, calling `remA` on it would resolve to the same method implementation. Like p_1 , this property is also automatically derivable, so we *can* leave it to the SMT solver, or explicitly prove it like we do for p_1 . In particular, p_3 represents a special case where we can add an axiom to the solver, to spare the efforts of automatic search and manual proof. As a result, it is not included in the method body. We will discuss this further in Section 5.3.

We need not prove the same property for `MagicAnchovy`, since it inherits the property from `Anchovy`. Similarly, we can prove other properties such as the fact that no `Anchovy` exists after `remA`, as well as the idempotence of `remA`; all have been included in our test suite.

2.3 Meta-theoretical Arguments

As we have seen in the previous sections: the design of RFJ aims at expressiveness and ease of use. At the same time, this very desirable combination leads to a tricky meta-theory. One major contribution of this paper is to establish the meta-theory rigorously (i.e., in Coq). The detailed development of the meta-theory is given in Section 4. In this section, we briefly overview the soundness theorems, and several challenges in proving them.

2.3.1 Soundness Theorems

Type Soundness. The type system should be able to preclude evaluation from being stuck. Formally, if a closed expression is well-typed ($\emptyset \vdash e : t$), then it would never be stuck in a state where it can not be evaluated and is not a value yet. Since type soundness is typically guaranteed by the base type system (in our case, the FJ type system) already, the core of proving that in refinement type systems is to ensure the additional refinement type mechanisms (e.g., general selfification) do not break the promise of the base type system.

Logical Soundness. The type system should infer only *true* refinements. Formally, if a typing judgment ($\Gamma \vdash e : \{w|p\}$) is made by the type system, the refinement formula p must be *true* whenever the conditions stipulated by Γ are fulfilled. Logical soundness serves as a complement to type soundness, going beyond the guarantee that the evaluations of well-typed programs would never get stuck by also ensuring that the evaluations of such programs adhere to the logical constraints specified by type refinements.

2.3.2 Challenges

Logical Interpretation. Refinements are logical formulas and should be interpreted logically. For example, the subtyping relation between two refinement types ($\Gamma \vdash \{w|p\} <: \{w|q\}$) is defined as the truth of the implication $p \Rightarrow q$ under the assumption set Γ . While our approach to algorithmic verification leverages a translation of RFJ into first-order logic (c.f., Section 2.2), employing this logic directly for defining the logical interpretation can prove both intricate and unwieldy. Rather, we choose to define it *inside the language*, allowing the algorithmic verification approach to serve as an external algorithm that scrutinizes the intrinsic logical interpretation. Nevertheless, articulating a precise logical interpretation is still challenging due to complex typing mechanisms like interfaces and nominal subtyping.

Type Substitution and General Selfification. Different from previous class-based refinement type calculus, RFJ uses type substitution instead of ANF [32] or existential types [34]. This increases the generality and usability (detailed in Section 7). However, this also increases its meta-theoretical complexity, and several nonstandard lemmas about type substitution and typing have to be proved. Similarly, although general selfification increases the precision of the verification by recording term information in refinements, it affects substitution and preservation lemmas intricately and several non-standard properties (e.g., exactness, $\Gamma \vdash e : t$ then $\Gamma \vdash e : \text{self}(t, e)$) of it have to be proved for proving those lemmas.

First Order Functions. The logical relation technique [62] is frequently employed in prior research [8, 29] to establish the logical soundness theorem. However, this technique can not be applied to RFJ, since RFJ is a first-order language without explicit function abstraction but with recursive method definition. Thus, we do not have a strong enough induction principle about methods when performing induction on typing. This challenge is not unique to us and has been encountered in previous studies [64, 55]. However, the workaround adopted by these studies, which essentially inlines methods at call-sites, is incompatible with RFJ, since that requires particular type structures supporting the strong normalisation of derivation reduction, a property that RFJ lacks.

3 Declarative Calculus: RFJ

This section outlines the syntax, semantics, and typing rules of RFJ, built upon the classical calculus FJ extended with primitive data types (integers and booleans) and let bindings. The FJ parts follow closely the classical textbook presentation [52]. To delineate the extensions unique to RFJ, we highlight the extended features in *gray background*.

3.1 Syntax and Lookup Functions

The syntax of RFJ is depicted on the left side of Figure 3. The metavariables C , D , and E range over class names; f and g range over field names; m ranges over method names; x ranges over parameter names; ν ranges over refinement binder names. We also use n to range over integers, and b to range over booleans (i.e., *true* and *false*). In a nutshell, RFJ extends FJ by refinement types, interfaces, and the \top type, each highlighted in dark gray to distinguish the enhancements. We have discussed refinement types and interfaces extensively. For the \top type, it is introduced mainly to characterize the equality between any two values, not just values of the same type. Compared to strictly monomorphic equality which demands type uniformity for comparands, \top -typed equality is closer to the actual Java equality [28] and the equality used in order-sorted logics [57].

Syntax	Sub-nominal	Base-subtyping	Subtyping
$C ::= \text{class definitions:}$	$N_1 <:_n N_2$	$w <:_b u$	$\Gamma \vdash s <: t$
$\text{class } C \text{ extends } D \text{ implements } \bar{I} \{\bar{t} \bar{f}; K \bar{M}\}$			$N <:_n N$
$\mathcal{I} ::= \text{interface } I\{\bar{Q}\} \text{ interface } \text{Defs.}$			
$K ::= C(\bar{t} \bar{f}) \{\text{super}(\bar{f}); \text{this.}\bar{f} = \bar{f};\}$			
$Q ::= t m(p, t x) \quad \text{method } \text{Decls.}$			
$M ::= Q\{\text{return } e;\}$			
$e, p, q ::= \text{terms:}$			
$x \quad \text{variable}$			
$e.f \quad \text{field access}$			
$e.m(e) \quad \text{method invocation}$			
$\text{new } C(\bar{e}) \quad \text{instance creation}$			
$n \quad \text{integer}$			
$b \quad \text{boolean}$			
$\neg e \quad \text{unary operation}$			
$e \oplus e \quad \text{binary operation}$			
$\text{let } x = e \text{ in } e \quad \text{let binding}$			
$\oplus ::= = \vee \wedge \quad \text{binary operators}$			
$v ::= n b \text{new } C(\bar{v}) \quad \text{values}$			
$N ::= C \mid I \quad \text{nominal types}$			
$w, u ::= \top \mid \text{int} \mid \text{bool} \mid N \quad \text{base types}$			
$s, t, r ::= \{\nu : w p\} \quad \text{refinement types}$			
	$N_1 <:_n N_2$	$w <:_b u$	$\Gamma \vdash s <: t$
			$N <:_n N$
	$\frac{N_1 <:_n N_2 \quad N_2 <:_n N_3}{N_1 <:_n N_3}$		
			$\frac{CT(C) = \text{class } C \text{ extends } D \dots \{\dots\}}{C <:_n D}$
		$\frac{CT(C) = \text{class } C \dots \text{implements } \bar{I}\{\dots\}}{C <:_n I_i}$	
			$w <:_b \top$
			$\text{int} <:_b \text{int}$
			$\text{bool} <:_b \text{bool}$
	$\frac{N_1 <:_n N_2}{N_1 <:_b N_2}$		
		$\frac{w <:_b u \quad \Gamma, \nu : w \models p \Rightarrow q}{\Gamma \vdash \{\nu : w p\} <: \{\nu : u q\}}$	
			(R-SUBTYPING)

Figure 3 Syntax and subtyping.

Besides the extension, RFJ simplifies FJ in two aspects, widely adopted in prior studies [55, 10, 42, 27]. First, casts are not included since they complicate the calculus and are orthogonal with refinement types, the focus of this work. Second, a single parameter is used instead of an arbitrary number of parameters. However, this does not impact the expressiveness of RFJ, because empty parameters can be modeled by a single parameter that is not referred to in the method body, while multiple parameters can be modeled by declaring a class containing those parameters and using it as a single parameter.

Finally, we introduce several remarkable notations. Firstly, note that we use e , p , and q to range over RFJ terms. The latter symbols (p and q) are used to range over RFJ terms that have bool type (also called *formulas*). Secondly, we use two shorthands for refinement types: we omit the binders declaration in $\{\nu : w|p\}$ when the binder is just ν (a reserved name), and we short $\{w|p\}$ as w when p is *true*.

Subtyping. The right half of Figure 3 explicates RFJ’s subtyping relations, featuring sub-nominal ($<:_n$), subtyping amongst base types ($<:_b$), and refinement subtyping ($<:$). The sub-nominal relation is a straightforward extension of FJ’s subclassing to account for interface types. The base subtyping relation is also standard. Refinement subtyping combines base subtyping and logical implication (defined in Section 3.3). It is parameterized by type environments with the usual construction, which is used for logical implication. Note that

39:10 Formalizing, Mechanizing, and Verifying Class-Based Refinement Types

when checking logical implication, we use the type of the sub-base-type (w) instead of the super-base-type (u) for ν , to make refinement subtyping transitive. In the remaining of this paper, we short refinement subtyping as subtyping when there is no ambiguity.

Field lookup $fields(C) = \bar{t} \bar{f}$ $fields(Object) = \bullet$ $\frac{CT(C) = class\ C\ exds\ D\ imps\ \bar{I}\{\bar{t}\ \bar{f};\ K\ \bar{M}\} \quad fields(D) = \bar{s}\ \bar{g}}{fields(C) = \bar{s}\ \bar{g}, \bar{t}\ \bar{f}}$ C-method-type $mtype(m, C) = p \rightarrow x : t \rightarrow r$ $\frac{CT(C) = class\ C\ exds\ D\ imps\ \bar{I}\{\bar{t}\ \bar{f};\ K\ \bar{M}\} \quad r\ m\ (\underline{p},\ t\ x)\ \{return\ e;\} \in \bar{M}}{mtype(m, C) = \underline{p} \rightarrow x : t \rightarrow r}$ $\frac{CT(C) = class\ C\ exds\ D\ imps\ \bar{I}\{\bar{t}\ \bar{f};\ K\ \bar{M}\} \quad m\ is\ not\ defined\ in\ \bar{M}}{mtype(m, C) = mtype(m, D)}$ C-method-body $mbody(m, C) = (x, e)$ $\frac{CT(C) = class\ C\ exds\ D\ imps\ \bar{I}\{\bar{t}\ \bar{f};\ K\ \bar{M}\} \quad r\ m\ (\underline{p},\ t\ x)\ \{return\ e;\} \in \bar{M}}{mbody(m, C) = (x, e)}$ $\frac{CT(C) = class\ C\ exds\ D\ imps\ \bar{I}\{\bar{t}\ \bar{f};\ K\ \bar{M}\} \quad m\ is\ not\ defined\ in\ \bar{M}}{mbody(m, C) = mbody(m, D)}$	Override $\frac{override(m, C, D, p \rightarrow x : t \rightarrow r) \quad mtype(m, D) = q \rightarrow x : t' \rightarrow r'}{\begin{array}{l} \Rightarrow (\emptyset \vdash \{C q\} <: \{C p\}) \\ \emptyset, this : \{C q\} \vdash t' <: t \\ \emptyset, this : \{C q\}, x : t' \vdash r <: r' \end{array}} \overline{override(m, C, D, p \rightarrow x : t \rightarrow r)}$ I-method-type $\frac{mtypei(m, I) = p \rightarrow x : t \rightarrow r \quad IT(I) = interface\ I\{\bar{Q}\} \quad r\ m\ (\underline{p},\ t\ x) \in \bar{Q}}{mtypei(m, I) = p \rightarrow x : t \rightarrow r}$ Implement $\frac{implement(m, C, I, p \rightarrow x : t \rightarrow r) \quad mtype(m, C) = q \rightarrow x : t' \rightarrow r' \quad \begin{array}{l} \emptyset \vdash \{C p\} <: \{C q\} \\ \emptyset, this : \{C p\} \vdash t <: t' \\ \emptyset, this : \{C p\}, x : t \vdash r' <: r \end{array}}{\overline{implement(m, C, I, p \rightarrow x : t \rightarrow r)}}$ Interface implemented $\frac{IT(I) = interface\ I\{\overline{r\ m(p,\ t\ x)}\} \quad implement(m, C, I, \overline{p \rightarrow x : t \rightarrow r})}{C \triangleright I}$
--	---

Figure 4 Auxiliary definitions.

Auxiliary Definitions. The lookup functions, override relation, and *interface implemented* relation are shown in Figure 4. The lookup functions should be pretty self-explanatory, only to note that although we use \rightarrow in *mtype* and *mtypei*, it is not *arrow type* constructor, but an intuitive type signature representation, as in original FJ [11]. We explain the override and *interface implemented* relations subsequently.

In RFJ, the criterion for valid method override differs from FJ’s strict type matching, utilizing co/contra-variance instead. This is encapsulated by the override relation ($override(m, C, D, p \rightarrow x : t \rightarrow r)$), which ensures the class C properly overrides the method m of the class D (if m does exists in D), encoding three constraints:

1. For **this**, we have co-variance in the base type (the base type is C , which is a subtype of D) and contra-variance in the refinement (as the $\emptyset \vdash \{C|q\} <: \{C|p\}$ states). Using covariance for the base type is widely known as a seminal work [11] on method overriding has pointed out: the parameters that determine the selection must be co-variantly overridden (i.e., have a lesser type). However, since method selection relies solely on the base type (note that *mbody* considers the class but disregards refinement), we must require the refinement to be more general (contra-variant) to ensure compatibility.

2. The contra-variance on the parameter type and co-variance on the return type (ignore the subtyping context for now) follow the function subtyping principle [52].
3. Since the parameter type refinement may refer to `this`, while the return type refinement may refer to `this` and the parameter, their co/contra-variance must be assessed under a type environment with those variables, as the definition shows. Here, note that we opt for “narrower” subtype contexts: we assess contra-variance ($t' <: t$) within the context of $\{C|q\}$ rather than $\{C|p\}$, and likewise for co-variance ($r <: r'$), within $\{C|q\}$ and t' . This decision renders the overriding rule more permissive: subtyping in a narrower context is easier to satisfy, as the narrowing property of subtyping shows (c.f., Section 4.3.1).

Finally, note that we simplify the presentation by assuming identical parameter names (x); otherwise, they should be renamed to a fresh variable for checking return type co-variance.

For valid interface implementations, $C \triangleright I$ confirms that a class properly implements all methods declared in the interface. The implementation relation ($implement(m, C, I, p \rightarrow x : t \rightarrow r)$) is a dual of the override relation, ensuring that the method m of interface I with type signature $p \rightarrow x : t \rightarrow r$, is overridden in the class C . Note that the formalization is different from override in that, *override* only requires the subtyping constraints to hold *if the method m exist*, while *implement* requires the method m does exist, and satisfies the subtyping constraints.

3.2 Operational Semantics

Evaluation	$e \rightsquigarrow e'$	
	$\boxed{e \rightsquigarrow e'}$	
	$\frac{fields(C) = \bar{t} \bar{f}}{(new\ C(\bar{v})).f_i \rightsquigarrow v_i}$	
	$\frac{mbody(m, C) = (x, e_0)}{(new\ C(\bar{v})).m(v) \rightsquigarrow [this \mapsto (new\ C(\bar{v})); x \mapsto v]e_0}$	
	$\frac{e_0 \rightsquigarrow e'_0}{e_0.f \rightsquigarrow e'_0.f}$	
	$\frac{e_0 \rightsquigarrow e'_0}{e_0.m(e) \rightsquigarrow e'_0.m(e)}$	
	$\frac{e \rightsquigarrow e'}{v_0.m(e) \rightsquigarrow v_0.m(e')}$	
	$\frac{e_i \rightsquigarrow e'_i}{new\ C(\bar{v}, e_i, \bar{e}) \rightsquigarrow new\ C(\bar{v}, e'_i, \bar{e})}$	
		$\frac{e \rightsquigarrow e'}{\neg e \rightsquigarrow \neg e'}$
		$\frac{\neg b \rightsquigarrow \neg_p(b)}{e_0 \rightsquigarrow e'_0}$
		$\frac{e_0 \oplus e \rightsquigarrow e'_0 \oplus e}{e \rightsquigarrow e'}$

		$\frac{}{= ok\ v_0\ v_1}$
		$\text{Valid binary operation}$

Figure 5 Small-step semantics of RFJ.

Now, we present the operational semantics of RFJ. We first present the small-step semantics, defined in Figure 5. The semantics aligns with that of FJ⁴, diverging only to accommodate the integration of new constructs – specifically, primitive operations and let bindings. The standard semantics of the boolean operations – including negation, conjunction, and disjunction, are preserved. The only thing worth noting is the equality operation, which is defined for every pair of values. RFJ equality is defined as the syntactic equality (i.e., we view values as finite term trees [22]: two values are equal *iff* their corresponding trees are identical).

Multi-step and Big-step Semantics. We define the multi-step semantics ($e \rightsquigarrow^* e'$) as the transitive closure of the small-step semantics, used for type soundness and logical truth later.

Despite being directly derivable from small-step semantics, multi-step semantics do not provide a convenient induction principle, which makes the related proof intricate. To mitigate this, we introduce big-step semantics and prove its coincidence with the multi-step semantics terminating with a value (i.e., $e \Downarrow v$ *iff* $e \rightsquigarrow^* v$). The big-step semantics mirrors the small-step semantics, and we omit its formal definition from this paper. We defer its comprehensive exposition to the accompanying Coq development.

3.3 Logical Interpretation

Figure 6 defines the logical notations, which are used in the refinement subtyping relation and logical soundness theorem. The definitions make use of closing substitutions, i.e., partial mappings from variables to values. The application of a closing substitution θ to a term e is defined as the function $\theta(e)$, which simply substitutes each variable-value pair sequentially. We also lift $\theta(\cdot)$ to refinement types: $\theta(\{\nu : w|p\}) = \{\nu : w|\theta(p)\}$.

Logical Truth and Entailment. The core of our logical interpretation is the logical truth relation, which means that the logical formula evaluates to *true* under the given interpretation (i.e., RFJ operational semantics). Note that this relation is defined only for closed formulas (i.e., *sentences*), and a closing substitution is applied whenever this relation is checked.

With the logical truth relation in hand, we can define the logical entailment relation ($\Gamma \models p$), which signifies the truth of a formula p under the type and logical constraints encoded within Γ . It requires that for every closing substitution that satisfies Γ (formally defined later), the closing substitution must also satisfy the formula p (i.e., make it a truth). Similarly, we define the logical implication relation ($\Gamma \models p \Rightarrow q$), by requiring all closing substitution that satisfies Γ and p also satisfies q .

The logical implication relation is used for defining the subtyping relation (c.f., Section 3.1). To illustrate, we revisit the subtype constraint (4) presented in Section 2.1, which imposes the following constraint by the definition of subtyping and logical implication:

$$\forall \theta \in [\Gamma]. \text{ if } \models \theta(\nu = p1.\text{rem}A()) \text{ then } \models \theta(\nu = \text{new } Ch(\text{new } Cr()))$$

where $\Gamma = p1 : \{An|\nu = \text{new } An(\text{new } Ch(\text{new } Cr()))\}$, $\nu : Pi$. There are infinite closing substitutions satisfying Γ . In particular, $p1$ can only be $\text{new } An(\text{new } Ch(\text{new } Cr()))$, but ν can be any *Pizza*, since any *Pizza* v satisfies $v \in [Pi]$. However, there is only one closing substitution that also satisfies the *if* condition ($\models \theta(\nu = p1.\text{rem}A())$), i.e., the one whose ν is $\text{new } Ch(\text{new } Cr())$. This closing substitution also satisfies the *then* condition. Thus, Constraint (4) holds under the logical interpretation.

⁴ To be specific, we align with the semantics in the textbook presentation [52], which diverges from the nondeterministic beta-reduction semantics in the original paper [30].

$\theta ::= \theta, x : v \mid \emptyset$	Environment Denotation	$\theta \in \llbracket \Gamma \rrbracket$
Closing Substitution		
$\emptyset(e) = e$		$\emptyset \in \llbracket \emptyset \rrbracket$
$(\theta, x : v)(e) = [x \mapsto v]\theta(e)$		$\frac{v \in \llbracket \theta(t) \rrbracket \quad \theta \in \llbracket \Gamma \rrbracket}{\theta, x : v \in \llbracket \Gamma, x : t \rrbracket}$
Logical Truth	$\models p$	Type Denotation
		$v \in \llbracket t \rrbracket$
$\frac{p \rightsquigarrow^* \text{true}}{\models p}$		$\frac{\models [\nu \mapsto n]p \quad n \in \llbracket \{\nu : \text{int} p\} \rrbracket}{n \in \llbracket \{\nu : \text{int} p\} \rrbracket}$
Logical Entailment	$\Gamma \models p$	(DENINT)
		$\frac{\models [\nu \mapsto b]p}{b \in \llbracket \{\nu : \text{bool} p\} \rrbracket}$
		(DENBOOL)
Logical Implication	$\Gamma \models p \Rightarrow q$	
		$\frac{\models [\nu \mapsto \text{new } C(\bar{v})]p \quad \text{fields}(C) = \bar{t} \quad \bar{v} \in \llbracket \text{this} \mapsto \text{new } C(\bar{v}) \mid t \rrbracket}{\text{new } C(\bar{v}) \in \llbracket \{\nu : C p\} \rrbracket}$
		(DENCLASS)
		$\frac{w <:_b u \quad v \in \llbracket \{\nu : w p\} \rrbracket}{v \in \llbracket \{\nu : u p\} \rrbracket}$
		(UPCAST)

Figure 6 Logical interpretation of RFJ.

Type and Environment Denotation. Now, we formally define what is meant by “a substitution satisfies a type environment.” This relation is defined by the environment denotation relation $\theta \in \llbracket \Gamma \rrbracket$, which is a natural lift of the type denotation relation ($v \in \llbracket t \rrbracket$), determining if a value is denoted by a type. Type denotation is defined by casing on the structure of the value, with an additional *upcast* rule for upcasting the base type. Basically, type denotation relation ($v \in \llbracket \{u|p\} \rrbracket$) encapsulates two facets: the value v belongs to the base type u , and it satisfies the refinement p . DENCLASS additionally requires the denotation for the fields of the class, to justify the nominal nature of class types.

3.4 Typing

In this section, we define the typing relations in RFJ, as shown in Figure 7. We first define the term typing, depending on the type well-formedness relation, which in turn depends on the FJ term typing. After the term typing is defined, we define the method typing ($M \text{ ok in } C$), class typing ($C \text{ ok}$), and interface typing ($I \text{ ok}$).

Well-formedness. For a refinement type $\{\nu : w|p\}$ to be deemed well-formed under environment Γ , denoted as $\Gamma \vdash_w \{\nu : w|p\}$, the refinement p must have *bool* type under the type environment. In the definition, \vdash_F is the FJ term typing relation, which is used to check if the refinement does have *bool* type. Note that we can not use the RFJ term typing here, since it depends on the type well-formedness relation. We do not define the FJ term typing separately. It is a standard textbook relation [52] and can be obtained by removing

Type well-formedness	$\boxed{\Gamma \vdash_w t}$	$\frac{\Gamma \vdash e_0 : s_0 \quad \Gamma, x : s_0 \vdash e : t \quad \Gamma \vdash_w t}{\Gamma \vdash \text{let } x = e_0 \text{ in } e : \boxed{\text{self}(\boxed{t}, \boxed{\text{let } x = e_0 \text{ in } e})}}$ (T-LET)
	$\frac{[\Gamma], \nu : w \vdash_F p : \text{bool}}{\Gamma \vdash_w \{\nu : w p\}}$	$\frac{\neg_t \doteq x : t_0 \rightarrow r \quad \Gamma \vdash s_0 <: t_0}{\Gamma \vdash \neg e_0 : \boxed{[x \mapsto e_0]} r}$ (T-UNOP)
RFJ Typing	$\boxed{\Gamma \vdash e : t}$ $\text{self}(\{\nu : w p\}, e) = \{\nu : w p \wedge \nu = e\}$	$\frac{x : t \in \Gamma \quad \boxed{\Gamma \vdash_w t}}{\Gamma \vdash x : \boxed{\text{self}(\boxed{t}, \boxed{x})}}$ (T-VAR)
		$\frac{x : t \in \Gamma \quad \Gamma \vdash_w t}{\Gamma \vdash n : \boxed{\text{int} \mid \nu = n}}$ (T-INT)
		$\frac{x : t \in \Gamma \quad \Gamma \vdash_w t}{\Gamma \vdash b : \boxed{\text{bool} \mid \nu = b}}$ (T-BOOL)
		$\frac{\Gamma \vdash e_0 : \{\boxed{C_0 \mid p}\} \quad \text{fields}(C_0) = \bar{t} \bar{f}}{\Gamma \vdash e_0.f_i : \boxed{\text{self}([\text{this} \mapsto e_0] t_i, \boxed{e_0.f_i})}}$ (T-FIELD)
		$\frac{\Gamma \vdash e_0 : \{\boxed{C_0 \mid p}\} \quad \Gamma \vdash \{C_0 p\} <: \{C_0 q\} \quad \Gamma \vdash e : s \quad \Gamma \vdash s <: \boxed{[\text{this} \mapsto e_0] t}}{\Gamma \vdash e_0.m(e) : \boxed{\text{self}([\text{this} \mapsto e_0; x \mapsto e] r, \boxed{e_0.m(e)})}}$ (T-INVOK)
		$\frac{\Gamma \vdash e_0 : \{I_0 p\} \quad \Gamma \vdash \{I_0 p\} <: \{I_0 q\} \quad \Gamma \vdash e : s \quad \Gamma \vdash s <: \boxed{[\text{this} \mapsto e_0] t}}{\Gamma \vdash e_0.m(e) : \boxed{\text{self}([\text{this} \mapsto e_0; x \mapsto e] r, \boxed{e_0.m(e)})}}$ (T-INVOKI)
		$\frac{\Gamma \vdash \bar{e} : \bar{s} \quad \Gamma \vdash \bar{s} <: \boxed{[\text{this} \mapsto \text{new } C(\bar{e})] t}}{\Gamma \vdash \text{new } C(\bar{e}) : \boxed{\text{self}(\boxed{C}, \boxed{\text{new } C(\bar{e})})}}$ (T-NEW)
		$\frac{\Gamma \vdash e_0 : s_0 \quad \Gamma, x : s_0 \vdash e : t \quad \Gamma \vdash_w t}{\Gamma \vdash \text{let } e_0 : \boxed{[x \mapsto e_0]} r}$ (T-BINOP)
		$\frac{\Gamma \vdash e : s \quad \Gamma \vdash s <: \boxed{[x \mapsto e_0] t}}{\Gamma \vdash e_0 \oplus e : \boxed{[x \mapsto e_0; y \mapsto e] r}}$ (T-BINOP)
		$\frac{\Gamma \vdash e : s \quad \Gamma \vdash s <: t \quad \boxed{\Gamma \vdash_w t}}{\Gamma \vdash e : t}$ (T-SUB)
method typing		$\frac{M \text{ ok in } C}{CT(C) = \text{class } C \text{ exds } D \text{ imps } \bar{I}\{\dots\}}$ $\text{this} : \{C p\}, x : t \vdash e_0 : r$ $\text{override}(m, C, D, p \rightarrow x : t \rightarrow r)$ $\emptyset \vdash_w \{C p\} \quad \text{this} : \{C p\} \vdash_w t$ $\text{this} : \{C p\}, x : t \vdash_w r$
class typing		$\frac{r m(p, t x)\{\text{return } e_0; \} \text{ ok in } C}{K = C(\bar{s} \bar{g}, \bar{t} \bar{f})\{\text{super}(\bar{g}); \text{this}.\bar{f} = \bar{f}; \}}$ $\text{fields}(D) = \bar{s} \bar{g} \quad \bar{M} \text{ ok in } C$ $\emptyset, \text{this} : C \vdash_w \bar{t} \quad C \triangleright \bar{I}$
interface method typing		$\frac{Q \text{ ok in } I}{\emptyset \vdash_w \{I p\} \quad \text{this} : \{I p\} \vdash_w t}$ $\text{this} : \{I p\}, x : t \vdash_w r$
interface ok		$\frac{r m(p, t x) \text{ ok in } I}{\overline{Q} \text{ ok in } I}$ $\overline{Q} \text{ ok in } I$
		$\text{interface } I\{\overline{Q}\} \text{ ok}$

Figure 7 Typing relations of RFJ.

the `gray` parts of RFJ typing. Since the FJ term typing is only defined for base types and base type environments, we must use an erase function ($\lfloor \cdot \rfloor$) to convert refinement type environments to base type environments. The erase function is naturally lifted from the erase function of refinement types (i.e., $\lfloor \{\nu : w|p\} \rfloor = w$).

Based on the type well-formedness, we define the well-formedness of type environment:

$$(1) \vdash_w \emptyset \quad (2) \vdash_w \Gamma, \Gamma \vdash_w t, x \notin \Gamma \implies \vdash_w \Gamma, x : t$$

which simply asserts that all types are well-formed and all variables are unique.

Term Typing. RFJ term typing is an extension of FJ term typing, replacing base types with refinement types and using refinement subtyping for subtyping. Notably, RFJ term typing utilizes an explicit subsumption rule (T-SUB), which deviates from the implicit algorithmic subtyping commonly attributed to FJ. This deviation is not borne from necessity but is rather a methodological choice, aimed at simplifying the meta-theoretical development.

The types of primitive operations (used in T-UNOP and T-BINOP) follow their semantics:

$$\begin{aligned}\neg_t &\doteq x : \text{bool} \rightarrow \{\text{bool} | v = \neg x\} \\ \wedge_t &\doteq x : \text{bool} \rightarrow y : \text{bool} \rightarrow \{\text{bool} | v = x \wedge y\} \\ \vee_t &\doteq x : \text{bool} \rightarrow y : \text{bool} \rightarrow \{\text{bool} | v = x \vee y\} \\ =_t &\doteq x : \top \rightarrow y : \top \rightarrow \{\text{bool} | v = x = y\}\end{aligned}$$

RFJ typing utilizes several mechanisms absent in FJ typing, i.e., well-formedness checking, type substitution, and general selfification. We briefly discuss those non-standard mechanisms.

1. Well-formedness checking. Three rules (T-VAR, T-LET, and T-SUB) include type well-formedness checking in their premises, guaranteeing the inference of only well-formed types, which is required to establish various lemmas (e.g., the structural properties).
2. Type substitution. Refinement types can refer to visible variables. For example, the type of a field `f` can be $\{\nu : \text{int} | \nu = \text{this}.h\}$, specifying it equal to the `h` field of the object. For those refinements to refer to proper variables, we must substitute these references with actual terms during typing. Continuing the example, suppose we are typing `a.f`, the type should be updated to $\{\nu : \text{int} | \nu = a.h\}$, by substituting `this` to `a`, as T-FIELD rule shows.
3. General selfification. Each rule except the subsumption rule and the rules for primitives (T-INT, T-BOOL, T-UNOP and T-BINOP) is companioned with a selfification operation (*self*), ensuring the terms are always recorded in their types. selfification is not required for subsumption, as it is performed in prior derivations, and primitive rules inherently equate terms in their types (e.g., T-INT assigns $\{\text{int} | \nu = 2\}$ to 2).

Method, Class Typing and Interface Typing. The method, class, and interface typings are relations to identifying valid methods, classes, and interfaces. RFJ's approach to these typings closely mirrors that of FJ, with the addition of well-formedness checks for method and field types. Additionally, the class typing judgment is extended with a checking $C \triangleright \bar{I}$ that ensures the interfaces are properly implemented.

Termination. Finally, we address one tricky issue in typing: termination. As a Turing-complete language, the well-typedness of RFJ terms does not ensure the termination of its evaluation. However, non-terminating evaluations can lead to unsound refinements. For instance, $\emptyset \vdash \text{new } C().m() : \{\text{bool} | 0 = 1\}$ is derivable, where `C.m` is defined as `bool m(){return this.m();}`. Consequently, our logical soundness theorem is strictly applicable to terms that are both well-typed and **terminating** (defined below). In practice, a termination checker should be equipped to ensure the termination where logical soundness is concerned.

$$\frac{\forall \theta \in \llbracket \Gamma \rrbracket. \theta(e) \rightsquigarrow^* v}{\Gamma \downarrow e} \text{ terminating}$$

Main Theorems. The following theorems link typing to semantics and logical entailment.

- **Theorem 1** (Type Soundness). *If $\emptyset \vdash e : t$ and $e \rightsquigarrow^* e'$, then e' is a value or $\exists e''. e' \rightsquigarrow e''$.*
- **Theorem 2** (Logical Soundness). *If $\Gamma \vdash e : \{\nu : w | p\}$, $\vdash_w \Gamma$, and $\Gamma \downarrow e$, then $\Gamma \models [\nu \mapsto e]p$.*

The major steps to establish those theorems are given in the next section.

4 Meta-theoretical Results

We argue the proposed system possesses type soundness and logical soundness. The proof of type soundness follows the “Type Soundness = Preservation + Progress” approach [70]. The approach to logical soundness is different from that of previous refinement type systems, as their approach does not apply to RFJ (c.f., Section 2.3). Our proof approach can be summarized as “Logical Soundness = Preservation + Typing Denotation + Closing Substitution.” We give an overview of the critical lemmas and theorems used in the proof and the dependency relation in Figure 8. In the remainder of this section, we provide a brief overview of the proof. For a detailed exposition, please refer to the Coq development.

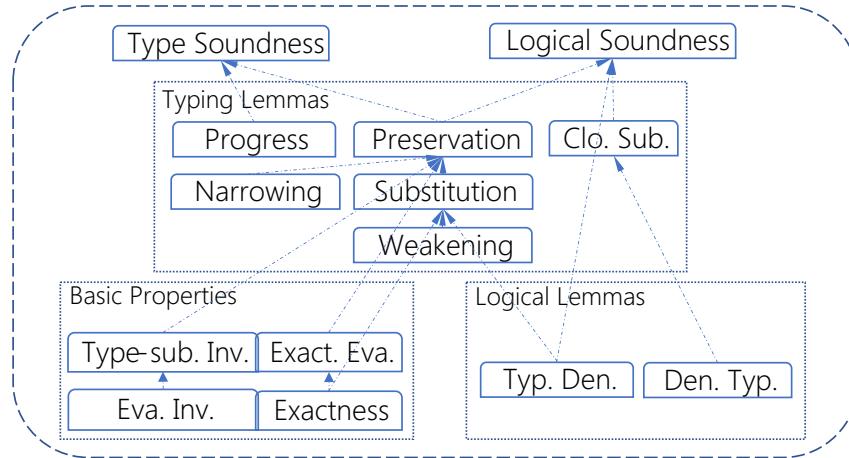

Figure 8 Proof Overview. Arrows signify the dependencies among lemmas and theorems.

4.1 Basic Properties

► **Lemma 3** (Evaluation Invariant). *If $e \rightsquigarrow e'$, then $[x \mapsto e]p \rightsquigarrow^* v \Leftrightarrow [x \mapsto e']p \rightsquigarrow^* v$.*

This lemma asserts that evaluation remains unaffected by the substitution with pre-or-post-evaluation terms, as the next lemma shows. Since the multi-step evaluation (\rightsquigarrow^*) does not give a very useful induction principle, we first prove this lemma using the big-step semantics, then link the lemma back to multi-step semantics via the correspondence between big-step and multi-step semantics (i.e., $e \Downarrow v \Leftrightarrow e \rightsquigarrow^* v$).

► **Lemma 4** (Type-substitution Invariant). *If $e \rightsquigarrow e'$, then $\Gamma \vdash [x \mapsto e]t <: [x \mapsto e']t$ and $\Gamma \vdash [x \mapsto e']t <: [x \mapsto e]t$.*

This lemma states the coherence of types under substitution with pre-or-post-evaluation terms. This lemma is important to prove the preservation lemma. Since subtyping relies eventually on evaluation, the primary challenge of proving this lemma hinges on Lemma 3.

► **Lemma 5** (Exactness). *If $\Gamma \vdash e : t$ then $\Gamma \vdash e : \text{self}(t, e)$.*

This lemma states what we mean by “term information is always recorded”: for any well-typed term e , we can always construct a typing where the term is selfified (recorded in the type). Apart from being used for Lemma 6, this lemma is important for the substitution lemma (Lemma 10).

► **Lemma 6** (Exactness Evaluation). *If $e \rightsquigarrow e'$ and $\Gamma \vdash e' : t$ then $\Gamma \vdash e' : \text{self}(t, e)$.*

This lemma ensures the term after evaluation (e') can have the type selfified with the term before evaluation (e), which is often needed to prove the preservation of typing throughout evaluation steps. This lemma requires the exactness lemma, as shown above.

4.2 Logical Lemmas

► **Lemma 7** (Typing Denotation). *If $\Gamma \vdash v : t$, then $\forall \theta \in \llbracket \Gamma \rrbracket. v \in \llbracket \theta(t) \rrbracket$.*

This lemma states that typing implies denotation. It can be proved by induction on the typing judgment. This lemma is important for the substitution lemma (Lemma 10) and is a milestone for logical soundness, as we discuss in Section 4.5.

► **Lemma 8** (Denotation Typing). *If $v \in \llbracket t \rrbracket$ and $\emptyset \vdash_w t$, then $\emptyset \vdash v : t$.*

This lemma states that denotation implies typing, which is crucial for Lemma 14. The basic proof idea is to first construct a “ground type” for v : $\emptyset \vdash v : \{\nu : w | \nu = v\}$, where w is the *inherent* base type of the value (*int* for n , *bool* for b , and C for *new C(...)*), and then link the “ground type” to t by $\emptyset \vdash \{\nu : w | \nu = v\} <: t$, which holds due to $v \in \llbracket t \rrbracket$.

4.3 Typing Lemmas

4.3.1 Structural Lemmas for Typing

As usual, we establish structural properties (weakening, narrowing and substitution) for RFJ typing. Since typing relies on subtyping which in turn, relies on logical implication, we need those structural properties for subtyping and logical implication, too.

► **Lemma 9** (Narrowing). *for any variable x not in Γ and Γ' :*

1. *If $\Gamma, x : r, \Gamma' \vdash p \Rightarrow q$ and $\Gamma \vdash r' <: r$, then $\Gamma, x : r', \Gamma' \vdash p \Rightarrow q$.*
2. *If $\Gamma, x : r, \Gamma' \vdash s <: t$ and $\Gamma \vdash r' <: r$, then $\Gamma, x : r', \Gamma' \vdash s <: t$.*
3. *If $\Gamma, x : r, \Gamma' \vdash e : t$ and $\Gamma \vdash r' <: r$, then $\Gamma, x : r', \Gamma' \vdash e : t$.*

The first narrowing lemma can be proved by observing that a denotation θ' of $\Gamma, x : r', \Gamma'$ is always a denotation of $\Gamma, x : r, \Gamma'$. Using the first lemma, the remaining two are easy.

► **Lemma 10** (Substitution). *for any distinct variables x and y not in Γ and Γ' :*

1. *If $\Gamma, x : r_x, y : r_y, \Gamma' \vdash p \Rightarrow q$ and $\Gamma \vdash v_x : r_x$, $\Gamma \vdash v_y : [x \mapsto v_x]r_y$, then $\Gamma, [x \mapsto v_x; y \mapsto v_y]\Gamma' \vdash [x \mapsto v_x; y \mapsto v_y]p \Rightarrow [x \mapsto v_x; y \mapsto v_y]q$.*
2. *If $\Gamma, x : r, y : r_y, \Gamma' \vdash s <: t$ and $\Gamma \vdash v_x : r_x$, $\Gamma \vdash v_y : [x \mapsto v_x]r_y$, then $\Gamma, [x \mapsto v_x; y \mapsto v_y]\Gamma' \vdash [x \mapsto v_x; y \mapsto v_y]s <: [x \mapsto v_x; y \mapsto v_y]t$.*
3. *If $\Gamma, x : r, y : r_y, \Gamma' \vdash e : t$ and $\Gamma \vdash v_x : r_x$, $\Gamma \vdash v_y : [x \mapsto v_x]r_y$, then $\Gamma, [x \mapsto v_x; y \mapsto v_y]\Gamma' \vdash [x \mapsto v_x; y \mapsto v_y]e : [x \mapsto v_x; y \mapsto v_y]t$.*

Since RFJ has double substitution operations in method invocation (we must substitute for *this* and the parameter), we need double substitution lemmas. The first substitution lemma follows from the observation that a denotation of $\Gamma, x : r_x, y : r_y, \Gamma'$ can be constructed from a denotation of $\Gamma, [x \mapsto v_x; y \mapsto v_y]\Gamma'$ by adding $x : v_x$ and $y : v_y$. The core step of this construction is to prove that v_x is indeed a denotation of r_x and v_y is indeed a denotation of $[x \mapsto v_x]r_y$, utilizing Lemma 7. Using the first lemma, the second lemma is easy. The third lemma can be proved by induction on typing. The T-VAR case requires the exactness lemma (Lemma 5) and weakening lemma (shown below). The other cases are easy.

► **Lemma 11** (Weakening). *for any variable x not in Γ, Γ' , p, q, s and t :*

1. *If $\Gamma, \Gamma' \models p \Rightarrow q$, then $\Gamma, x : r, \Gamma' \models p \Rightarrow q$.*
2. *If $\Gamma, \Gamma' \vdash s <: t$, then $\Gamma, x : r, \Gamma' \vdash s <: t$.*
3. *If $\Gamma, \Gamma' \vdash e : t$, then $\Gamma, x : r, \Gamma' \vdash e : t$.*

The first weakening lemma can be proved by observing that we can always construct a denotation θ' of Γ, Γ' from a denotation θ of $\Gamma, x : t, \Gamma'$, by removing the x entry from θ . Since x is fresh, removing it from θ does not impact the validity of this implication. With the first weakening lemma in hand, the remaining two are straightforward.

4.3.2 Progress & Preservation

► **Lemma 12** (Progress). *If $\emptyset \vdash e : t$ then e is a value or $\exists e'. e \rightsquigarrow e'$.*

The proof is done by induction on typing, following the standard approach of FJ.

► **Lemma 13** (Preservation). *If $\emptyset \vdash e : t$ and $e \rightsquigarrow e'$, then $\emptyset \vdash e' : t$.*

The proof is done by induction on the typing judgment and using the structural lemmas for substitutions and environment narrowings. To argue the preservation in the presence of general selfification and type substitution, Lemma 6 and Lemma 4 must also be utilized.

4.3.3 Closing Substitution

► **Lemma 14** (Closing Substitution). *If $\Gamma \vdash e : t$, then $\forall \theta \in [\Gamma]. \emptyset \vdash \theta(e) : \theta(t)$.*

The closing substitution lemma bears a similarity with the substitution lemma (Lemma 10). They both concern the invariance of typing under substitution. The closing substitution lemma can be proved by induction on typing. Most of the cases are standard, except for the variable case, which requires proving $\emptyset \vdash \theta(x) : \theta(t)$ under $\Gamma \vdash x : t$. Since θ is a denotation of Γ , we know that x must be in θ and $\theta(x) \in [\theta(t)]$. Thus, Lemma 8 can be applied to construct the expected typing judgment.

4.4 Type Soundness

To improve the readability, we reproduce Type Soundness (Theorem 1) below:

► **Corollary 15** (Type Soundness). *If $\emptyset \vdash e : t$ and $e \rightsquigarrow^* e'$, then e' is a value or $\exists e''. e' \rightsquigarrow e''$.*

Type soundness is an easy corollary of progress and preservation [70].

4.5 Logical Soundness

To improve readability, we reproduce the Logical Soundness (Theorem 2) below:

► **Corollary 16** (Logical Soundness). *If $\Gamma \vdash e : \{\nu : w | p\}$, $\vdash_w \Gamma$, and $\Gamma \downarrow e$, then $\Gamma \models [\nu \mapsto e]p$.*

The key to proving logical soundness is to observe that it can be reduced to closed logical soundness (shown below) if we can derive a corresponding closed typing judgment given any typing judgment. This is facilitated by the closing substitution lemma (Lemma 14).

► **Theorem 17** (Closed Logical Soundness). *If $\emptyset \vdash e : \{\nu : w | p\}$ and $\downarrow e$, then $\models [\nu \mapsto e]p$.*

Closed logical soundness is a natural consequence of preservation and typing denotation. Supposing e evaluates to v , the proof skeleton is that:

1. Due to the preservation lemma, $\emptyset \vdash v : \{\nu : w | p\}$.
2. Due to the typing denotation lemma, $v \in [\{\nu : w | p\}]$, thus $\models [\nu \mapsto v]p$.
3. Lastly, we can apply the evaluation invariant lemma to get $\models [\nu \mapsto e]p$.

5 Logical Encoding: LFJ

Following the standard procedure as outlined in, e.g., [6], we convert RFJ to an algorithmic bidirectional type system. The only judgment whose algorithmic property was unexplored was the class-based refinement subtyping. In this section, we present an encoding of RFJ to an order-sorted first-order logic [57], named LFJ, which gives a convenient axiomatic approach to determine RFJ refinement subtyping by invoking logical decision procedures.

5.1 Language

Figure 9 presents the syntax of LFJ. The constant symbols (c) are for RFJ values. We assume each RFJ value has a corresponding LFJ constant symbol. The function symbols (g) are for methods (N_m), field selectors (C_f), class constructors (C_{cr}), and primitive operations in RFJ. We associate methods with nominal names and field selectors with class names, for attributing more precise semantics (detailed later). Note that interfaces have no fields. The terms in LFJ do not contain quantification: they are viewed as implicitly quantified and a universal quantification would be added to the outermost to close them. Sorts in LFJ consist of \top , Int , $Bool$, and N . The sorts have an apparent correspondence with RFJ base types. We denote $|w|$ as the translation of a base type w to its sort, and $|t|$ as the translation from a refinement type t to its sort. The subsort relation \sqsubseteq is straightforwardly translated from the base-subtyping relation. The signatures of functions are also translated from their RFJ type definitions, e.g., the signature of C_m is $C \rightarrow |t| \rightarrow |r|$ if $mtype(m, C) = p \rightarrow x : t \rightarrow r$.

Syntax		Term Translation
$e, p ::=$	<i>terms:</i>	
x	<i>variable</i>	$ x = x$

		<i>Environment Translation</i>

Figure 9 LFJ syntax and translation.

Translation. The translation from RFJ terms and type environments to LFJ terms is mostly straightforward. The only thing to note is the association of type information during the translation of method invocations and field accesses, marked **brown** in Figure 9. This is facilitated by the *typeof* function: $\delta(e)$ is the static type of expression e . δ can be constructed during type checking. The association of type information is important for two purposes (we take method invocations as an example, but the argument also applies to field accesses):

- *Disambiguation.* Suppose the method m is defined by two classes C and D , which share no common superclass except `Object`. If methods are not associated with nominal types, the LFJ function representation of m would necessitate an assumed domain of *Object* for its first parameter, rendering the model for the function inherently partial, because not all *Object* has an m implementation. Incorporating type information ensures model totality for the first parameter by guaranteeing the existence of at least one implementation of m ; such existence is verified by static type checking. This totality guarantee plays an important role in the intended model (c.f., Section 5.2).
- *Axiomatization.* The aim of LFJ is to provide an axiomatization of its intended model (c.f., Section 5.3). By associating type information, the axiomatization can be crafted with greater specificity and accuracy.

5.2 Intended Model

Domain:	Functions:
$G_I = G_{\top} = \emptyset$	$\neg, \wedge, \vee = normal$
$G_C = \{C(\bar{d}_s) \mid \bar{d}_s \in \bar{D}_{ t }\}, fs(C) = \bar{t} \bar{f}$	$C_{cr}(\bar{d}) = C(\bar{d})$
$G_{Int} = \mathcal{Z}$	$C_{fi}(C'(\bar{d})) = d_i, C' \sqsubseteq C \text{ and } fs(C) = \bar{t} \bar{f}$
$G_{Bool} = \{T, F\}$	$N_m(this, x) = \begin{cases} \llbracket mb(m, C) \rrbracket(this, x) \text{ if } this = C(\bar{d}) \\ \dots \text{ proceeds for all } C \sqsubseteq N \end{cases}$
$D_s = \{d \mid d \in G_{s'} \wedge s' \sqsubseteq s\}$	

Figure 10 The intended model of LFJ. fs is short for *fields*.

In this section, we delineate the construction of an intended model \mathcal{A} for LFJ, given in Figure 10. This model bears similarities with several denotational semantics of class-based languages [58, 12], especially in the usage of *conditional functions* as models of method invocations, whereas we work with order-sorted logic, different from those semantics.

Domains. Each sort s is associated with a dynamic domain G_s and a static domain D_s . The dynamic domain of a sort is a *set* containing all values inherently belonging to the sort. The dynamic domains of \top and I (i.e., interfaces) are both \emptyset . G_{Int} and G_{Bool} are standard. G_C is the finite term trees [22] generated in a sort-correct manner (i.e., each field is drawn from the static domain of the corresponding sort). The static domain (or simply, domain) for a sort s aggregates the dynamic domains of its subsorts, as in standard OS-FOL [57].

Functions. The model adopts conventional interpretations for equality and boolean operators. The intended functions for constructors and fields are the constructing and destructing functions for term trees. The intended function of N_m is just a *conditional function* composed of the denotations of the implementation functions conditioned by the first parameter (i.e., the receiving object). We do not detail the denotations in this paper: because we require termination for well-typed RFJ programs, those denotations are total on their domains and can be constructed using standard fixed-point techniques as shown in, e.g, [46].

Algorithmic Subtyping. With the intended model \mathcal{A} in hand, we now define the algorithmic subtyping relation:

$$\frac{w <_b u \quad \mathcal{A} \models_L \forall \bar{x}. |\Gamma| \wedge |p| \Rightarrow |q|}{\Gamma \vdash \{\nu : w|p\} <_L \{\nu : u|q\}} A\text{-Subtyping}$$

where \models_L is the normal semantics of OS-FOL [57]. We assume all variables in Γ are distinct and are not ν . We use a universal quantification $\forall \bar{x}$ to close the formula, where \bar{x} is the variables used in Γ , p and q .

We establish the soundness of the algorithmic subtyping with respect to the refinement subtyping, which is a corollary of the semantic equivalence and translation-substitution distributivity. Semantic equivalence states the true sentences in RFJ logical interpretation are also true in \mathcal{A} , and vice versa. Translation-substitution distributivity states it does not matter whether we apply a closing substitution prior to or after the translation.

- **Proposition 18** (Semantic Equivalence). $\mathcal{A} \models_L |p| \Leftrightarrow \models p$
- **Proposition 19** (Translation-substitution Distributivity). $\mathcal{A} \models_L |\theta|(|p|) \Leftrightarrow \mathcal{A} \models_L |\theta(p)|$
- **Corollary 20.** If $\Gamma \vdash s <:_L t$, then $\Gamma \vdash s <: t$.

Proof. We give a brief proof sketch of Corollary 20 here. Suppose s is $\{\nu : w|p\}$ and t is $\{\nu : u|q\}$. To prove $\Gamma \vdash \{\nu : w|p\} <: \{\nu : u|q\}$, we need to prove $\forall \theta \in [\Gamma, \nu : w]. \text{if } \models \theta(p) \text{ then } \models \theta(q)$. By $\Gamma \vdash s <:_L t$, we have $\mathcal{A} \models_L \forall \bar{x}. |\Gamma| \wedge |p| \Rightarrow |q|$, which gives us $\forall \sigma. \mathcal{A} \models_L \sigma(|\Gamma| \wedge |p|) \Rightarrow \mathcal{A} \models_L \sigma(|q|)$ (by the semantics of OS-FOL). Pick σ as $|\theta|$, due to Propositions 18 and 19, we have $\mathcal{A} \models_L |\theta|(|\Gamma| \wedge |p|)$, which let us deduce $\mathcal{A} \models_L |\theta|(|q|)$. Using Propositions 18 and 19 again, but in the reverse direction, we have $\models \theta(q)$. ◀

5.3 Theory

To utilize the capability of deductive reasoning for checking subtyping algorithmically, we axiomatize the intended model \mathcal{A} by a theory $\mathcal{T}_{\mathcal{J}}$. $\mathcal{T}_{\mathcal{J}}$ includes the usual theory of Equality, Uninterpreted Functions, and Linear Integer Arithmetic (EUFLIA) [1]. Besides, it is equipped with axioms for N_m , C_f , and C_{cr} . We specify and explain them in this section.

- (1) *generate* : \rightarrow $\forall x : N. \bigvee_{C \sqsubseteq N} \exists \bar{y} : |fs(C)_t|. x = C(\bar{y})$
- (2) *inject* : \rightarrow $\forall \bar{x} : |fs(C)_t|, \bar{y} : |\bar{t}|. C_{cr}(\bar{x}) = C_{cr}(\bar{y}) \Rightarrow \bar{x} = \bar{y}$
- (3) *discriminate* : $C \neq D \rightarrow \forall \bar{x} : |fs(C)_t|, \bar{y} : |fs(D)_t|. C_{cr}(\bar{x}) \neq D_{cr}(\bar{y})$
- (4) *access* : $fs(C) = \bar{f} \bar{t}, C' \sqsubseteq C \rightarrow \forall \bar{x} : |fs(C')_t|. C_{fi}(C'_{cr}(\bar{x})) = x_i$
- (5) *invoke* : $mt(m, N)_x = t_x, C \sqsubseteq N, mb(m, C) = (x, e) \rightarrow$
 $\forall o : N, x : |t_x|, \bar{d} : |fs(C)_t|. o = C(\bar{d}) \Rightarrow N_m(o, x) = |e|$

The above listing gives five axiom schemata. The symbol \rightarrow means “instantiate”: if the condition on the left is satisfied, one can instantiate an axiom following the schema on the right. The symbols fs , mb , fs_t , and mt_x short for *fields*, *mbody*, the type part of *fields*, and the parameter part of *mtype* (or *mtypei* for interfaces), respectively.

The axiom schemata are straightforward given the intended model \mathcal{A} . However, they may not be as efficient as we want. To address this, we add two derivable properties as axioms, to speed up deductive reasoning. The first covers cases where the branches of a method direct to the same implementation. We have seen such a case in our example: *Anchovy.remA* has two branches that direct to the same implementation. We call these methods like *Anchovy.remA final methods*. Final methods have the same implementation on all branches, and there is no need to actually do the branching. We axiomatize their semantics using the axiom schema (6) shown below. An instantiation of (6) gives the property p_3 we discussed in Section 2.2. The second covers cases where a method is called on a subclass of the declared type. For

example, suppose we have $\nu = Pi_{remA}(x)$ and $x : An$, and we want to prove $\nu = An_{remA}(x)$. With basic axioms (1) through (5) above, we have to first deduce the fact that x can only be $An(\dots)$ or $Ma(\dots)$, then analyze the semantics of Pi_{remA} and An_{remA} for those two cases, and finally deduce that the equality holds for both cases. However, this is mostly redundant: Pi_{remA} and An_{remA} are the same function if the first argument is known to be an An . We axiomatize this fact using schema (7) shown below. For certain cases involving comparing method-call results, axiom schema (7) can speed up reasoning significantly.

- (6) $final : mt(m, C)_x = t_x, C.m \text{ final}, mb(m, C) = (x, e), \Rightarrow \forall o : C, x : |t_x|. C_m(o, x) = |e|$
- (7) $override : N' \sqsubseteq N, mt(m, N')_x = t_x \Rightarrow \forall o : N', x : |t_x|. N_m(o, x) = N'_m(o, x)$

Encoding into Many-sorted Logic. The aforementioned axioms are defined in OS-FOL and should be used in order-sorted deductive reasoning. Unfortunately, we are not aware of any SMT solver that supports order-sortedness. Thus, we translate the axioms into many-sorted logic following the strategy suggested by Leino [38]. The translation of primitive data types is straightforward. For objects, a unified sort *Object* is designated. We then introduce a sort *Nominal* to encompass all nominal entities, i.e., classes and interfaces in the targeting RFJ program. We also declare the sub-nominal relation between those entities. The association of nominal information with objects is facilitated through the *Tag* function, which relates objects with their nominal identifiers. The sort requirements become sub-nominal checkings on tags, e.g., instead of $\forall x : C. p(x)$, we use $\forall x : Object. sub-nominal(Tag(x), C) \Rightarrow p(x)$.

The direct encoding of the sort \top into many-sorted logic is beyond our current scope, primarily influencing the polymorphic nature of equality. Nevertheless, given the uniform *Object* sort for all object values, object equality is still \top -typed essentially, circumventing potential limitations posed by the absence of a direct \top sort.

6 Mechanization and Implementation

6.1 Coq Mechanization

We mechanize the meta-theory of RFJ in Coq. There are two major technical challenges around the mechanization. (1) *Binders*. Handling binders is cumbersome and complex [3], especially considering the number of binder structures present in RFJ (e.g., methods, let-bindings, and refinement types). To address this issue, we adopt the locally nameless representation [13]. Although the locally nameless representation has been widely used in mechanizing functional languages [8, 29, 13], to the best of our knowledge, ours is the first mechanization of a class-based language that utilizes this technique. (2) *Nested Inductive Types*. The presence of nested inductive types within our definitions poses a significant challenge; that is, the default induction principles generated by Coq fell short when proving the most critical properties. To mitigate this issue, we specify the custom induction principles for a range of inductive definitions (e.g., terms, typing judgments, and big-step semantics), following the classical methodology [15].

We briefly overview the structure of the mechanization, which contains about 15K lines of Coq code:

1. Definitions (3K): language definitions as presented in Section 3.
2. Lemmas (11K):
 - a. Basic Lemmas (5K): miscellaneous lemmas concerning basic operations, semantics, and class/interface definitions (some of which are listed in Section 4.1).
 - b. Logical Lemmas (2K): lemmas concerning the logical interpretation (c.f., Section 4.2).
 - c. Typing Lemmas (4K): basic, structural, and crucial lemmas of typing (c.f., Section 4.3).
3. Theorems (1K): type and logical soundness theorems (c.f., Sections 4.4 and 4.5).

6.2 Python Implementation

We implement a refinement type checker for RFJ. The implementation is written in roughly 2,000 lines of Python code, with Z3 [19] as the SMT backend. In addition to all features of RFJ, the type checker also supports a form of *if-then-else* following the standard practice [32], to increase the scope of the evaluation. The concrete syntax supported in the implementation is a subset of Python with static types. We opt for Python just to reuse its parser and editor supports. RFJ can be implemented for any other class-based language.

To test the type checker, we handcraft a test suite, including all the major examples that do not use type-test/downcast or imperative features from a Java textbook [23], as well as some interesting examples inspired by previous work [65]. Each example is paired with some non-trivial properties. In total, there are 14 examples with about 1,500 LOC, covering all important features of RFJ. We list several representative examples in Table 1.

Table 1 Several representative examples.

Name	Features	LOC	Properties
pizza	classes, overrides	135	remA_noinc_price, remA_idempotent
pizza visitor	visitors, upcasts	110	noObj_after_rem, noObj_after_effective_sub
tree	visitor interfaces	152	height_ge_root
geometry	factory methods	184	origin_in_shape
list	data structures	125	contains_weakening, inserts_preserve_sortedness
λ calculus	data structures	71	size_positive, substitution_nodec_size
stlc	meta-theories	307	map_extend_included, typing_weakening

Type-checking each example took under 5 seconds, on an Apple M1 machine.

7 Discussion

In this section, we discuss specific designs of RFJ in greater detail.

Type Substitution vs ANF and Existential types. In the realm of refinement type systems, the conventional strategy often involves leveraging ANF [32, 37] or existential types [47, 34, 8] to maintain the logic of refinements within a decidable framework, such as EUFLIA [9]. Our approach, however, consciously eschews these mechanisms and sticks to simple type substitution for three compelling reasons. (1) *From the theoretical perspective.* We want to argue the soundness of our system within a broader, more generalized framework: all RFJ programs expressed in ANF are inherently valid within our system, while the converse does not hold. Thus, our results perfectly apply to the condition where ANF is required (e.g., a particular implementation may perform ANF transformation before type checking). (2) *From the algorithmic perspective.* Recent advances [41, 44] have shown a complete algorithm for formula validity under a user-specified theory exists, which is exactly what we need to perform algorithmic subtyping checking. The fact that all our examples are checked costing only a little time also evidences that a reasonably efficient algorithm exists even if the logic falls outside the familiar decidable fragment. (3) *From the pragmatical perspective.* Eliminating ANF and existential types significantly lowers the barrier between the programmer’s intent and the underlying type system, simplifying the debugging process. To further lower the barrier, our typing rules are carefully formulated without using any implicit environment extension (e.g., the *Field* and *Invoke* rules in [47]). The only cases that would extend the typing and subtyping environment are *Let* and method typing, thereby maintaining a clear correspondence between the code and its type-level representation.

Axiomatization vs. Reflection. As pointed out by prior work [66], there are two kinds of methodologies to support user-defined functions in refinement type systems: axiomatization and reflection. Axiomatization articulates the semantics of user-defined functions through logical axioms, an approach we adopt and have elaborated on in Section 5.3. In contrast, reflection directly incorporates the function definition into the return type’s refinement (e.g., the return type of `Anchovy.remA` can be declared as $\{\nu : \text{Pizza} | \nu = \text{this}.p.\text{remA}()\}$ to reflect its definition). In our system, programmers can utilize reflection by manually specifying the method return type (reflection annotation could also be provided to automate this process). Those reflections are always valid thanks to general reflection, which ensures that terms are always recorded in refinements. Notably, reflection offers an alternative to the *final* constraint of the invoke axiom schema (c.f. Section 5.3): one can reflect the definition of an overriding method and the overridden method simultaneously, as long as the return types of those methods obey the co-variance principle.

The major difference between reflection and axiomatization resides in the instantiation strategy of method definitions. With reflection, instantiations of the reflected functions are performed within the type system, either by the programmer or an algorithm (e.g., PLE in [66]). With axiomatization, instantiation is delegated to the SMT solver, although special mechanisms such as *trigger/fuel* [2, 40] are needed to keep the process in control. Currently, no special algorithm or mechanism for reflection or axiomatization is employed in RFJ. However, we identify the comparison of these two methodologies in RFJ, especially in the context of a reflection instantiation algorithm and more advanced type system features (e.g., occurrence typing and union/intersection types) as important future work.

8 Related Work

This work intersects three research topics: class-based refinement type systems, mechanization of refinement types and class-based languages, and SMT-based reasoning in program verifiers.

Class-based Refinement Type Systems. Class is an important and time-honored abstraction in object-oriented programming [16, 59, 25, 31], with numerous pieces of literature devoted [69, 60, 5, 55] to its extensions. In particular, many works have focused on class-based refinement type systems. For example, Nystrom et al. [47] formalize core X10 as a refinement type system. However, they focus only on the functional aspects. Vekris et al. [67] introduce a refinement type calculus that not only conducts immutability analysis but also integrates union and intersection types, with the caveat that only immutable fields are subject to refinement. Campos et al. [10] combine refinement types with class-based linear types, further increasing the support for imperative features. Kuncak et al. [56] present qualified type, a form of refinement type, and offer an in-depth discussion on qualifier inference. Gamboa et al. [26] address the practical challenges of incorporating refinement types into existing class-based systems by proposing a design approach to usability.

All the aforementioned work limits their refinements to well-established decidable SMT theories (e.g., EUFLIA), and thus have significant issues concerning soundness and expressiveness, as we have explained before. Meanwhile, although there are systems [33, 63] exploring the support for more expressive refinements, their approach is mainly pragmatic (i.e., they both rely on external verification tools to support the expressive refinements), which complicates the analysis of their meta-theoretical properties further.

This work addresses the expressiveness and soundness issues in a fundamental way, by providing an expressive and mechanized calculus grounded in Featherweight Java. We anticipate that extensions such as generics and imperative features could be seamlessly integrated into our framework, prospects we reserve for future exploration.

Mechanization of Refinement Types and Class-based Languages. Several pieces of recent work have been dedicated to the mechanization of refinement types. Lehmann et al. [37] formalize a refinement type system in Coq. Their logical interpretation is axiomatized via a few basic requirements. This interpretation, however, leaves the semantics of logical formulas nebulous. Meanwhile, their proof focuses solely on the closed logical soundness, rather than general logical soundness. Wang et al. [68] mechanize in Coq a calculus that uses refinement types for complexity analysis, defining logical interpretations through denotational semantics that link refinements to Coq definitions. This method restricts the scope of terms that can be utilized as refinements due to the limitation of denotational semantics. Borkowski et al. [8] mechanizes a polymorphic refinement type system in Coq. They use an axiomatized logical interpretation for type soundness, and an operational-semantics-based logical interpretation for logical soundness. Hamza et al. [29] formalize a polymorphic refinement type system in Coq. They also employ an operational-semantics-based logical interpretation (named reducibility in the original paper). Our work draws inspiration from the two works on using operational-semantics-based logical interpretations, yet our proof diverges notably, especially given the inapplicability of logical relation techniques in our context. Moreover, our framework includes several special mechanisms such as general selfification and nominal subtyping, extending beyond the capabilities of the systems devised by those authors. Chen’s work [14] in Agda takes a unique route by integrating Agda to define a denotational semantics for refinements. However, the algorithmic properties are complicated, due to the reliance on Agda’s logic. Ghalayini et al. [26] opt for a categorical-theoretical perspective for logical interpretation in their mechanized refinement type system in Lean [18], contrasting with the semantic logical interpretation in our work.

Apart from the abovementioned differences, our research sets itself apart by focusing on a class-based calculus. This foundation renders our model particularly adept at mirroring object-oriented programming paradigms, a facet not directly addressed by the aforementioned mechanizations. There are also several mechanizations of class-based languages [42, 20, 17]. However, neither of them supports refinement types.

SMT-based Deductive Reasoning in Program Verifiers. Since its inception, SMT solvers have played a pivotal role in the automated verification of **functional** properties. Simplify [21] and ESC/Java [24] are among the earliest examples. Subsequently, a wave of advanced program verifiers like Dafny [39], Leon/Stainless [7, 29], F* [61] and Liquid Haskell [65, 66] have garnered attention in both academia and industry. Among those systems, Dafny and Leon/Stainless all support some object-oriented constructs. However, they lack RFJ’s support for nominal subtyping and method inheritance. Recent scholarly work has delved into the foundational aspects of SMT-based deductive reasoning, focusing especially on the completeness problem [44, 41, 45]. However, the arguments of those papers are all set upon many-sorted logic, diverging from the order-sorted logic in our study.

On the other hand, SMT solvers have also been extensively used in verifying **heap** properties. The modeling and verification of those properties (typically in separation logic [48, 49]) are, in general, beyond the ability of vanilla SMT theories [43]. Despite these challenges, research has successfully identified certain significant fragments yielding effective decision procedures falling into the SMT realm [43, 54, 53]. Currently, RFJ is a purely functional calculus. However, we believe that it is promising to incorporate those advancements to support the reasoning of heaps, considering imperative features are ambitious in class-based object-oriented languages [50].

9 Conclusion and Future Work

This paper introduces Refinement Featherweight Java (RFJ), advancing class-based refinement types with expressive refinements for comprehensive logical constraints. We mechanize RFJ in Coq, proving its soundness rigorously. We bridge the declarative calculus and algorithmic verification via a specified fragment in OS-FOL, making RFJ’s refinements accessible for SMT reasoning. The deliberate choice of FJ and OS-FOL for our fundamental framework facilitates important future extensions, such as polymorphic and imperative features, and a thorough exploration of algorithmic properties.

Abstract

Protection of confidential data is an important security consideration of today's applications. Of particular concern is to guard against unintentional leakage to a (malicious) observer, who may interact with the program and draw inference from made observations. Information flow control (IFC) type systems address this concern by statically ruling out such leakage. This paper contributes an IFC type system for message-passing concurrent programs, the computational model of choice for many of today's applications such as cloud computing and IoT applications. Such applications typically either implicitly or explicitly codify protocols according to which message exchange must happen, and to statically ensure protocol safety, behavioral type systems such as session types can be used. This paper marries IFC with session typing and contributes over prior work in the following regards: (1) support of realistic cyclic process networks as opposed to the restriction to tree-shaped networks, (2) more permissive, yet entirely secure, IFC control, exploiting cyclic process networks, and (3) considering deadlocks as another form of side channel, and asserting deadlock-sensitive noninterference (DSNI) for well-typed programs. To prove DSNI, the paper develops a novel logical relation that accounts for cyclic process networks. The logical relation is rooted in linear logic, but drops the tree-topology restriction imposed by prior work.

2012 ACM Subject Classification Theory of computation → Linear logic; Security and privacy → Logic and verification; Theory of computation → Process calculi; Theory of computation → Type theory

Keywords and phrases Cyclic process networks, linear session types, logical relations, deadlock-sensitive noninterference

1 Introduction

Many of today's emerging applications and systems such as cloud computing and IoT applications are inherently *concurrent* and *message passing*. Message passing also enjoys popularity in mainstream languages such as Erlang, Go, and Rust. Similar to functional languages with the λ -calculus as their theoretical model, the model of message-passing

concurrent languages is the process calculus [31, 47, 48]. A program in this setting amounts to a number of *processes* connected by *channels*, which compute by exchanging messages along these channels, rather than by β -reductions or writing to and reading from shared memory. Messages may even include channels themselves, a feature supported in the π -calculus [49, 59] and referred to as *higher-order* message passing.

Originally untyped [49], the π -calculus has gradually been enriched with types to prescribe the kinds of messages that can be exchanged over a channel [59] and to assert correctness properties, such as deadlock freedom and data-race freedom [40, 38, 39, 42]. Following in these footsteps, *session types* [32, 33] were conceived to additionally express the *protocols* underlying the exchange. Session types rely on a *linear* treatment of channels to model the state transitions induced by a protocol, which was even substantiated by a Curry-Howard correspondence between the session-typed π -calculus and linear logic [9, 66, 67, 64, 45, 10, 46]. Session types based on linear logic enjoy strong properties, comprising not only race and deadlock freedom but also protocol fidelity.

Security is another correctness consideration arising from today’s applications and systems. One security concern in particular is the protection of confidential information, by preventing unintentional leakage to a (malicious) observer, who may interact with the program and draw inference from made observations. Type systems for *information flow control (IFC)* rule out such leakage by type checking [65, 60, 57], given a lattice over security levels and the labeling of observables (e.g., output, locations, channels) with these levels. Well-typed programs then prevent “flows from high to low” and guarantee *noninterference*, i.e., that an observer cannot infer any secrets from made observations. To guarantee noninterference, advanced proof methods such as logical relations [54, 2, 22, 50, 37, 63] and bisimulations [44, 62, 61, 58] are used. If side channels [57], such as the termination channel, are present, then the literature distinguishes *progress-sensitive* noninterference (PSNI) from *progress-insensitive* noninterference (PINI), where the former only equates a divergent program run with another diverging one, whereas the latter equates a divergent program run with any other run [24].

Whereas the development of IFC type systems has been an active research field for decades for imperative and predominantly sequential languages, their exploration in a concurrent, message-passing setting has been more confined to typed process calculi [34, 35, 17, 25, 41, 68, 55] and multiparty session types [13, 11, 14, 12]. Only recently, IFC has been adopted for session types based on linear logic [20, 5]. The resulting type systems exploit the strong guarantees arising from linear logic, which in particular curtail the network of processes arising at runtime to a tree structure. However, many real-world application scenarios are precluded from an insistence on a tree structure, instead requiring support of *cyclic process networks*. Session type systems [6, 7, 19, 29, 30] that allow for cyclic process networks increase expressivity while remaining rooted in linear logic.

This paper scales IFC to cyclic process networks and contributes an IFC type system for an asynchronous π -calculus with linear session types. To prove that well-typed processes in the resulting language enjoy noninterference, we develop a novel logical relation. Our development was challenged by the possibility of *deadlocks* that can arise in cyclic process networks and that constitute another form of side channel. To rule out side-channel attacks due to deadlocks, we introduce the notion of *deadlock-sensitive noninterference (DSNI)*, which only equates a deadlocking program with another deadlocking one. Using our logical relation we prove that well-typed processes in our language enjoy DSNI (fundamental theorem).

Cyclic process networks also turn out to be beneficial for IFC, as they permit secure programs that are rejected by existing IFC type systems for linear session types [20, 5]. These are programs that exploit the possibility of setting up several channels – rather than just one channel – between two processes, to separate low-security from high-security communication.

Contributions. Our contributions are threefold:

1. An IFC session type system for an asynchronous π -calculus with support for cyclic process networks (Sec. 3), that satisfies protocol fidelity and communication safety (Thm. 3.12).
2. A logical relation that induces an equivalence between typed processes (Sec. 4), defining our notion of DSNI (Def. 4.9).
3. The main result that well typedness implies DSNI (Thm. 5.1 in Sec. 5), following from the fundamental theorem (Thm. 5.7).

Outline. In addition to the above contributions, Sec. 2 gently introduces the key ideas behind the developments in this paper, Sec. 6 discusses related work, and Sec. 7 concludes the paper. Important proofs are detailed in part; remaining details, proofs, and auxiliary definitions are given in the extended version of this paper [27].

2 Key Ideas

In this section, we discuss the key ideas behind our contributions.

2.1 Cyclic Process Networks Afford Flexible Information Flow Control

We motivate our developments through a high-level example, focusing on how cyclicity in process networks improves over prior works by increasing the flexibility of information flow control to support more realistic scenarios.

Collaborating governments. Consider two governments that want to collaborate on scientific and intelligence efforts. Clearly, the interactions between a government and an intelligence agency is confidential, whereas interactions between a government and the scientific community is not; intelligence may not leak to the scientific community, where there may be spies.

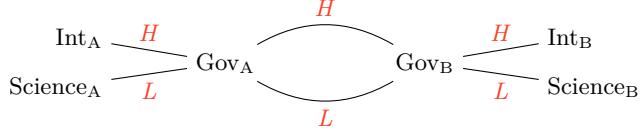

We make this more precise by establishing that information can be of *High* or *Low* confidentiality, and that communication channels can be of *High* or *Low* security. Clearly, information of *Low* confidentiality can be transmitted over *High*-security channels, but not vice versa. We identify our two governments as $X \in \{A, B\}$, each with departments (processes) $\text{Gov}_X, \text{Int}_X, \text{Science}_X$. We consider three scenarios, each of which connects these processes to form different process networks.

Scenario 1: No cyclicity. In Fig. 1a, the governments have only one channel to communicate on. Lines between departments denote communication channels, and their annotations indicate security levels. In this scenario, no processes are cyclically connected.

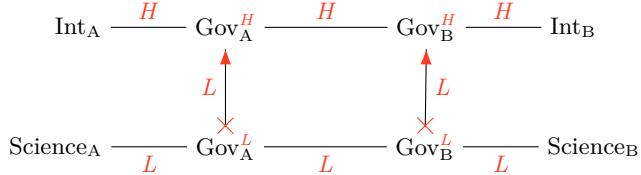

Notice that the channel connecting the two governments does not have a security level assigned. If we insist on intelligence exchange (i.e., on exchanging *High*-confidentiality information), this channel must be of *High* security. However, this inhibits scientific exchange: when a government receives information on a *High*-security channel, it cannot guarantee that the information is of *Low* confidentiality, so it cannot share it with its scientific department over a *Low*-security channel. Hence, the single channel of communication between the governments is unrealistic.

(a) Scenario 1: No cyclicity.

(b) Scenario 2: Doubly connected governments.

(c) Scenario 3: Extended cyclicity for more flexible IFC.

Figure 1 Collaborating governments: three scenarios.

Scenario 2: Doubly-connected governments. In Fig. 1b, we attempt to remedy this problem by adding a second channel of *Low* security between the governments. Since the governments are connected on two separate channels, they are cyclically connected.

Now the governments can exchange scientific information and share this with their intelligence agencies. However, it is conceivable that a government makes decisions about which scientific information to share based on intelligence information. A clever spy may then be able to infer intelligence information from scientific information, *indirectly*. Hence, once a government receives intelligence information, it should refrain from sharing scientific information. Clearly, this scenario is still not realistic.

Scenario 3: Extended cyclicity for more flexible IFC. In Fig. 1c, we split our governments into *High*- and *Low*-confidentiality departments. The *High*-confidentiality departments share intelligence information, and the *Low*-confidentiality departments share scientific information. Crucially, the *Low*-confidentiality department can share information with the *High*-confidentiality department, but not vice versa.

2.2 Threats to Noninterference due to Deadlocks

When process networks contain cyclic connections, there is a risk of *deadlocked* communication. For example, consider again the process network in Fig. 1b. Let us refer to the *High*-security channel between the governments as *h*, and the *Low*-security channel between the governments as *l*. Suppose the two governments are implemented as follows (in pseudocode):

$\text{Gov}_A := \text{receive on } h; \text{send on } l$

$\text{Gov}_B := \text{receive on } l; \text{send on } h$

The communication between the governments is deadlocked: each government is waiting to receive from the other, but the corresponding sends are blocked.

In process networks without cyclicity, this kind of deadlock does not occur. There are ways to prevent them through typing (cf., e.g., [19, 30, 7]), but the possible occurrence of deadlock introduced by cyclicity is realistic and a possible threat to noninterference. To see how, consider another pseudocode implementation, where s_A refers to the *Low*-security channel between Gov_A and Science_A :

$$\text{Gov}_A := \text{receive } x \text{ on } h; \text{if } x == \text{true} \text{ then send on } s_A \text{ else deadlock} \quad (1)$$

In this scenario, a spy monitoring the information exchanged on s_A is indirectly able to infer *High*-confidentiality information: if information is sent on s_A , then the spy knows for sure that the value of x is true. This is why we are after IFC for noninterference that is *deadlock sensitive*.

2.3 IFC Type System in a Nutshell

In this paper, we implement IFC similarly as in previous works: by enriching a session type system with IFC annotations and requirements. We build on the session-typed asynchronous variant of the π -calculus of Van den Heuvel and Pérez [29, 30] (stripped from the “priority” mechanisms that rule out deadlock).

As anticipated in Sec. 2.1, channels are appointed *maximum-secrecy levels* (secrecy levels, for short), indicating the maximum secrecy of messages that can be sent on channels securely. For example, in Fig. 1b, the channel between Int_A and Gov_A has a secrecy level of *High*, while the channel between Science_A and Gov_A has a secrecy level of *Low*. This indicates that a spy with low-level security clearance can observe the messages sent on channels of secrecy level *Low* but not *High*. A partial order on these secrecy levels forms a *secrecy lattice*; for example, $L \sqsubseteq H$ (*Low* is lower than *High*).

As processes receive messages on channels, they learn “secrets”, possibly influencing the information sent in future messages (referred to in the literature as *flow sensitivity* [57]). Key in our IFC is thus that it is forbidden to send messages on a channel if the level of secrecy learned so far exceeds the secrecy level of the channel. To ensure this, our type system assigns to each process a *running secrecy* that increases as the process receives higher-secrecy-level information. As processes evolve, the secrecy levels of their channels do not change, whereas their running securties do.

For example, in Fig. 1b, suppose Gov_A starts with a *Low* running secrecy, thus being able to send messages to both Int_A and Science_A . After receiving a message from Int_A , the running secrecy of Gov_A becomes *High*: the secrecy level of the channel between them is *High*. Hence, after this message, Gov_A can no longer send messages to Science_A .

Finally, we need to address how our IFC handles deadlock sensitivity, as introduced in Sec. 2.2. It turns out that it is sufficient to rely on running securties and their dynamics as described above. To see how, consider again the implementation of Gov_A in (1). Assuming it starts with *Low* running secrecy, the process receives on a *High*-security channel, so its running secrecy becomes *High*. Our IFC then disallows the process from sending on the *Low* security channel. Hence, this example would be considered ill typed in our type system.

2.4 Logical Relation for DSNI in a Nutshell

Let us be more precise in what we mean by DSNI. A process may have a number of “unconnected” channels. By connecting these channels to other processes, we create a *context* in which to run the process. We refer to the channels connecting the process to its context as the *interface*. For example, in Fig. 1b, Gov_A can be considered as a standalone process, with the rest of the processes being a potential context for it. The interface is then the four channels connecting Gov_A to the other processes.

With DSNI, we assume the existence of an “attacker”, a more precise definition of the “spy” mentioned in Sec. 2.1. This attacker knows the specification of our process, and has the ability to observe messages from and to the process over *observable channels*: channels in the interface that have secrecy levels up to a given secrecy level ξ . Moreover, the attacker cannot measure time but can observe the relative order in which messages are sent through different channels. By running our process in different contexts and observing the messages on observable channels, the attacker may be able to use its knowledge of the process’ specification to infer information about messages on unobservable channels. As such, noninterference means that the attacker is not able to do so; in our case, we are after DSNI, because we do not want the attacker to infer information from deadlocks either.

In this paper, we define DSNI as an *equivalence* between the behavior on observable channels of the same process in different contexts. This equivalence is defined by means of a *logical relation*. The relation scrutinizes messages from and to the process on observable channels, and “ignores” messages on unobservable channels. Our main result is that well typedness implies DSNI (Thm. 5.1).

2.5 Technical Challenges

The subsequent sections first introduce our process language and then develop an IFC type system for that language and state and prove DSNI using a logical relation. These sections are naturally quite technical. To bridge the divide, we briefly survey here the main challenges our development had to overcome.

Asynchronous communication. Our process language is an *asynchronous π -calculus* with linear session types, based on Van den Heuvel and Pérez’s Asynchronous Priority-based Classical Processes (APCP) [29, 30], but without recursion and “priority” mechanisms (which prevent deadlocks). As in the asynchronous π -calculus, outputs in our calculus do not have any continuations but are atomic processes composed in parallel with other processes. To model session sequencing, a process must adopt a *continuation-passing* style, in the sense that an output not only comprises a message but also a continuation channel.

When continuation channels are part of messages exchanged over an observable channel in the interface between a process and its context, the question comes up whether the continuation channel becomes observable as well. The natural impulse might be to consider them observable too. For sure this is the right choice in linear session-typed process calculi that confine process networks to trees [20, 5], guaranteeing that the continuation channel sent as part of the message resides within the sending process itself. However, due to the possibility of cycles in our setting, a continuation channel sent as part of a message may actually reside within the context outside the sending process. As a result, the logical relation has to consider the binding structure of the process and the context when determining observability of continuation channels. We detail this case analysis in Sec. 4 when we introduce the logical relation, with a pictorial illustration in Fig. 7.

Observable deadlocks. Deadlock-sensitive noninterference (DSNI) provides a very strong notion of noninterference in that it equates a deadlocking process only with another deadlocking one (as opposed to an arbitrary one). As a result, it prevents leakage through deadlocks, a side channel similar to the termination channel. DSNI is asserted by the definition of the logical relation and challenges the proof of Thm. 5.1, stating that well typedness implies DSNI. Thm. 5.1 is proved a generalized *fundamental theorem* (Thm. 5.7), which asserts that all executions of a process, if well typed, are related by the logical relation, up to the secrecy

level ξ of the observer. Because this theorem relates two different processes, but with the same observable behavior (where deadlocks are observable), the proof must maintain a tight correspondence between the two processes. This correspondence is achieved by employing the notion of *relevant nodes* (Def. 5.5), which are the parts of a process that can have observable outcomes either directly (by sending a message over the interface) or indirectly (by initiating a chain of messages ending with an observable one), and asserting that the relevant nodes of both processes are indistinguishable (up to structural congruence). Our notion of relevant nodes is inspired by Derakhshan et al. [20], but accounts for cyclic process networks.

Structural congruence and alpha equivalence. Our logical relation makes use of structural congruence to single out the action in a process producing an observable message. Because structural congruence permits alpha renaming, process relatedness must account for alpha-equivalence classes. As usual, proofs require a careful treatment of alpha renaming, which additionally becomes more nuanced by the existence of binders for observable names in contexts. This treatment becomes especially apparent in the so-called *catch-up* lemma (Lem. 5.10), a lemma used in the proof of the fundamental theorem to assert that two observably equivalent processes can “catch up” on each other’s unobservable reductions.

3 Linear Session Types for Information Flow Control

In this section, we define our information flow control (IFC) type system. We first introduce our process language (an asynchronous π -calculus) along with a linear session-type system in Sec. 3.1. Then, we enrich the type system with IFC in Sec. 3.2. In Sec. 3.3, we prove that well-typed processes enjoy communication safety and protocol fidelity as corollaries of a type-preservation result. As we will see in Sec. 5, well typedness in the resulting IFC type system implies noninterference.

3.1 Process Language: Syntax, Semantics, and Types

Our process language is an asynchronous π -calculus, where parallel subprocesses communicate on connected channels. To be precise, we adapt the non-recursive fragment of Van den Heuvel and Pérez’s Asynchronous Priority-based Classical Processes (APCP) [29, 30] by removing their “priority” mechanisms that prevent deadlock and adding our IFC.

Syntax. The syntactic elements of our language are typeset in a black and non-italic font. In our language, channels have two distinct endpoints, denoted a, b, c, \dots, x, y, z and further referred to as *names*. By design, all names are used linearly, meaning that they are used for a communication exactly once.

► **Definition 3.1** (Syntax). Processes P, Q, R, \dots are defined by the following syntax:

$$P, Q, R, \dots ::= 0 \mid (P \mid Q) \mid (\nu xy)P \mid x[] \mid x(); P \mid x[b] \triangleleft j \mid x(z) \triangleright \{i : P_i\}_{i \in I} \mid x[a, b] \mid x(y, z); P$$

We write $P\{x/y\}$ to denote the capture-avoiding substitution of y for x in P . Process 0 denotes inaction. In $(P \mid Q)$, processes P and Q run in parallel; we often omit the parentheses. Restriction $(\nu xy)P$ binds x and y in P to form a channel, enabling communication.

Process $x[]$ closes the channel to which x belongs, and $x(); P$ waits for the channel to close before continuing as P . Selection $x[b] \triangleleft j$ sends the label j over x along with a name b ; we refer to b as the selection’s *continuation*, as it provides a means to continue communicating after the selection. Branch $x(z) \triangleright \{i : P_i\}_{i \in I}$ waits to receive on x a label $j \in I$ along with

a continuation b before continuing as $P_j\{b/z\}$; this binds z in each P_i . Send $x[a, b]$ sends names a and b over x ; we typically refer to a and b as the send's payload and continuation, respectively, but there is no technical distinction between them. Receive $x(y, z); P$ waits to receive on x two names a and b before continuing as $P\{a/y, b/z\}$; this binds y and z in P . All names in a process are free unless bound as described above; we write $fn(P)$ to denote the set of free names of P .

► **Example 3.2.** To illustrate process syntax, we further develop the example introduced in Sec. 2.1. We develop two simple accounts of Gov_A : one where information flow is secure, and one where it is not.

In the first scenario, Gov_A^L passes a research outcome (oc) to Gov_A^H , which determines a command for Int_A :

$$\begin{aligned}\text{Gov}_A^L &:= (\nu a_H^{1'} a_H^1)(a_H[a_H^{1'}] \triangleleft oc_2 | a_H^1[])) \\ \text{Gov}_A^H &:= a_L(a_L^1) \triangleright \left\{ \begin{array}{l} oc_1 : (\nu a_I^{1'} a_I^1)(a_I[a_I^{1'}] \triangleleft act | a_L^1(); a_I^1[]), \\ oc_2 : (\nu a_I^{1'} a_I^1)(a_I[a_I^{1'}] \triangleleft wait | a_L^1(); a_I^1[])) \end{array} \right\} \\ \text{Int}_A &:= i_A(i_A^1) \triangleright \{act : i_A^1(); 0, wait : i_A^1(); 0\} \\ A_{\text{secure}} &:= (\nu a_H a_L)(\nu a_I i_A)(\text{Gov}_A^L | \text{Gov}_A^H | \text{Int}_A)\end{aligned}$$

In the second scenario, Gov_A^H receives intelligence (int) from Int_A and shares the information (inf) with Gov_A^L :

$$\begin{aligned}\text{Int}_A &:= (\nu i_A^{1'} i_A^1)(i_A[i_A^{1'}] \triangleleft int_1 | i_A^1[]) \\ \text{Gov}_A^H &:= a_I(a_I^1) \triangleright \left\{ \begin{array}{l} int_1 : (\nu a_L^{1'} a_L^1)(a_L[a_L^{1'}] \triangleleft inf_1 | a_I^1(); a_L^1[]), \\ int_2 : (\nu a_L^{1'} a_L^1)(a_L[a_L^{1'}] \triangleleft inf_2 | a_I^1(); a_L^1[])) \end{array} \right\} \\ \text{Gov}_A^L &:= a_H(a_H^1) \triangleright \{inf_1 : a_H^1(); 0, inf_2 : a_H^1(); 0\} \\ A_{\text{insecure}} &:= (\nu a_H a_L)(\nu a_I i_A)(\text{Gov}_A^L | \text{Gov}_A^H | \text{Int}_A)\end{aligned}$$

Variants of the π -calculus often include the forwarder process $[x \leftrightarrow y]$ which forwards any communications between x and y by fusing x and y . Here, we choose to omit forwarders for a smoother definition of our logical relation; they can be added as syntactic sugar using *identity expansion* (cf. the extended paper).

Semantics. The dynamics of our language is defined in terms of a reduction semantics, where each step represents the synchronization of complementary communications on the two endpoints of a channel. As usual, reduction relies on structural congruence, which restructures processes without affecting channel connections and the order of communications.

► **Definition 3.3 (Reduction Semantics).** Structural congruence is the least congruence on the syntax of processes (i.e., closed under arbitrary process contexts), denoted $P \equiv Q$, induced by the axioms in Fig. 2 (top).

Reduction is a binary relation on processes, denoted $P \rightarrow Q$, defined by the rules in Fig. 2 (bottom). We write $P \not\rightarrow$ to denote that there is no Q such that $P \rightarrow Q$.

Rule [SC-ALPHA] allows alpha conversion, i.e., renaming bound names. Rule [SC-PAR-NIL] defines 0 as the unit of parallel composition, and Rules [SC-PAR-SYMM] and [SC-PAR-ASSOC] define parallel composition as symmetric and associative, respectively. Rules [SC-RES-SYMM] and [SC-RES-ASSOC] define symmetry and associativity of restriction, respectively. Rule [SC-RES-COMM] defines commutativity of restriction, as long as this does not capture or free any names; this is often referred to as *scope extrusion*.

Structural congruence ($P \equiv Q$):

$$\begin{array}{c}
 \frac{[\text{SC-ALPHA}]}{P \equiv_\alpha Q} \quad \frac{[\text{SC-PAR-NIL}]}{P \mid 0 \equiv P} \quad \frac{[\text{SC-PAR-SYMM}]}{P \mid Q \equiv Q \mid P} \quad \frac{[\text{SC-PAR-ASSOC}]}{(P \mid Q) \mid R \equiv P \mid (Q \mid R)} \quad \frac{[\text{SC-RES-SYMM}]}{(\nu xy)P \equiv (\nu yx)P} \\
 \\
 \frac{[\text{SC-RES-ASSOC}]}{(\nu xy)(\nu zw)P \equiv (\nu zw)(\nu xy)P} \quad \frac{[\text{SC-RES-COMM}]}{x, y \notin \text{fn}(Q)} \quad \frac{}{(\nu xy)(P \mid Q) \equiv (\nu xy)P \mid Q}
 \end{array}$$

Reduction ($P \rightarrow Q$):

$$\begin{array}{c}
 \frac{[\text{RED-CLOSE-WAIT}]}{(\nu xy)(x[] \mid y(); P) \rightarrow P} \quad \frac{[\text{RED-SEL-BRA}]}{j \in I} \quad \frac{[\text{RED-SC}]}{P \equiv P' \quad P' \rightarrow Q' \quad Q' \equiv Q} \quad \frac{[\text{RED-PAR}]}{P \rightarrow P'} \\
 \\
 \frac{[\text{RED-SEND-RECV}]}{(\nu xy)(x[a, b] \mid y(z, w); Q) \rightarrow Q\{a/z, b/w\}} \quad \frac{P \rightarrow Q}{P \rightarrow Q} \quad \frac{P \rightarrow P'}{P \mid Q \rightarrow P' \mid Q} \\
 \\
 \frac{[\text{RED-RES}]}{P \rightarrow P'} \quad \frac{(\nu xy)P \rightarrow (\nu xy)P'}{(\nu xy)P \rightarrow (\nu xy)P'}
 \end{array}$$

■ **Figure 2** Structural congruence (top) and reduction (bottom); cf. Def. 3.3.

Rules [RED-CLOSE-WAIT], [RED-SEL-BRA], and [RED-SEND-RECV] define synchronizations of complementary communications on names connected by restriction; these rules formalize the behavior described below Def. 3.1. Rules [RED-SC], [RED-PAR], and [RED-RES] close reduction under structural congruence, parallel composition, and restriction, respectively.

► **Example 3.4.** We illustrate process semantics on A_{secure} defined in Example 3.2. We have

$$\begin{aligned}
 A_{\text{secure}} &= (\nu a_H a_L)(\nu a_I i_A)(\text{Gov}_A^L \mid \text{Gov}_A^H \mid \text{Int}_A) \\
 &\equiv (\nu a_I i_A)((\nu a_H^1 a_H^1)((\nu a_H a_L)(a_H[a_H^1] \triangleleft \text{oc}_2 \mid a_L(a_L^1) \triangleright \{\dots\}) \mid a_H^1[]) \mid \text{Int}_A) \\
 &\rightarrow (\nu a_I i_A)((\nu a_H^1 a_H^1)((\nu a_I^1 a_I^1)(a_I[a_I^1] \triangleleft \text{wait} \mid a_H^1() \mid a_I^1[]) \mid a_H^1[]) \mid \text{Int}_A),
 \end{aligned}$$

from where asynchronous communication enables further communication between a_H^1 and a_H^1 or between a_I and i_A ; for example,

$$\rightarrow (\nu a_I i_A)((\nu a_I^1 a_I^1)(a_I[a_I^1] \triangleleft \text{wait} \mid a_I^1[]) \mid \text{Int}_A).$$

Types. We use linear session types to “tame” our processes. The system we use is derived from classical linear logic, so types are expressed as linear-logic propositions¹; they are typeset in a blue and sans-serif font.

► **Definition 3.5 (Types).** Types A, B, C, \dots are defined by the following syntax:

$$A, B, C, \dots ::= 1 \mid \perp \mid \oplus\{i : A\}_{i \in I} \mid \&\{i : A\}_{i \in I} \mid A \otimes B \mid A \wp B$$

¹ This choice is usually motivated as it comes with deadlock freedom, but we have two different reasons: (1) it allows for direct compatibility with session-type systems for deadlock freedom, and (2) a logical basis gives us a very clean and well-behaved linear session type system, which we can carefully extend to serve our goals (here, guaranteeing noninterference by typing).

$$\begin{array}{c}
 \frac{[\text{TYP-INACT}]}{\Omega \vdash 0 @ d :: \emptyset} \quad \frac{[\text{TYP-PAR}]}{\Omega \Vdash d \sqsubseteq d'_1 \sqcap d'_2 \quad \Omega \vdash P @ d'_1 :: \Gamma \quad \Omega \vdash Q @ d'_2 :: \Delta}{\Omega \vdash P | Q @ d :: \Gamma, \Delta} \\
 \\
 \frac{[\text{TYP-RES}]}{\Omega \vdash P @ d :: \Gamma, x : A[c], y : A^\perp[c]} \quad \frac{[\text{TYP-CLOSE}]}{\Omega \Vdash d \sqsubseteq c}{\Omega \vdash x[] @ d :: x : 1[c]} \quad \frac{[\text{TYP-WAIT}]}{\Omega \Vdash d' = d \sqcup c \quad \Omega \vdash P @ d' :: \Gamma}{\Omega \vdash x(); P @ d :: \Gamma, x : \perp[c]} \\
 \\
 \frac{[\text{TYP-SEL}]}{\Omega \Vdash d \sqsubseteq c \quad j \in I}{\Omega \vdash x[b] \triangleleft j @ d :: x : \oplus\{i : A_i\}_{i \in I}[c], b : A_j^\perp[c]} \quad \frac{[\text{TYP-BRA}]}{\Omega \Vdash d' = d \sqcup c \quad \forall i \in I. \Omega \vdash P_i @ d' :: \Gamma, z : A_i[c]}{\Omega \vdash x(z) \triangleright \{i : P_i\}_{i \in I} @ d :: \Gamma, x : \&\{i : A_i\}_{i \in I}[c]} \\
 \\
 \frac{[\text{TYP-SEND}]}{\Omega \Vdash d \sqsubseteq c}{\Omega \vdash x[a, b] @ d :: x : A \otimes B[c], a : A^\perp[c], b : B^\perp[c]} \\
 \\
 \frac{[\text{TYP-RECV}]}{\Omega \Vdash d' = d \sqcup c \quad \Omega \vdash P @ d' :: \Gamma, y : A[c], z : B[c]}{\Omega \vdash x(y, z); P @ d :: \Gamma, x : A \wp B[c]}
 \end{array}$$

Figure 3 Typing rules; cf. Def. 3.6.

Duality is a unary operation on types, denoted A^\perp , defined as follows:

$$\begin{array}{lll}
 1^\perp := \perp & \oplus\{i : A_i\}_{i \in I}^\perp := \&\{i : A_i^\perp\}_{i \in I} & A \otimes B^\perp := A^\perp \wp B^\perp \\
 \perp^\perp := 1 & \&\{i : A_i\}_{i \in I}^\perp := \oplus\{i : A_i^\perp\}_{i \in I} & A \wp B^\perp := A^\perp \otimes B^\perp
 \end{array}$$

Type 1 is associated with names that close channels, and \perp with names that wait for channels to close. Types $\oplus\{i : A_i\}_{i \in I}$ and $\&\{i : A_i\}_{i \in I}$ are associated with names that make and expect labeled selections, respectively; given $j \in I$, A_j is the type of the continuation after j has been selected/received. Types $A \otimes B$ and $A \wp B$ are associated with names that send and receive, respectively; A and B are the types of the payload and continuation afterwards.

Duality is a key component of session types, as it defines precisely what is meant by complementary behavior; for example, $1^\perp = \perp$ is complementary to 1 . Clearly, duality is an involution (i.e., $(A^\perp)^\perp = A$).

Our type system is defined as a sequent calculus. In the following, ignore the annotations in *red and italic*; these annotations are for IFC, explained in Sec. 3.2.

► **Definition 3.6** (Type System). Typing contexts Γ, Δ, \dots are defined by the following syntax:

$$\Gamma, \Delta, \dots ::= \emptyset \mid \Gamma, x : A[c]$$

Typing judgments are denoted $\Omega \vdash P @ d :: \Gamma$. They are derived using the rules in Fig. 3.

Typing contexts are thus sets of types assigned to names; the type system allows implicitly reordering these assignments in typing contexts. Whenever we write Γ, Δ , we assume that the sets of names appearing in Γ and Δ are disjoint.

Rule [TYP-INACT] types inaction under empty context. Rule [TYP-PAR] types parallel composition by splitting the typing context into disjoint parts, one for each parallel process. Rule [TYP-RES] types restriction by requiring the connected names to be dually typed. Rule [TYP-CLOSE] types a close with only its subject in the context. Dually, Rule [TYP-WAIT]

types a wait by removing its subject from the context of the continuation. Rule [TYP-SEL] types a selection; note that the continuation is typed dually to the continuation type of the selection itself, as this name will be received by a corresponding branch and used for further communications there. Dually, Rule [TYP-BRA] types a branch; it requires every continuation to be typed with the same context besides the type of the continuation name. Rule [TYP-SEND] types a send; the payload and continuation are typed dually, similar to the continuation in Rule [TYP-SEL]. Dually, Rule [TYP-RECV] types a receive.

► **Example 3.7.** To illustrate process typing, we type the secure variant of Gov_A^H introduced in Example 3.2 as follows. We omit the *red and italic* IFC annotations entirely, as well as the typing of the oc_2 branch which is analogous to the oc_1 branch.

$$\begin{array}{c}
 \frac{}{\vdash a_I[a_I^{1'}]\triangleleft\text{act}} \quad \frac{\vdash a_I^1[]::a_I^1:1}{\vdash a_L^1();a_I^1[]} \quad \vdots \\
 \text{[TYP-SEL]} \qquad \text{[TYP-CLOSE]} \qquad \text{[TYP-WAIT]} \\
 ::a_I:\oplus\{act:1,wait:1\},a_I^{1'}:\perp \qquad ::a_L^1:\perp,a_I^1:1 \qquad ::a_L^1:\perp,a_I:\oplus\{act:1,wait:1\} \\
 \frac{}{\vdash a_I[a_I^{1'}]\triangleleft\text{act}|a_L^1();a_I^1[]}\qquad \frac{}{\vdash a_L^1:\perp,a_I:\oplus\{act:1,wait:1\},a_I^{1'}:\perp,a_I^1:1} \quad \text{[TYP-PAR]} \\
 ::a_L^1:\perp,a_I:\oplus\{act:1,wait:1\},a_I^{1'}:\perp,a_I^1:1 \qquad \frac{\vdash (\nu a_I^{1'}a_I^1)(a_I[a_I^{1'}]\triangleleft\text{act}|a_L^1();a_I^1[])}{::a_L^1:\perp,a_I:\oplus\{act:1,wait:1\}} \quad \text{[TYP-RES]} \\
 \frac{}{\vdash a_L(a_L^1)\triangleright\left\{\begin{array}{l} oc_1:(\nu a_I^{1'}a_I^1)(a_I[a_I^{1'}]\triangleleft\text{act}|a_L^1();a_I^1[]), \\ oc_2:(\nu a_I^{1'}a_I^1)(a_I[a_I^{1'}]\triangleleft\text{wait}|a_L^1();a_I^1[]) \end{array}\right\}::a_L:\&\{oc_1:\perp,oc_2:\perp\},a_I:\oplus\{act:1,wait:1\}} \quad \text{[TYP-BRA]}
 \end{array}$$

3.2 Information Flow Control

We now enrich the type system presented thus far with IFC, such that well typedness guarantees noninterference (Sec. 5). That is, we introduce and explain the annotations in *red and italic* in Fig. 3, and formalize the intuitions given in Sec. 2.3.

We use c, d, \dots to denote secrecy levels. The relation between secrecy levels is denoted $c \sqsubseteq d$ (c is at most as secret as d), forming a lattice Ω . We write $\Omega \Vdash \phi$ to denote that the relation ϕ between secrecy levels holds within Ω . The least upper bound (join) and greatest lower bound (meet) are denoted $c \sqcup d$ and $c \sqcap d$, respectively.

Every name is assigned a secrecy level, denoted in typing contexts using square brackets after the name's type, as in $x:A[c]$. To remember the level of secrecy of the messages received by a process, we annotate the process in typing judgments with a *running secrecy*, denoted $P @ d$. Given the running secrecy d of the process before an input and the secrecy level c of the input's subject, the input updates the running secrecy to the join $d \sqcup c$. When a process then performs an output, to make sure that the name is secured for handling the secrecy level of the outgoing message, our IFC requires that its running secrecy is not higher than that of the output's subject name.

We make these intuitions precise by discussing the IFC annotations on each typing rule in Fig. 3. Since Rule [TYP-INACT] does not involve communication, no secrecy checks are necessary. Rule [TYP-CLOSE] types an output, so it requires that the running secrecy d of the close is at most the secrecy level c of the closed name ($d \sqsubseteq c$): the information received so far (the running secrecy) is not more secret than the closed name. Rules [TYP-SEL] and [TYP-SEND] also type outputs, so their checks are similar. Rule [TYP-WAIT] types an input, so it sets the running secrecy d' of the continuation of the wait to the least upper bound of the running secrecy d before the wait and the secrecy level c of the name of the wait ($d' = d \sqcup c$; i.e., to the least secrecy level that is at least as high as both involved secrecyies).

Rules [TYP-BRA] and [TYP-RECV] also type inputs, so they update running seccrecies similarly. Rule [TYP-PAR] combines the running seccrecies d'_1 and d'_2 of the parallel processes by taking a seccrecy level d that is at most the greatest lower bound of d'_1 and d'_2 ($d \sqsubseteq d'_1 \sqcap d'_2$); this way, the parallel composition has a running seccrecy of at most the least common seccrecy level of its components, ensuring that each process in the composition has at least as much information as the parallel composition itself. Rule [TYP-RES] requires that the seccrecies of the connected names coincide, ensuring that seccrecy checks are consistent on both names of the created channel. Note that channels in typing contexts may have different seccrecy levels. However, typing rules enforce that the channels in the same session (e.g., a send and its continuation) have the same seccrecy levels. For example, Rule [TYP-SEL] ensures that channel x and its continuation b are both of the same seccrecy level c .

► **Example 3.8.** To illustrate IFC in our type system, we consider again the typing of Gov_A^H from Examples 3.2 and 3.7. We repeat the typing derivation and include IFC annotations, but omit processes and types to save space. Let Ω be the lattice with the only relation $L \sqsubseteq H$.

$$\frac{\frac{\frac{L \sqsubseteq H}{\Omega \vdash @L :: a_I : [H], a_I^1 : [H]} \text{[TYP-SEL]} \quad \frac{\frac{L \sqsubseteq H}{\Omega \vdash @L \sqcup L = L :: a_I^1 : [H]} \text{[TYP-CLOSE]} \quad \frac{\frac{L \sqsubseteq H}{\Omega \vdash @L :: a_L^1 : [L], a_I^1 : [H]} \text{[TYP-WAIT]}}{\Omega \vdash @L :: a_L^1 : [L], a_I^1 : [H]} \text{[TYP-PAR]}}{\Omega \vdash @L :: a_L^1 : [L], a_I : [H], a_I^1 : [H], a_I^1 : [H]} \text{[TYP-RES]}}{\Omega \vdash @L \sqcup L = L :: a_L^1 : [L], a_I : [H]} \text{[TYP-BRA]}$$

Hence, Gov_A^H is considered secure in our type system, and as we will show in Sec. 5 this means that noninterference holds for this process.

However, the initial assignment of maximum seccrecies to endpoints is chosen by the user. Well typedness and thus noninterference depends on this initial choice. To illustrate, reconsider the derivation above but now swapping the initial maximum seccrecies:

$$\frac{\frac{\frac{H \not\sqsubseteq L}{\Omega \vdash @H :: a_I : [L], a_I^1 : [L]} \text{[TYP-SEL]} \quad \frac{\frac{H \not\sqsubseteq L}{\Omega \vdash @H \sqcup H = H :: a_I^1 : [L]} \text{[TYP-CLOSE]} \quad \frac{\frac{H \not\sqsubseteq L}{\Omega \vdash @H :: a_L^1 : [H], a_I^1 : [L]} \text{[TYP-WAIT]}}{\Omega \vdash @H :: a_L^1 : [H], a_I^1 : [L]} \text{[TYP-PAR]}}{\Omega \vdash @H :: a_L^1 : [H], a_I : [L], a_I^1 : [L], a_I^1 : [L]} \text{[TYP-RES]}}{\Omega \vdash @L \sqcup H = H :: a_L^1 : [H], a_I : [L]} \text{[TYP-BRA]}$$

This time, Gov_A^H is not well typed: the IFC requirements of Rules [TYP-SEL] and [TYP-CLOSE] do not hold.

3.3 Type Preservation

Our type system guarantees by well typedness the usual correctness properties: *session fidelity* and *communication safety*. The former states that a process correctly implements the session types assigned to its names, and the latter that no communication mismatches take place (such as simultaneous outputs on both names of a channel).

Both these properties follow directly from *type preservation*: well typedness is preserved across structural congruences (subject congruence; Thm. 3.11) and reduction (subject reduction; Thm. 3.12). These results rely on two lemmas:

- Lem. 3.9 states that names that are not free in a process are not assigned in the typing of the process.
- Lem. 3.10 states that substitution in a process is reflected in its typing.

► **Lemma 3.9.** *Given $\Omega \vdash P @ d :: \Gamma$, if $x \notin \text{fn}(P)$, then $x \notin \text{dom}(\Gamma)$.*

► **Lemma 3.10 (Substitution).** *Given $\Omega \vdash P @ d :: \Gamma, x : A[c]$, we have*

$$\Omega \vdash P\{y/x\} @ d :: \Gamma, y : A[c].$$

► **Theorem 3.11 (Subject Congruence).** *If $\Omega \vdash P @ d :: \Gamma$ and $P \equiv Q$ for some Q , then $\Omega \vdash Q @ d :: \Gamma$.*

Proof. By induction on the derivation of $P \equiv Q$. The inductive cases correspond to closure under arbitrary process contexts in Def. 3.1; these cases follow from the IH straightforwardly. The base cases correspond to the seven rules in Fig. 2 (top). In each case, we apply inversion on the typing of P to derive the typing of Q , and vice versa, with straightforward reasoning about running seccuries. The only interesting case is Rule [SC-PAR-ASSOC] $((P | Q) | R \equiv P | (Q | R))$, where we derive the running secrecy of $Q | R$ from that of $P | Q$, and vice versa. The full proof is in the extended paper. ◀

The following theorem states that (i) reduction preserves the well typedness of processes, and (ii) the running secrecy of processes may either stay the same or increase during reduction. This implies that a process never forgets the secrets it has learned, but it may learn more secrets as it reduces.

► **Theorem 3.12 (Subject Reduction).** *If $\Omega \vdash P @ d :: \Gamma$ and $P \rightarrow Q$ for some Q , then $\Omega \vdash Q @ d' :: \Gamma$ for some d' such that $\Omega \Vdash d \sqsubseteq d'$.*

Proof. By induction on the derivation of $P \rightarrow Q$. The cases correspond to the reduction rules in Fig. 2 (bottom). In each case, we apply inversion on the typing of P to derive the typing of Q . The full proof is in the extended paper; here, we show the interesting case of Rule [RED-SEND-RECV]: $(\nu xy)(x[a, b] | y(z, w); P) \rightarrow P\{a/z, b/w\}$. Given

$$\Omega \Vdash d \sqsubseteq d'_1 \sqcap d'_2, \tag{2}$$

$$\frac{\Omega \Vdash d'_1 \sqsubseteq c}{\Omega \vdash x[a, b] @ d'_1 :: x : A \otimes B[c], a : A^\perp[c], b : B^\perp[c]} \text{ [TYP-SEND]}, \tag{3}$$

$$\Omega \Vdash d''_2 = d'_2 \sqcup c, \tag{4}$$

we have

$$\frac{\begin{array}{c} (4) \quad \Omega \vdash P @ d''_2 :: \Gamma, z : A^\perp[c], w : B^\perp[c] \\ (2) \quad \frac{(3) \quad \Omega \vdash y(z, w); P @ d'_2 :: \Gamma, y : A^\perp \wp B^\perp[c]}{\Omega \vdash x[a, b] | y(z, w); P @ d :: \Gamma, x : A \otimes B[c], y : A^\perp \wp B^\perp[c], a : A^\perp[c], b : B^\perp[c]} \text{ [TYP-PAR]} \end{array}}{\Omega \vdash (\nu xy)(x[a, b] | y(z, w); P) @ d :: \Gamma, a : A^\perp[c], b : B^\perp[c]} \text{ [TYP-RES]}$$

$$\Rightarrow \frac{\text{Lem. 3.10 twice}}{\Omega \vdash P\{a/z, b/w\} @ d''_2 :: \Gamma, a : A^\perp[c], b : B^\perp[c]}$$

By assumption and by definition, $\Omega \Vdash d''_2 \sqsupseteq d'_2$. Also, by definition, $\Omega \Vdash d'_2 \sqsupseteq d'_1 \sqcap d''_2$, so, by assumption, $\Omega \Vdash d'_2 \sqsupseteq d$. Hence, $\Omega \Vdash d''_2 \sqsupseteq d$. ◀

Liveness / Progress. Liveness / Progress properties specify the conditions under which processes can reduce. The progress property of APCP states that reduction takes place for a syntactic notion of “live” processes [30]. Since this result does not rely on APCP’s priority mechanisms, it applies to our process language as well.

4 Logical Relation

This section defines an equivalence on typed processes up to “observable messages” (Def. 4.9) that we will use to state and prove DSNI in Sec. 5. We first give some preliminary definitions in Sec. 4.1, before defining the logical relation that induces this equivalence in Sec. 4.2.

4.1 Preliminary Definitions

As anticipated in Sec. 2.4, we are interested in the behavior of a process when it runs in different contexts. That is, we want to connect all the free names of the process in arbitrary ways. To this end, we define evaluation contexts: processes with a hole inside which a process may reduce (so under parallel composition and restriction). Evaluation contexts are typeset using an orange and monospaced font.

► **Definition 4.1** (Evaluation Context). Evaluation contexts ($\textcolor{orange}{E}$) are defined as follows:

$$\textcolor{orange}{E} ::= [\cdot] \mid \textcolor{orange}{E} \mid P \mid (\nu xy)\textcolor{orange}{E}$$

We write $\textcolor{orange}{E}[P]$ to denote the process obtained by replacing the hole $[\cdot]$ in $\textcolor{orange}{E}$ by P .

Any definitions on processes before and after this definition are lifted to evaluation contexts, without assigning any meaning to the hole. The exception is that alpha renaming does not apply to names that are bound by restriction but not free inside the scope of the restriction.

► **Example 4.2.** The following is an evaluation context:

$$\textcolor{orange}{E} := (\nu uw)(\nu xy)(\nu zv)(x(); u[] \mid z[] \mid [\cdot])$$

Both u and w are bound in $\textcolor{orange}{E}$. Since u appears free within the scope of the restriction as the subject of a close, alpha renaming applies: $\textcolor{orange}{E} \equiv_{\alpha} (\nu aw)(\nu xy)(\nu zv)(x(); a[] \mid z[] \mid [\cdot])$. However, the same does not hold for w : $\textcolor{orange}{E} \not\equiv_{\alpha} (\nu ua)(\nu xy)(\nu zv)(x(); u[] \mid z[] \mid [\cdot])$.

We refer to the names that connect the process and its context as the *interface*. Our logical relation focuses on messages between context and process, i.e., messages that must pass through the interface. The following definition identifies outputs in process and context that are not blocked by prefixes. In particular, $\text{aon}(P)$ is the set of names *along* which P is ready to output, and $\text{acon}(\textcolor{orange}{E})$ is the set of names *to* which the context is ready to output.

► **Definition 4.3** (Active Interface Names). We define the set of active output names of P , denoted $\text{aon}(P)$, as the subjects of non-blocked outputs in P :

$$\begin{array}{lll} \text{aon}(0) := \emptyset & \text{aon}(P \mid Q) := \text{aon}(P) \cup \text{aon}(Q) & \text{aon}((\nu xy)P) := \text{aon}(P) \setminus \{x, y\} \\ \text{aon}(x[]) := \{x\} & \text{aon}(x[a, b]) := \{x\} & \text{aon}(x[b] \triangleleft j) := \{x\} \\ \text{aon}(x(); P) := \emptyset & \text{aon}(x(y, z); P) := \emptyset & \text{aon}(x(z) \triangleright \{i : P_i\}_{i \in I}) := \emptyset \end{array}$$

We define the set of active context output names of $\textcolor{orange}{E}$, denoted $\text{acon}(\textcolor{orange}{E})$, as the names in the interface of $\textcolor{orange}{E}$ that are connected to active output names of $\textcolor{orange}{E}$ through restriction:

$$\text{acon}(\textcolor{orange}{E}) := \{x \mid \exists y, \textcolor{orange}{E}' . (\textcolor{orange}{E} \equiv (\nu xy)\textcolor{orange}{E}' \wedge x \notin \text{fn}(\textcolor{orange}{E}') \wedge y \in \text{aon}(\textcolor{orange}{E}'))\}$$

We define the set of active interface names of E and P as the union of the active context output names of E and the active output names of P :

$$\text{ain}(E, P) := \text{acon}(E) \cup \text{aon}(P)$$

► **Example 4.4.** We illustrate the active interface names between $P := y[] | w(); v(); 0$ and E from Example 4.2. It is easy to see that $\text{aon}(P) = \{y\}$. To determine $\text{acon}(E)$ we search for names in E that are bound by restriction to names used for output, but not used themselves. That is, we look for names in the interface between the context and the containing process, on which the containing process can expect to receive an output from the context. For example, in E , name v is bound to z which is used for an output, while v itself is not used (it appears in the interface). Since there are no further such names, we have $\text{acon}(E) = \{v\}$. As such, $\text{ain}(E, P) = \{y, v\}$.

The interface is where an attacker (cf. Sec. 2.4) may observe the behavior of our process. In this, we assume that the attacker can only observe messages up to a certain secrecy level ξ . As such, our relation is only interested in the behavior of the process on *observable* channels. To this end, we define a projection on typing contexts to filter out unobservable channels. Also, we define when a process in context is well typed with respect to a given typing context of observable channels.

► **Definition 4.5 (Projection and Networks).** Given a secrecy lattice Ω , a secrecy level $\xi \in \text{dom}(\Omega)$, and a typing context Γ , we define the projection $\Gamma \Downarrow_{\Omega} \xi$ as follows:

$$(\Gamma, x : A[c]) \Downarrow_{\Omega} \xi := \begin{cases} (\Gamma \Downarrow_{\Omega} \xi), x : A[c] & \text{if } \Omega \Vdash c \sqsubseteq \xi \\ \Gamma \Downarrow_{\Omega} \xi & \text{if } \Omega \Vdash c \not\sqsubseteq \xi \end{cases} \quad \emptyset \Downarrow_{\Omega} \xi := \emptyset$$

We often omit Ω when it is clear from the context.

We say E and P form a network with interface Γ observable up to ξ under Ω , denoted $(E, P) \in \text{Net}^{\Omega; \xi}(\Gamma)$ if and only if there are d, d', Γ' such that $\Gamma = \Gamma' \Downarrow_{\Omega} \xi$, $\Omega \vdash P @ d' :: \Gamma'$, and $\Omega \vdash E[P] @ d :: \emptyset$. By abuse of notation, we write $(E_1, P_1; E_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma)$ to denote $(E_1, P_1) \in \text{Net}^{\Omega; \xi}(\Gamma)$ and $(E_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma)$.

► **Example 4.6.** We anticipate illustrating noninterference on the secure running example introduced in Example 3.2 on a *Low* secrecy channel, by considering the projection of its typing context and an evaluation context to form a network. Recall the typing and IFC annotations from Examples 3.7 and 3.8:

$$\vdash \text{Gov}_A^H @ L :: \Gamma' = a_L : \&\{oc_1 : \perp, oc_2 : \perp\}[L], a_I : \oplus\{\text{act} : 1, \text{wait} : 1\}[H].$$

We have $\Gamma := \Gamma' \Downarrow L = a_L : \&\{oc_1 : \perp, oc_2 : \perp\}[L]$. Let $E := (\nu a_H a_L)(\nu a_I i_A)(\text{Gov}_A^L | [\cdot] | \text{Int}_A)$. It is straightforward to confirm that $\vdash E[\text{Gov}_A^H] @ L :: \emptyset$. Hence, $(E, \text{Gov}_A^H) \in \text{Net}^L(\Gamma)$.

In our relation, we want to exhaust reductions on unobservable channels, after which we scrutinize behavior on observable names in the interface. To this end, we define *unobservable reductions*, which entail reductions internal to the process or the context, but also communications between process and context on unobservable interface channels.

► **Definition 4.7 (Unobservable Reduction).** We define unobservable reduction as

$$E, P \longrightarrow_{\Omega; \xi; \Gamma} E', P'$$

if and only if $(E, P) \in \text{Net}^{\Omega; \xi}(\Gamma)$, $E[P] \longrightarrow E'[P']$ and $(E', P') \in \text{Net}^{\Omega; \xi}(\Gamma)$. We write $\longrightarrow_{\Omega; \xi; \Gamma}^?$ (resp. $\longrightarrow_{\Omega; \xi; \Gamma}^*$) for the reflexive (resp. reflexive transitive) closure of $\longrightarrow_{\Omega; \xi; \Gamma}$, and $E, P \not\longrightarrow_{\Omega; \xi; \Gamma}$ to denote that there are no E', P' such that $E, P \longrightarrow_{\Omega; \xi; \Gamma} E', P'$.

$$(E_1[P_1]; E_2[P_2]) \in E^{\Omega; \xi}[\Gamma] \iff \quad (5)$$

$$\wedge (E_1, P_1; E_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma) \quad (6)$$

$$\wedge \forall E'_1, P'_1. E_1, P_1 \xrightarrow{*_{\Omega; \xi; \Gamma}} E'_1, P'_1 \xrightarrow{\cdot}_{\Omega; \xi; \Gamma} \quad (7)$$

$$\implies \exists E'_2, P'_2. E_2, P_2 \xrightarrow{*_{\Omega; \xi; \Gamma}} E'_2, P'_2 \xrightarrow{\cdot}_{\Omega; \xi; \Gamma} \quad (8)$$

$$\wedge \forall x \in (\text{ain}(E'_1, P'_1) \cup \text{ain}(E'_2, P'_2)) \cap \text{dom}(\Gamma). (E'_1, P'_1; E'_2, P'_2) \in V_x^{\Omega; \xi}[\Gamma]$$

$$\wedge \text{aon}(P'_1) \cap \text{dom}(\Gamma) = \text{aon}(P'_2) \cap \text{dom}(\Gamma)$$

 **Figure 4** Term interpretation.

Our relation often requires “zooming in” on specific parts of processes. To this end, we define notions to deal with atomic parts of processes.

► **Definition 4.8** (Nodes and Normal Forms). *Given a process P, we say P is a node if P $\not\equiv Q \mid R$, P $\not\equiv (\nu xy)Q$, and P $\not\equiv 0$.*

We say a process $Q = (\nu x_i y_i)_{i \in I} \prod_{j \in J} P_j$ is in normal form if, for every $j \in J$, P_j is a node, and Q is a normal form of P if $P \equiv Q$. Normal forms are closed under structural congruence: every process induces an equivalence class of structurally congruent normal forms.

Given a process in normal form $Q = (\nu x_i y_i)_{i \in I} \prod_{j \in J} P_j$, we define $\text{nodes}(Q) := \{P_j \mid j \in J\}$ and $\text{binders}(Q) := \{\{x_i, y_i\} \mid i \in I\}$. By abuse of notation, given a process P not necessarily in normal form, we write $\text{nodes}(P)$ to denote $\text{nodes}(Q)$ for an arbitrary normal form Q of P.

For example, let

$$P := (\nu uw)((\nu xy)(z(); x[] | y(); u[]) | w(); 0) | 0 \quad Q := (\nu uw)(\nu xy)(z(); x[] | y(); u[] | w(); 0).$$

Then Q is a normal form of P, with $\text{nodes}(Q) = \{z(); x[], y(); u[], w(); 0\}$ and $\text{binders}(Q) = \{\{u, w\}, \{x, y\}\}$.

4.2 The Relation

Having presented all its ingredients, we now introduce our logical relation. As usual, the relation consists of two parts: a *term interpretation* and a *value interpretation*, defined by mutual multiset induction on the interfaces of processes. The term interpretation is the main part of the relation, and is responsible for calling on the value interpretation when a message is ready to be communicated across the observable interface, as well as ensuring deadlock sensitivity of our noninterference result. The value interpretation zooms in on the interface, and ensures that the two runs of the process behave identically on observable messages that are to be communicated across the interface.

Let us start by presenting our term interpretation, denoted $E^{\Omega; \xi}[\Gamma]$, in Fig. 4. It relates pairs of processes, given a secrecy lattice Ω , a secrecy level $\xi \in \text{dom}(\Omega)$, and an interface Γ . We break down its definition part by part. Part (5) implicitly requires each process to be separable into a context E_i and a process P_i . Part (6) then requires the interface between E_i and P_i to correspond to Γ up to observability ξ (cf. Def. 4.5). Part (7) exhausts unobservable reductions for E_1, P_1 (cf. Def. 4.7) in every way possible, resulting in E'_1, P'_1 . Part (8) first requires E_2, P_2 to “catch up” through exhaustive unobservable reductions, resulting in E'_2, P'_2 . Then, Part (8) invokes the value interpretation, presented next, to scrutinize any messages that are ready to be transferred across the observable part of the interface of either E'_i, P'_i (cf. Def. 4.3). Finally, Part (8) ensures deadlock sensitivity by requiring the observable messages

$$\begin{aligned}
& \text{1 } (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in V_x^{\Omega; \xi} [\Gamma, x : 1[c]] \iff ((\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma, x : 1[c]) \\
& \quad \wedge P_1 \equiv x[] | P'_1 \wedge P_2 \equiv x[] | P'_2 \wedge (\mathbf{E}_1[x[] | P'_1]; \mathbf{E}_2[x[] | P'_2]) \in E^{\Omega; \xi}[\Gamma]) \\
\hline
& \oplus \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in V_x^{\Omega; \xi} [\Gamma, x : \oplus\{i : A_i\}_{i \in I}[c]] \iff & (9) \\

& \quad \wedge a_1, b_1 \in \text{dom}(\Gamma) \implies a_1 = b_1 \wedge a_2 = b_2 \wedge P_1 \equiv x[a_1, b_1] | P'_1 \wedge P_2 \equiv x[a_2, b_2] | P'_2 \\
& \quad \quad \wedge (\mathbf{E}_1[x[a, b] | P'_1]; \mathbf{E}_2[x[a, b] | P'_2]) \in E^{\Omega; \xi}[\Gamma \setminus a, b] \\
& \quad \wedge (a_1 \in \text{dom}(\Gamma) \wedge b_1 \notin \text{dom}(\Gamma)) \implies (a_1 = a_2 \wedge b_2 \notin \text{dom}(\Gamma) \\
& \quad \quad \wedge P_1 \equiv (\nu b_1 b')(x[a_1, b_1] | P'_1) \wedge P_2 \equiv (\nu b_2 b')(x[a_2, b_2] | P'_2) \\
& \quad \quad \wedge (\mathbf{E}_1[(\nu b_1 b')(x[a_1, b_1] | P'_1)]; \mathbf{E}_2[(\nu b_2 b')(x[a_2, b_2] | P'_2)]) \in E^{\Omega; \xi}[\Gamma, b' : B[c] \setminus a]) \\
& \quad \wedge (a_1 \notin \text{dom}(\Gamma) \wedge b_1 \in \text{dom}(\Gamma)) \implies (a_2 \notin \text{dom}(\Gamma) \wedge b_1 = b_2 \\
& \quad \quad \wedge P_1 \equiv (\nu a_1 a')(x[a_1, b_1] | P'_1) \wedge P_2 \equiv (\nu a_2 a')(x[a_2, b_2] | P'_2) \\
& \quad \quad \wedge (\mathbf{E}_1[(\nu a_1 a')(x[a_1, b_1] | P'_1)]; \mathbf{E}_2[(\nu a_2 a')(x[a_2, b_2] | P'_2)]) \in E^{\Omega; \xi}[\Gamma, a' : C[c] \setminus b]) \\
& \quad \wedge a_1, b_1 \notin \text{dom}(\Gamma) \implies (a_2, b_2 \notin \text{dom}(\Gamma) \\
& \quad \quad \wedge P_1 \equiv (\nu a_1 a')(\nu b_1 b')(x[a_1, b_1] | P'_1) \wedge P_2 \equiv (\nu a_2 a')(\nu b_2 b')(x[a_2, b_2] | P'_2) \\
& \quad \quad \wedge (\mathbf{E}_1[(\nu a_1 a')(\nu b_1 b')(x[a_1, b_1] | P'_1)]; \mathbf{E}_2[(\nu a_2 a')(\nu b_2 b')(x[a_2, b_2] | P'_2)]) \in E^{\Omega; \xi}[\Gamma, a' : A[c], b' : B[c]])
\end{aligned}$$

■ **Figure 5** Value interpretation, output cases (1, \oplus , \otimes).

of P'_1 and P'_2 to coincide. In particular, if P'_1 does not produce any observable messages along a name in the interface due to a deadlock imposed by a secret, Part (8) guarantees that P'_2 does not produce any observable messages on that name either.

We present our value interpretation, denoted $V_x^{\Omega; \xi} [\Gamma]$, in Figs. 5 and 6. It relates pairs of context-process tuples $(\mathbf{E}_1, P_1; \mathbf{E}_2, P_2)$, given a secrecy lattice Ω , a secrecy level $\xi \in \text{dom}(\Omega)$, an (observable) interface Γ , and a name $x \in \text{dom}(\Gamma)$. The relation is defined by cases on the type A assigned to x in Γ . If A is output-like (1, \oplus , \otimes ; Fig. 5), the relation looks for a corresponding output on x in the processes to (observably) move across the interface into the contexts²; if A is input-like ($\perp, \&, \otimes$; Fig. 6), the relation looks for a corresponding output on a name y connected by restriction to x in the contexts to (observably) move across the interface into the processes. We detail the representative cases where $A \in \{\oplus, \&\}$.

When $A = \oplus\{i : A_i\}_{i \in I}$ (9), we first check well typedness as usual (10) (cf. Def. 4.5). We then assert that both P_1 and P_2 have ready a selection on x , both on the same label $j \in I$ (11).

² In the rest of the paper, we often write $\Gamma \setminus x$ to denote Γ' given $\Gamma = \Gamma', x : A[c]$.

$$\begin{aligned}
 \perp & \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in V_x^{\Omega; \xi}[\Gamma, x : \perp[c]] \iff ((\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma, x : \perp[c]) \\
 & \quad \wedge (\mathbf{E}_1 \equiv (\nu yx)(y[] | \mathbf{E}'_1) \wedge \mathbf{E}_2 \equiv (\nu yx)(y[] | \mathbf{E}'_2)) \\
 & \quad \implies (\mathbf{E}'_1[(\nu yx)(y[] | P_1)]; \mathbf{E}'_2[(\nu yx)(y[] | P_2)]) \in E^{\Omega; \xi}[\Gamma]) \\
 \& & \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in V_x^{\Omega; \xi}[\Gamma, x : \&\{i : A_i\}_{i \in [c]}] \iff & (14) \\
 & & \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma, x : \&\{i : A_i\}_{i \in [c]}) & (15) \\
 & \wedge & \quad (\exists j \in I. \mathbf{E}_1 \equiv (\nu bb')(\nu yx)(y[b] \triangleleft j | \mathbf{E}'_1) \wedge \mathbf{E}_2 \equiv (\nu bb')(\nu yx)(y[b] \triangleleft j | \mathbf{E}'_2)) & (16) \\
 & \implies & \quad ((\nu bb')\mathbf{E}'_1[(\nu yx)(y[b] \triangleleft j | P_1)]; & (17) \\
 & & \quad (\nu bb')\mathbf{E}'_2[(\nu yx)(y[b] \triangleleft j | P_2)]) \in E^{\Omega; \xi}[\Gamma, b : A_j[c]] \\
 \wp & \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in V_x^{\Omega; \xi}[\Gamma, x : A \wp B[c]] \iff \\
 & & \quad (\mathbf{E}_1, P_1; \mathbf{E}_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma, x : A \wp B[c]) \\
 & \wedge & \quad (\mathbf{E}_1 \equiv (\nu aa')(\nu bb')(\nu yx)(y[a, b] | \mathbf{E}'_1) \wedge \mathbf{E}_2 \equiv (\nu aa')(\nu bb')(\nu yx)(y[a, b] | \mathbf{E}'_2)) \\
 & \implies & \quad ((\nu aa')(\nu bb')\mathbf{E}'_1[(\nu yx)(y[a, b] | P_1)]; & \\
 & & \quad (\nu aa')(\nu bb')\mathbf{E}'_2[(\nu yx)(y[a, b] | P_2)]) \in E^{\Omega; \xi}[\Gamma, a : A[c], b : B[c]]
 \end{aligned}$$

■ **Figure 6** Value interpretation, input cases (\perp , $\&$, \wp).

We find that the selections carry continuations b_1 and b_2 , respectively. Since we intend to move the selections across the interface into the contexts, we need to inspect where these b_i are bound: in the context or in the process.

- If b_1 appears in the interface (12), it is bound in \mathbf{E}_1 . We then assert that b_1 and b_2 actually represent the same name, and thus that b_2 is bound in \mathbf{E}_2 . Next, we use structural congruence (Def. 3.3) to separate the selections from the rest of the processes. The case ends with a call on the term interpretation, where the selections have been moved into the contexts. Note that here we remove b_1 ($= b_2$) from the interface, as the processes have relinquished control over this name to their respective contexts: we no longer need to monitor behavior on b_1 . Fig. 7a illustrates this case.
- If b_1 does not appear in the interface (13), it is bound in P_1 . We first assert that b_2 also does not appear in the interface, and thus is bound in P_2 . We then use structural congruence to identify the names to which each b_i is bound – since they are both bound, we conveniently apply alpha conversion and use b' in both cases –, and to separate the selections from the rest of the processes. Finally, we call on the term interpretation, where the selections along with the binders $(\nu b_i b')$ are moved into the contexts. Here, we add b' to the interface, as it must be used in the remainder of the processes, and thus must be monitored. Fig. 7b shows this case.

When $A = \&\{i : A_i\}_{i \in I}$ (14), the processes are expecting a selection from the contexts. We again start with the usual well typedness check (15) (cf. Def. 4.5). The purpose of our relation is to compare runs of the same process in different contexts, and so we cannot make assertions about the readiness of the contexts to make the required selection, or that these are selections of the same label. We therefore proceed only under the condition that indeed the contexts are both ready to select the same label (16). This condition uses structural congruence to identify the names in the contexts to which x is connected, conveniently referred to as y in both contexts. It also identifies the continuations b of the selections and the names b' to which they are connected, as well as the remainder of the contexts. It then calls on the term evaluation (17), where the selections along with the restrictions binding x to y are moved into the processes. As such, x is no longer in the interface, but now the continuations of the selections are: we add b to the interface. Fig. 7c illustrates this case.

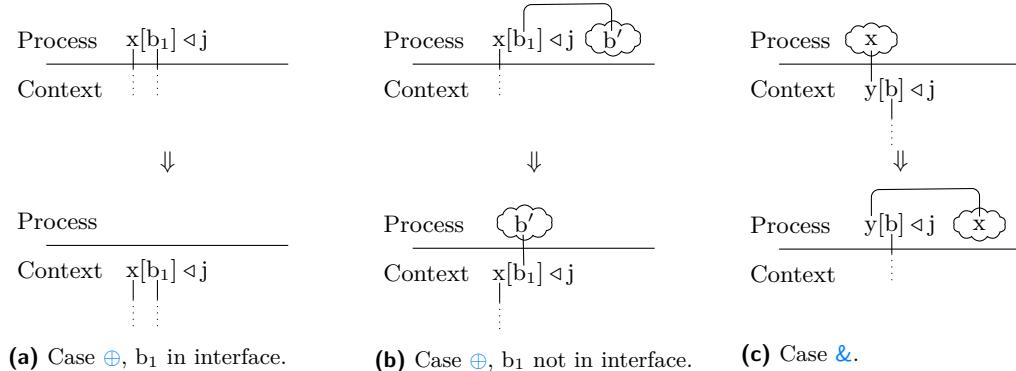

Figure 7 Illustrations of the value interpretation on selections: the selection is moved to/from the process, influencing name connections through the interface. Names in clouds represent parts of the process where the name is used.

Finally, we use our logical relation to define *equivalence up to observable messages*. We say two processes are equivalent up to secrecy level ξ if they agree on their observable interface and they are related by the logical relation when placed inside any two arbitrary evaluation contexts (cf. Def. 4.1). This ensures that, regardless of the context in which the processes run, they will behave the same with respect to the observable interface.

► **Definition 4.9** (Equivalence up to Observable Messages). *The relation*

$$(\Omega \vdash P_1 @ d_1 :: \Gamma_1) \equiv_\xi (\Omega \vdash P_2 @ d_2 :: \Gamma_2)$$

holds if and only if $\Gamma_1 \Downarrow \xi = \Gamma_2 \Downarrow \xi = \Gamma$, and for every E_1, E_2 such that $\Omega \vdash E_1[P_1] @ d_1 :: \emptyset$ and $\Omega \vdash E_2[P_2] @ d_2 :: \emptyset$, $(E_1[P_1]; E_2[P_2]) \in E^{\Omega; \xi}[\Gamma]$ and $(E_2[P_2]; E_1[P_1]) \in E^{\Omega; \xi}[\Gamma]$.

► **Example 4.10.** Consider again the secure variant of Gov_A^H from Example 3.2. Anticipating noninterference, it is straightforward to check that the continuations of the initial branch are equivalent up to observable messages:

$$\begin{aligned} & (\vdash (\nu a_I^{1'} a_I^1)(a_I[a_I^{1'}] \triangleleft \text{act} \mid a_L^1(); a_I^1[])) @ L :: a_I : \oplus\{\text{act} : 1, \text{wait} : 1\}[H], a_L^1 : \perp[L]) \\ & \equiv_L (\vdash (\nu a_I^{1'} a_I^1)(a_I[a_I^{1'}] \triangleleft \text{wait} \mid a_L^1(); a_I^1[])) @ L :: a_I : \oplus\{\text{act} : 1, \text{wait} : 1\}[H], a_L^1 : \perp[L]) \end{aligned}$$

The crucial part is that the different selections on a_I are unobservable.

On the other hand, consider also the insecure variant of Gov_A^H from Example 3.2. Even though their typing contexts are equal (and, hence, so are the projections onto L), the continuations of the initial branch are *not* equivalent up to observable messages:

$$\begin{aligned} & (\vdash (\nu a_L^{1'} a_L^1)(a_L[a_L^{1'}] \triangleleft \text{inf}_1 \mid a_I^1(); a_L^1[])) :: a_L : \oplus\{\text{inf}_1 : 1, \text{inf}_2 : 1\}[L], a_I^1 : \perp[H]) \\ & \not\equiv_L (\vdash (\nu a_L^{1'} a_L^1)(a_L[a_L^{1'}] \triangleleft \text{inf}_2 \mid a_I^1(); a_L^1[])) :: a_L : \oplus\{\text{inf}_1 : 1, \text{inf}_2 : 1\}[L], a_I^1 : \perp[H]) \end{aligned}$$

Here, the different selections on a_L are observable.

5 Deadlock-Sensitive Noninterference (DSNI)

Our main result is that the observable behavior (up to a given secrecy level ξ) of any well-typed process is the same when placed in different contexts. We formalize this using our logical relation (Def. 4.9):

► **Theorem 5.1** (DSNI). *For all secrecy lattices Ω , secrecy levels $\xi \in \text{dom}(\Omega)$ and processes $\Omega \vdash P @ d :: \Gamma$, we have $(\Omega \vdash P @ d :: \Gamma) \equiv_\xi (\Omega \vdash P @ d :: \Gamma)$.*

► **Example 5.2.** Following up on Example 4.10, we can conclude that DSNI holds for the secure variant of Gov_A^H , but not for the insecure variant.

To prove this main result, we prove a more general result (the *fundamental theorem*; Thm. 5.7) that relates two processes through Def. 4.9 given that they are *observably equivalent*. We first define precisely what we mean with observable equivalence before presenting and proving our fundamental theorem in Sec. 5.2.

5.1 Observable Equivalence

Towards defining observable equivalence, we want to identify the nodes (cf. Def. 4.8) of processes that can contribute to messages on observable names in the interface, referred to as *relevant nodes*. Nodes with running secrecy $\not\sqsubseteq \xi$ obviously cannot influence observable interface names. However, nodes with running secrecy $\sqsubseteq \xi$ are not necessarily capable of influencing observable interface names either. In particular, two types of nodes with running secrecy $\sqsubseteq \xi$ cannot influence the observable interface:

- Nodes that input on unobservable names increase their running secrecy after the input, such that they no longer influence observable interface names.
- Nodes that output on unobservable names can only influence nodes that input on unobservable names (and thus cannot influence observable interface names indirectly via the receiving node).

The following notion of *quasi-running secrecy* anticipates these scenarios by assigning a secrecy level to a process based on the influence of its foremost prefix corresponding to the subsequent input/output. It is defined as the join of the current running secrecy of the process and the secrecy level of the name on which the next input/output occurs. If either of the two levels is unobservable, the quasi-running secrecy will be unobservable. In such cases, we know that the foremost prefix of the process cannot influence the observable interface.

► **Definition 5.3** (Quasi-running Secrecy). *Given a node typed $\Omega \vdash P @ d :: \Gamma$, we define the quasi-running secrecy of P , denoted $\text{quasi}(\Omega \vdash P @ d :: \Gamma)$ as follows:*

$$\text{quasi}(\Omega \vdash P @ d :: \Gamma) := \begin{cases} d \sqcup c & \text{if } P = x[] \text{ and } x : 1[c] \in \Gamma \\ d \sqcup c & \text{if } P = x(); P' \text{ and } x : \perp[c] \in \Gamma \\ d \sqcup c & \text{if } P = x[b] \triangleleft j \text{ and } x : \oplus\{i : A_i\}_{i \in I}[c] \in \Gamma \\ d \sqcup c & \text{if } P = x(z) \triangleright \{i : P_i\}_{i \in I} \text{ and } x : \&\{i : A_i\}_{i \in I}[c] \in \Gamma \\ d \sqcup c & \text{if } P = x[a, b] \text{ and } x : A \otimes B[c] \in \Gamma \\ d \sqcup c & \text{if } P = x(y, z); P' \text{ and } x : A \wp B[c] \in \Gamma \end{cases}$$

To compute which nodes of a process are relevant, we start with nodes that have connections to the interface (through free names). We then look at nodes that are connected to these relevant nodes through restrictions. However, not all connections imply a possible influence on the observable interface. Consider a node $x[a, b]$ that is connected to a relevant node on a : the node does not define behavior on a but merely outputs the name, and so a cannot influence the observable interface through this name. For example, in $(\nu xy)(\nu au)(x[a, b] \mid y(z, w); z(); \dots \mid u[])$, the name a is not used for communication until it has been received on y ; hence, the close on u is not considered relevant even if the send on x were relevant. We make this precise by defining *free communication names*: free names that are used as the subjects of unblocked prefixes.

► **Definition 5.4** (Free Communication Names). We define the free communication names of P , denoted $\text{fcn}(P)$, as follows:

$$\begin{array}{ll} \text{fcn}(0) := \emptyset & \\ \text{fcn}(P \mid Q) := \text{fcn}(P) \cup \text{fcn}(Q) & \text{fcn}((\nu xy)P) := \text{fcn}(P) \setminus \{x, y\} \\ \text{fcn}(x[]) := \{x\} & \text{fcn}(x(); P) := \{x\} \cup \text{fcn}(P) \\ \text{fcn}(x[a, b]) := \{x\} & \text{fcn}(x(y, z); P) := \{x\} \cup \text{fcn}(P) \setminus \{y, z\} \\ \text{fcn}(x[b] \triangleleft j) := \{x\} & \text{fcn}(x(z) \triangleright \{i : P_i\}_{i \in I}) := \{x\} \cup \bigcup_{i \in I} \text{fcn}(P_i) \setminus \{z\} \end{array}$$

We now have all the ingredients to determine the relevant nodes of a process. We define the set of relevant nodes of a process inductively by following chains of nodes connected through restriction (of which there are finitely many). We start with nodes connected to the interface directly, and add them if their quasi-running secrecy is $\sqsubseteq \xi$. We then keep adding nodes that are connected to already relevant nodes on observable channels (names with secrecy level $\sqsubseteq \xi$) with quasi-running secrecy $\sqsubseteq \xi$.

► **Definition 5.5** (Relevant Nodes and Binders, and Relevant Form). Suppose given a process in normal form P typed $\Omega \vdash P @ d :: \Gamma$. Suppose every node $Q \in \text{nodes}(P)$ is typed $\Omega \vdash Q @ d_Q :: \Gamma_Q$. Given a secrecy level $\xi \in \text{dom}(\Omega)$, we define the set of relevant nodes of P , denoted $N(P)$, by induction on the size of binders(P) as follows ($N(P) := N_{|\text{binders}(P)|}(P)$):

$$\begin{aligned} N_0(P) &:= \{Q \in \text{nodes}(P) \mid \exists z \in \text{fcn}(Q). z \in \text{dom}(\Gamma \Downarrow \xi) \wedge \text{quasi}(\Omega \vdash Q @ d_Q :: \Gamma_Q) \sqsubseteq \xi\} \\ N_{n+1}(P) &:= N_n(P) \cup \left\{ Q \in \text{nodes}(P) \mid \begin{array}{l} \exists z \in \text{fcn}(Q). \exists Q' \in N_n(P). \exists w : A_w[c] \in \Gamma_{Q'} \\ (\Omega \Vdash c \sqsubseteq \xi \wedge \{z, w\} \in \text{binders}(P)) \\ \wedge \text{quasi}(\Omega \vdash Q @ d_Q :: \Gamma_Q) \sqsubseteq \xi \end{array} \right\} \\ &\forall 0 \leq n < |\text{binders}(P)| \end{aligned}$$

We also define the set of relevant binders of P , denoted $B(P)$, as the subset of $\text{binders}(P)$ used in the inductive step of the definition of $N(P)$. We then define the relevant form of a process in normal form P , denoted $P \Downarrow \xi$, as $(\nu xy)_{\{x, y\} \in B(P)} \prod_{Q \in N(P)} Q$.

Processes are then observably equivalent if their relevant nodes and relevant binders are indistinguishable (up to structural congruence).

► **Definition 5.6** (Observable Equivalence). We say that two processes P and P' are observably equivalent, denoted $P \equiv_\xi P'$, if and only if there are normal forms Q, Q' of P, P' respectively such that $Q \Downarrow \xi \equiv Q' \Downarrow \xi$.

5.2 The Fundamental Theorem

We now state and prove our fundamental theorem, from which DSNI (Thm. 5.1) follows.

► **Theorem 5.7** (Fundamental Theorem). For all secrecy lattices Ω , secrecy levels $\xi \in \text{dom}(\Omega)$ and processes $\Omega \vdash P_1 @ d_1 :: \Gamma_1$ and $\Omega \vdash P_2 @ d_2 :: \Gamma_2$ with $P_1 \equiv_\xi P_2$ and $\Gamma_1 \Downarrow \xi = \Gamma_2 \Downarrow \xi$, we have $(\Omega \vdash P_1 @ d_1 :: \Gamma_1) \equiv_\xi (\Omega \vdash P_2 @ d_2 :: \Gamma_2)$.

We first give several auxiliary results and definitions, before proving Thm. 5.7 on Page 23:

- Lem. 5.8 splits a process that reduces into an evaluation context (Def. 4.1) containing the source of the reduction originating from one of the reduction axioms in Fig. 2 (bottom).
- Lem. 5.9 splits unobservable reduction (Def. 4.7) into one of three cases: reduction internal in the context, reduction internal in the process, and communication between context and process on unobservable names.

- Lem. 5.10 asserts that two observably equivalent (Def. 5.6) processes can “catch up” on each other’s unobservable reductions (Def. 4.7). That is, if one process reduces unobservably, then the other process can do zero or one unobservable reductions such that the resulting processes are again observably equivalent.
- Def. 5.11 defines a *weight* on types and typing context, which we use for induction in the proof of Thm. 5.7 on Page 23.

Lems. 5.8 and 5.9 are proven in the extended paper.

► **Lemma 5.8.** Suppose given a process typed $\Omega \vdash P @ d :: \Gamma$. If $P \rightarrow P'$, then there exists an E for which either of the following holds:

1. $P \equiv E[(\nu xy)(x[] | y(); Q)]$ and $P' \equiv E[Q]$;
2. $P \equiv E[(\nu xy)(x[a, b] | y(z, w); Q)]$ and $P' \equiv E[Q\{a/z, b/w\}]$;
3. $P \equiv E[(\nu xy)(x[b] \triangleleft j | y(w) \triangleright \{i : Q_i\}_{i \in I})]$ for $j \in I$ and $P' \equiv E[Q_j\{b/w\}]$.

► **Lemma 5.9.** Suppose $(E, P) \in \text{Net}^{\Omega; \xi}(\Gamma)$ and $E, P \rightarrow_{\Omega; \xi; \Gamma} E', P'$. Then $E \rightarrow E'$ and $P = P'$, or $P \rightarrow P'$ and $E = E'$, or Lem. 5.8 applies, on names not in Γ .

► **Lemma 5.10 (Catch Up).** Suppose $(E_1, P_1; E_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma)$ such that $P_1 \equiv_{\xi} P_2$. If $E_1, P_1 \rightarrow_{\Omega; \xi; \Gamma} E'_1, P'_1$, then there exists P'_2 such that $E_2, P_2 \rightarrow_{\Omega; \xi; \Gamma}^? E_2, P'_2$ and $P'_1 \equiv_{\xi} P'_2$.

Proof. For a smoother proof, we consider a normal form Q_1 of P_1 , and obtain from Q_1 a normal form Q_2 of P_2 such that $Q_1 \Downarrow \xi = Q_2 \Downarrow \xi$. By Def. 4.8, the thesis follows by proving the thesis for these Q_1, Q_2 .

By Lem. 5.9, we can distinguish three cases from which $E_1, Q_1 \rightarrow_{\Omega; \xi; \Gamma} E'_1, Q'_1$ follows.

- (**Internal in context:** $E_1 \rightarrow E'_1$ and $Q_1 = Q'_1$) The thesis holds directly with $Q'_2 := Q_2$.
- (**Internal in process:** $Q_1 \rightarrow Q'_1$ and $E_1 = E'_1$) By Lem. 5.8, Q_1 ’s reduction is due to one of three possible synchronizations inside some evaluation context. Note that Lem. 5.8 may give us processes that are alpha variant to Q_1 and Q'_1 ; in the following we implicitly apply further alpha renaming to match the names in Q_1 and Q'_1 . For space considerations, we sketch only the (**Close-Wait**) case; the other two cases are analogous. Full details are in the extended paper.

We have $Q_1 \equiv F_1[(\nu xy)(x[] | y(); R)] \rightarrow F_1[R] \equiv Q'_1$. The analysis depends on whether the close on x is a relevant node of Q_1 or not.

If not, we derive that the wait on y is also not relevant. It follows by well typedness that the continuation R will neither add relevant nodes nor influence relevancy of other nodes, so $Q_1 \Downarrow \xi = Q'_1 \Downarrow \xi$ and the thesis follows with $Q'_2 := Q_2$.

If the close is indeed a relevant node of Q_1 , we derive that the wait on y and the binder between x and y are also relevant. By assumption, they are then also relevant in Q_2 , so we can derive a similar reduction to Q'_2 .

It remains to show that $Q'_1 \Downarrow \xi \equiv Q'_2 \Downarrow \xi$, which boils down to showing that these processes have coinciding sets of relevant nodes and binders. Both directions of these set inclusions are analogous, so we focus on one: from Q'_1 to Q'_2 . The analysis is by induction on the construction of the sets of relevant nodes and binders. In each case, we consider the appearance of the node: in R or in F_1 . In both cases, a thorough analysis of how the node was included as a relevant node – through a path of relevant binders and nodes that were added before – reveals an analogous relevant node in Q'_2 .

- (**Communication between context and process on names not in Γ**) By definition, the secrecy levels of the involved names are incomparable to ξ . Therefore, none of the nodes involved are relevant or influence relevancy of any other nodes, so $Q_1 \Downarrow \xi = Q'_1 \Downarrow \xi$ and the thesis holds with $Q'_2 := Q_2$. ◀

► **Definition 5.11** (Weight). *The weight of a type A , denoted $\varpi(A)$, is defined as follows:*

$$\begin{aligned}\varpi(1) &:= 1 & \varpi(A \otimes B) &:= \varpi(A) + \varpi(B) + 1 & \varpi(\oplus\{i : A_i\}_{i \in I}) &:= \max_{i \in I}(\varpi(A_i)) + 1 \\ \varpi(\perp) &:= 1 & \varpi(A \wp B) &:= \varpi(A) + \varpi(B) + 1 & \varpi(\&\{i : A_i\}_{i \in I}) &:= \max_{i \in I}(\varpi(A_i)) + 1\end{aligned}$$

The weight of a typing context $\varpi(\Gamma)$ is the sum of the weights of its types.

► **Theorem 5.7** (Fundamental Theorem). *For all secrecy lattices Ω , secrecy levels $\xi \in \text{dom}(\Omega)$ and processes $\Omega \vdash P_1 @ d_1 :: \Gamma_1$ and $\Omega \vdash P_2 @ d_2 :: \Gamma_2$ with $P_1 \equiv_\xi P_2$ and $\Gamma_1 \Downarrow \xi = \Gamma_2 \Downarrow \xi$, we have $(\Omega \vdash P_1 @ d_1 :: \Gamma_1) \equiv_\xi (\Omega \vdash P_2 @ d_2 :: \Gamma_2)$.*

Proof. Let $\Gamma := \Gamma_1 \Downarrow \xi = \Gamma_2 \Downarrow \xi$. Take any E_1, E_2 such that $\Omega \vdash E_1[P_1] @ d'_1 :: \emptyset$ and $\Omega \vdash E_2[P_2] @ d'_2 :: \emptyset$. We need to show that $(E_1[P_1]; E_2[P_2]) \in E^{\Omega; \xi}[\Gamma]$, which we do by induction on $\varpi(\Gamma)$.

The first condition is that $(E_1, P_1; E_2, P_2) \in \text{Net}^{\Omega; \xi}(\Gamma)$; this holds by assumption.

Next, take any E'_1, P'_1 such that $E_1, P_1 \xrightarrow{*_{\Omega; \xi; \Gamma}} E'_1, P'_1 \not\rightarrow_{\Omega; \xi; \Gamma}$. A straightforward induction on the length of these unobservable reductions shows that, by Def. 4.7 and Lem. 5.10, there are E'_2, P'_2 such that $E_2, P_2 \xrightarrow{*_{\Omega; \xi; \Gamma}} E'_2, P'_2 \not\rightarrow_{\Omega; \xi; \Gamma}$, $(E'_1, P'_1; E'_2, P'_2) \in \text{Net}^{\Omega; \xi}(\Gamma)$, and $P'_1 \equiv_\xi P'_2$.

Now, we need to show that, for every $x \in (\text{ain}(E'_1, P'_1) \cup \text{ain}(E'_2, P'_2)) \cap \text{dom}(\Gamma)$,

$$(E'_1, P'_1; E'_2, P'_2) \in V_x^{\Omega; \xi}[\Gamma].$$

Take any such x . Either $x \in \text{ain}(E'_1, P'_1)$ or $x \in \text{ain}(E'_2, P'_2)$; w.l.o.g., assume the former. The rest of the analysis depends on the type of x in Γ .

First, we discuss the output-like cases $(1, \oplus, \otimes)$. In each case, by well typedness, x is the subject of an output-like prefix in P'_1 . Since $x \in \text{ain}(E'_1, P'_1)$, this prefix is unguarded. Since $x \in \text{dom}(\Gamma) = \text{dom}(\Gamma_1 \Downarrow \xi)$, the node in which the prefix appears is relevant in P'_1 . Therefore, since $P'_1 \equiv_\xi P'_2$, there is also a relevant node in P'_2 where this prefix appears unguarded.

For space considerations, we only detail the case where x has type $\oplus\{i : A_i\}[c]$; the other cases are discussed in the extended paper. There exists $j \in I$ such that $x[b_1] \triangleleft j \in \text{nodes}(P'_1)$ and $x[b_2] \triangleleft j \in \text{nodes}(P'_1)$. The analysis depends on whether $b_1 \in \text{dom}(\Gamma)$ or not.

- $(b_1 \in \text{dom}(\Gamma))$ By well typedness, $b_1 \in \text{fn}(P'_1) \cap \text{fn}(P'_2)$. Since $P'_1 \equiv_\xi P'_2$, then $b_1 = b_2$. Hence, $P'_1 \equiv x[b_1] \triangleleft j | P''_1$ and $P'_2 \equiv x[b_2] \triangleleft j | P''_2$. Similar to the case above, and since $\varpi(\Gamma \setminus x) < \varpi(\Gamma)$, it follows from the IH that $(E'_1[x[b_1] \triangleleft j | P''_1]; E'_2[x[b_2] \triangleleft j | P''_2]) \in E^{\Omega; \xi}[\Gamma \setminus x]$. This proves that $(E'_1, P'_1; E'_2, P'_2) \in V_x^{\Omega; \xi}[\Gamma]$.
- $(b_1 \notin \text{dom}(\Gamma))$ By well typedness, $P'_1 \equiv (\nu b_1 b')(x[b_1] \triangleleft j | P''_1)$. The selection on x is a relevant node of P'_1 . Since $P'_1 \equiv_\xi P'_2$, it is also a relevant node of P'_2 . Moreover, $b_2 \notin \text{fn}(P'_2)$: otherwise, $b_2 = b_1$, and then $b_1 \in \text{fn}(P'_1)$. Hence, $P'_2 \equiv (\nu b_2 b')(x[b_2] \triangleleft j | P''_2)$. Clearly, $\Omega \vdash P''_1 @ d''_1 :: \Gamma_1 \setminus x, b'$ and $\Omega \vdash P''_2 @ d''_2 :: \Gamma_2 \setminus x, b'$, and $\Omega \vdash E'_1[(\nu b_1 b')(x[b_1] \triangleleft j | P''_1)] @ d''_1 :: \emptyset$ and $\Omega \vdash E'_2[(\nu b_2 b')(x[b_2] \triangleleft j | P''_2)] @ d''_2 :: \emptyset$. Again, since $P'_1 \equiv_\xi P'_2$, the chain of nodes and binders that are relevant in P'_1 through the binder $(\nu b_1 b')$ has an equivalent such chain in P'_2 through $(\nu b_2 b')$ and the selection on b_2 . Hence, the effect on relevant nodes and binders by removing the binder and the selection on x is the same on P''_1 as it is on P''_2 : $P''_1 \equiv_\xi P''_2$. Clearly, $\Gamma_1 \setminus x, b' \Downarrow \xi = \Gamma_2 \setminus x, b' = \Gamma \setminus x, b'$. Also, $\varpi(A_j) < \varpi(\oplus\{A_i\}_{i \in I})$, so $\varpi(\Gamma \setminus x, b') < \varpi(\Gamma)$. It then follows from the IH that $(E'_1[(\nu b_1 b')(x[b_1] \triangleleft j | P''_1)]; E'_2[(\nu b_2 b')(x[b_2] \triangleleft j | P''_2)]) \in E^{\Omega; \xi}[\Gamma \setminus x, b']$. This proves that $(E'_1, P'_1; E'_2, P'_2) \in V_x^{\Omega; \xi}[\Gamma]$.

Next, we discuss the negative cases (\perp , $\&$, \wp). In each case, by well typedness, x is the subject of an input-like prefix in P'_1 . The context E'_1 binds x to some y by restriction, and E'_1 contains a complementary output-like prefix on y . Following similar reasoning, the same holds for E'_2 . Since $x \in \text{ain}(E'_1, P'_1)$, this output-like prefix appears unguarded in E'_1 . To prove the thesis, we assume that this prefix also appears unguarded in E'_2 .

For space considerations, we only detail the case where x has type $\perp[c]$; the other cases require additional care in handling continuation endpoints and are discussed in the extended paper. We have $E'_1 \equiv (\nu yx)(y[] | E''_1)$ and $E'_2 \equiv (\nu yx)(y[] | E''_2)$. Let $P''_1 := (\nu yx)(y[] | P'_1)$ and $P''_2 := (\nu yx)(y[] | P'_2)$. Clearly, $\Omega \vdash P''_1 @ d''_1 :: \Gamma_1 \setminus x$ and $\Omega \vdash P''_2 @ d''_2 :: \Gamma_2 \setminus x$, and $\Omega \vdash E''_1[P''_1] @ d''_1 :: \emptyset$ and $\Omega \vdash E''_2[P''_2] @ d''_2 :: \emptyset$.

Let Q_1, Q_2 denote the nodes of P'_1, P'_2 , respectively, in which x appears. To prove that $P''_1 \equiv_{\xi} P''_2$, it suffices to show that Q_1 and any related binders are relevant in P''_1 if and only if Q_2 and any related binders are relevant in P''_2 ; any connected nodes/binders follow similar reasoning. We detail only the left-to-right direction; the other direction is analogous. Suppose Q_1 is relevant in P''_1 . Then $\text{quasi}(Q_1) \sqsubseteq \xi$, and thus Q_1 is also relevant in P'_1 through x in the interface. Then also Q_2 is relevant in P'_2 , where $Q_1 \equiv Q_2$ and $\text{quasi}(Q_2) \sqsubseteq \xi$. The analysis depends on how Q_1 is relevant in P''_1 : (i) through the interface, or (ii) through a restriction with another relevant node. In case (i), it follows straightforwardly that Q_2 is also relevant in P'_2 . In case (ii), the connected node is also relevant in P'_1 , and hence there is a related node that is also relevant in P'_2 . Since the two processes agree on observable channels, the channel responsible for including Q_1 as a relevant node of P''_1 is also bound in P''_2 . Then we can conclude that Q_2 is a relevant node of P''_2 .

Since $\varpi(\Gamma \setminus x) < \varpi(\Gamma)$, it then follows from the IH that $(E''_1[P''_1]; E''_2[P''_2]) \in E^{\Omega; \xi}[\Gamma \setminus x]$. This proves that $(E'_1, P'_1; E'_2, P'_2) \in V_x^{\Omega; \xi}[\Gamma]$.

Finally, we show that $\text{aon}(P'_1) \cap \text{dom}(\Gamma) = \text{aon}(P'_2) \cap \text{dom}(\Gamma)$. To prove this set equality, we take any $x \in \text{aon}(P'_1) \cap \text{dom}(\Gamma)$ and prove that $x \in \text{aon}(P'_2) \cap \text{dom}(\Gamma)$; the other direction is analogous. Clearly, x is the subject of an output-like prefix in P'_1 . Since $x \in \text{dom}(\Gamma)$, this output-like prefix must appear unguarded in a node in P'_1 . If the quasi-running secrecy of this node is observable, this node is relevant in P'_1 . Since $P'_1 \equiv_{\xi} P'_2$, P'_2 must also have a relevant node in which the output-like prefix appears unguarded. Otherwise, the node is not relevant in P'_1 , and hence the node in which the output-like prefix appears in P'_2 is also not relevant in P'_2 . Hence, $x \in \text{aon}(P'_2) \cap \text{dom}(\Gamma)$. \blacktriangleleft

DSNI and deadlock freedom. As mentioned in Sec. 3.1, our process language is based on the finite fragment of APCP with priority mechanisms removed. By enriching our process language with APCP’s priority mechanisms, we restrict well typedness to deadlock-free processes. As such, our results remain relevant if we only consider deadlock-free processes.

6 Related Work

Logical relations for session types. Existing logical relations for session types are primarily unary, focusing on proving termination [52, 53, 21]. Binary logical relations have been contributed for proving parametricity [8] and noninterference [20, 5]. All of these logical relations are developed for intuitionistic linear session types, where process networks form trees and, as a result, neither permit cyclic networks nor deadlocks. Whereas our logical relation has its foundations in linear session types, it differs in that it is based on classical linear logic and allows for cycles and deadlocks.

Our work is most similar to prior work by Derakhshan et al. [20] and Balzer et al. [5] on a binary logical relation, in which the authors develop a flow-sensitive IFC type system and use the logical relation to prove noninterference. Our IFC type system is also flow sensitive, but it is designed for an adaptation of APCP (the background of which we discuss separately) that allows for cyclic process networks and deadlocks. Our logical relation resembles the one by the authors in that it employs an interface of names along which observations can be made. In contrast to Derakhshan et al. [20] and Balzer et al. [5], our interface is a set of names with types, rather than a sequent that singles out the providing name from the names being used. The distinction becomes necessary in an intuitionistic linear logic setting, whereas our work is grounded in classical linear logic. The contrast between the intuitionistic and classical setting manifests itself in other aspects of our development, too. For example, in prior intuitionistic IFC session type systems [20, 5], the offering channel always caps the secrecy of the channels in the context and the running secrecy. In our setting, however, the running secrecy of a process and the secrecy levels of its context are not necessarily related. In particular, waiting for a channel to close may increase the running secrecy of a process. Once the channel is closed, it disappears from the context, leaving the running secrecy entirely unrelated to the secracies of the remaining channels.

Like our language, Derakhshan et al. [20]’s language lacks any recursion construct. On the other hand, the possibility of deadlocks introduces a side channel similar to non-termination, which is present in the work by Balzer et al. [5] that supports general recursive session types and thus possibly looping processes. Here, we decided to consider non-recursive processes to focus on side channels through deadlocks only and not through non-termination. In future work we would like to consider scaling our work to support general recursive session types as well. We envision employing an observation index similar to Balzer et al. [5] to stratify the logical relation in the number of observable messages exchanged over the interface. The co-presence of both non-termination and deadlocks will need careful consideration.

Our idea of an observable interface is reminiscent of the free channels with visible communications in prior work by Atkey [4]. Atkey establishes observational equivalence for Wadler’s Classical Processes (CP) by defining a denotational semantics for CP and a logical-relations argument. However, the logical relation in Atkey’s work does not relate two processes of a certain type but rather identifies the possible observations for each type in terms of the input/output behavior of its connectives.

Cyclic process networks. Traditionally, (typed) π -calculi permit cyclic process networks, and as such do not guarantee deadlock freedom. However, since the discovery of Curry-Howard correspondences between linear logic and session types [9, 67], the majority of works on session types restrict their network shapes to trees, such that deadlock freedom is guaranteed. The line of work including APCP (to which our process language is highly related) [42, 51, 19, 29, 30] considers restrictions to session type systems that allow cyclic process networks without deadlocks.

IFC type systems for multiparty session types. Capecchi et al. [13, 11] explore secure information flow with controlled forms of declassification for multiparty sessions and prove a noninterference result via a bisimulation. Our work differs in being flow sensitive and using a binary rather than multiparty session type paradigm. Our use of a logical relation to show noninterference, and our foundations in linear logic also set us apart. Follow-up works by Castellani et al. [14, 12] also study run-time monitoring techniques to ensure secure information flow control in multiparty sessions.

IFC type systems for process calculi. Several approaches have been explored for designing IFC type systems that prevent the leakage of information through message passing in process calculi [34, 35, 15, 16, 17, 36, 18, 26, 25, 41, 68, 55]. Some of these approaches include associating a security label with types or channels [36], associating a security label with actions [35], associating read and write policies with channels [26, 25], and associating a security label with processes and capabilities with expressions [15]. Our approach differs from previous work in having a dynamic running secrecy that makes our system flow sensitive, using session types instead of process calculi, and the design of our novel logical relations for establishing noninterference.

Logical relations for stateful languages. Kripke logical relations have been used to reason about stateful programs [54]. The relation is indexed by a possible world that serves as a semantic model for the heap. It establishes an invariant on the heap and ensures that the invariant is preserved for all future worlds. When combined with step indexing [3, 1], Kripke logical relations can address circularity that arises in higher-order stores [2, 22, 23]. Our logical relation is similar to Kripke logical relations in being developed for a stateful language; names, like locations, are subject to concurrent mutation. However, our session types are rooted in linear logic and thus internalize Kripke’s logical worlds into the type system.

7 Conclusions

We have presented a new session type system with information flow control (IFC) for an asynchronous π -calculus, and a notion of noninterference by means of a logical relation between typed processes. Our development flexibly supports realistic cyclic process networks that may deadlock. As such, our main result is that IFC well typedness implies deadlock-sensitive noninterference (DSNI).

In future work, we plan to study the interplay between IFC / DSNI and several interesting features of message-passing concurrency, such as recursion and non-determinism. As commented on in the previous section, we expect the notion of an observation index [5] to be applicable to circular process networks with recursive processes, although the interplay between potential leakage through non-termination and deadlocks will need careful consideration. Support of non-determinism may be more challenging, especially when combining recursion with non-deterministic choice, which without further restriction permits loop guards at mixed confidentiality level. We will consider focusing on more curtailed but logically motivated notions of non-determinism, such as coexponentials [56], HCP_{ND}^- [43], and linear non-determinism [28]. We are also interested in exploring “name-sensitive” noninterference: the choice of names in outputs is a possible source of information leakage outside the scope of this paper.

Refinements for Multiparty Message-Passing Protocols

Specification-Agnostic Theory and Implementation

Martin Vassor 

University of Oxford, UK

Nobuko Yoshida 

University of Oxford, UK

Abstract

Multiparty message-passing protocols are notoriously difficult to design, due to interaction mismatches that lead to errors such as deadlocks. Existing protocol specification formats have been developed to prevent such errors (e.g. multiparty session types (MPST)). In order to further constrain protocols, specifications can be extended with *refinements*, i.e. logical predicates to control the behaviour of the protocol based on previous values exchanged. Unfortunately, existing refinement theories and implementations are tightly coupled with specification formats.

This paper proposes a framework for multiparty message-passing protocols with refinements and its implementation in Rust. Our work *decouples* correctness of refinements from the underlying model of computation, which results in a *specification-agnostic* framework.

Our contributions are threefold. First, we introduce a trace system which characterises *valid refined traces*, i.e. a sequence of sending and receiving actions correct with respect to refinements. Second, we give a correct model of computation named *refined communicating system* (RCS), which is an extension of communicating automata systems with refinements. We prove that RCS only produce valid refined traces. We show how to generate RCS from mainstream protocol specification formats, such as *refined multiparty session types* (RMPST) or *refined choreography automata*. Third, we illustrate the flexibility of the framework by developing both a static analysis technique and an improved model of computation for dynamic refinement evaluation. Finally, we provide a Rust toolchain for decentralised RMPST, evaluate our implementation with a set of benchmarks from the literature, and observe that refinement overhead is negligible.

1 Introduction

Message passing programming is a notoriously difficult task with new bugs arising with respect to sequential programming, for instance deadlocks. To address this increased complexity, various specifications have been introduced (e.g., message sequence charts [24], multiparty session types [38, 19, 18], choreography automata [1]). In general, specifications are used to

constrain messages, in order to prevent errors such as deadlocks (via message ordering) or payload mismatch (by enforcing the sender and the receiver of a message to agree on the datatype exchanged).

In this paper, we tackle an important and advanced aspect of protocol specification, *logical constraints* (or *contracts*) on asynchronous message-passing communications. Contracts for heterogeneous systems are predominant for correctly designing, implementing, and composing software services, and have a long history in distributed software development as found in Design-by-Contracts [28], Service Level Agreements, and Component-Based Software Engineering. With contracts, software designers can define more precise (refined) and verifiable specifications for distributed software components. Contracts have been investigated from a variety of perspectives, using many different analysis techniques and formalisms. Our goal is to distill an essence of those models for protocol refinements by answering the following questions affirmatively:

- (i) what does it mean for an execution of contracts for message-passing systems to be correct;
- (ii) how do we integrate a theory to a variety of models;
- (iii) how do we analyse their correctness?; and
- (iv) how do we implement correct systems in a programming language?

To explain our framework, consider a *guessing game* (from [41]) with three participants where the first one (participant A) chooses a *secret* integer and sends it to the second participant (B). Then, the third participant (C) tries to *guess* this number. Depending on the guess, B replies with hints (*more* and *less*) until C succeeds in guessing the *correct* value.

The developer writing the specification for such protocol would like to ensure, *in the specification*, that hints from B are consistent with the previous values exchanged. For instance, if the *secret* is 5 and the guess is 10, the specification should constrain B to send *less*. Figure 1 shows a communication diagram of the protocol with constraints (which we call *refinements*) shown in light blue.

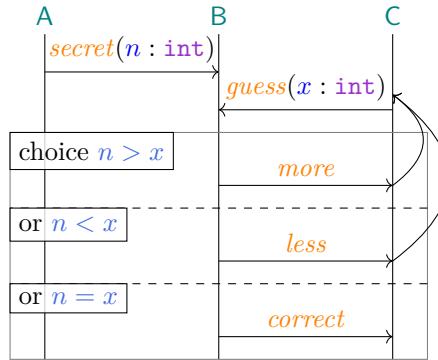

Figure 1 Communication diagram for the guessing game protocol with refinements.

In this paper, we develop a formal framework for refinements, agnostic to any particular specification formalism. Its core part is composed of a characterisation of refinement correctness: *Valid Refined Traces*, and a model of computation: *Refined Communicating Systems* (RCS), where communication is asynchronous and refinements are centrally and dynamically evaluated. For illustration, we use *Refined Multiparty Session Types* as the main specification format for multiparty protocols.

In addition, we demonstrate the versatility of our framework with multiple extensions. First, our framework can accommodate other protocol specification formats (e.g. choreography automata [1]). Second, it is used as a baseline for improved refinement evaluation: we present an optimised model of computation (decentralised refinement evaluation). Finally, it is also used as a baseline for implementing static analysis techniques: we present a simple strategy for statically removing redundant refinements.

Valid Refined Traces. The first building block is a common notion of *correct* executions with respect to added refinements. We introduce *valid refined traces* which are consistent traces with respect to refinements. This approach allows us to establish a general notion of refinements, which is applicable to different logics for constraints, type theories, models of computations, and programming languages. We consider asynchronous communications (FIFOs), distinguishing *sending* and *receiving* actions in traces.

To illustrate our approach, consider the guessing game example shown above. Each execution of that protocol is recorded in a trace, i.e. a sequence of the individual events that take place during the execution (c.f. Section 2.2). For instance, a possible trace of the first four events of the protocol is the following:

$$\text{A!B}\langle\text{secret}, \langle n, 5 \rangle\rangle : \top \cdot \text{A?B}\langle\text{secret}, \langle n, 5 \rangle\rangle : \top \cdot \text{C!B}\langle\text{guess}, \langle x, 5 \rangle\rangle : \top \cdot \text{C?B}\langle\text{guess}, \langle x, 5 \rangle\rangle : \top$$

This trace contains four actions, and each action records an event, i.e. a message emission (denoted with a !) or reception (denoted with a ?). For instance, $\text{A!B}\langle\text{secret}, \langle n, 5 \rangle\rangle : \top$ records **A** sending a message to **B**, the payload of this message is a variable *n*, which has value 5. In the first four actions, we do not need any constraint, therefore actions are guarded by \top which denotes a tautology predicate. The next action following this trace would be for **B** to send either *more*, *correct*, or *less*. Choosing *more* or *less* would be inconsistent with our protocol, since **C** guessed the correct number. For instance, choosing *more* would add the action $\text{B!C}\langle\text{more}\rangle : n > x$ at the end of the queue: the refinement $n > x$ would be violated, since $x = n = 5$.

Valid Refined Traces characterise consistency based on the produced trace; and we aim to provide a model of computation constrained in a way that prevents such inconsistent choices.

Refined Communicating Systems. The second building block of our framework is a model of computation that only produces correct traces. *Communicating Systems* (CS) [5] are a model of concurrent computation, where *Communicating Finite State Machines* communicate asynchronously using unbounded FIFO queues. CS are often used to model and implement MPST [12, 13, 7]. We adapt CS to accommodate refinements, which we call *Refined Communicating Systems* (RCS). The semantics is modified in order to check refinements at every step. For this, we introduce a shared map in order to keep track of variables and their values that are exchanged in messages (e.g. the values of *x* and *n* in the guessing game example). This record of values is used to evaluate refinements, preventing undesired transitions. In this paper, we show that RCS only produce valid refined traces and we explain how to generate an RCS from a RMPST.

Refined MPST. Working with CS is cumbersome, and, in practice, we would prefer to adapt existing specification formats. We present in depth how to integrate refinements in *Multiparty Session Types* (MPST) [38, 19, 18], which are a family of type systems that aims to prevent communication bugs.

The following refined global type (G_{\pm}) is a specification of the guessing game protocol (Figure 1), with refinements: a participant **A** begins by sending a *secret* to **B**; the value of the *secret* is stored in the variable *n*. Then, **C** tries to guess the value (stored in variable *x*),

and \mathbf{B} replies with *more*, *less* (in which case the protocol loops and \mathbf{C} can make another guess: $\mu\mathbf{T}.G$ denotes the recursion) or *correct*, at which point the protocol terminates (*end* denotes the termination). The refinements specify conditions upon which the *more*, *less*, and *correct* branches are possible. For instance, the protocol can take the *correct* branch only if the values in the *secret* and the *guess* messages are the same, i.e. if $x = n$.

$$G_{\pm} = \mathbf{A} \rightarrow \mathbf{B} \left\{ \begin{array}{l} \text{i} \text{ } \mathbf{secret}(n : \text{int} \models \top). \mu\mathbf{T}. \mathbf{C} \rightarrow \mathbf{B} \left\{ \begin{array}{l} \text{i} \text{ } \mathbf{guess}(x : \text{int} \models \top). \mathbf{B} \rightarrow \mathbf{C} \left\{ \begin{array}{l} \text{i} \text{ } \mathbf{more}(\models x < n). \mathbf{T}, \\ \text{i} \text{ } \mathbf{less}(\models x > n). \mathbf{T}, \\ \text{i} \text{ } \mathbf{correct}(\models x = n). \mathbf{end} \end{array} \right\} \end{array} \right\} \end{array} \right\}$$

Compared to standard MPST, *Refined MPST* (RMPST) contain variable names (n and x) and refinements (denoted with $\models r$ in the payloads, meaning that to send the message, r must hold). We present those extensions as well as the relation between RMPST and RCS.

Applications and Extensions. To show the versatility of our framework, we extend it:

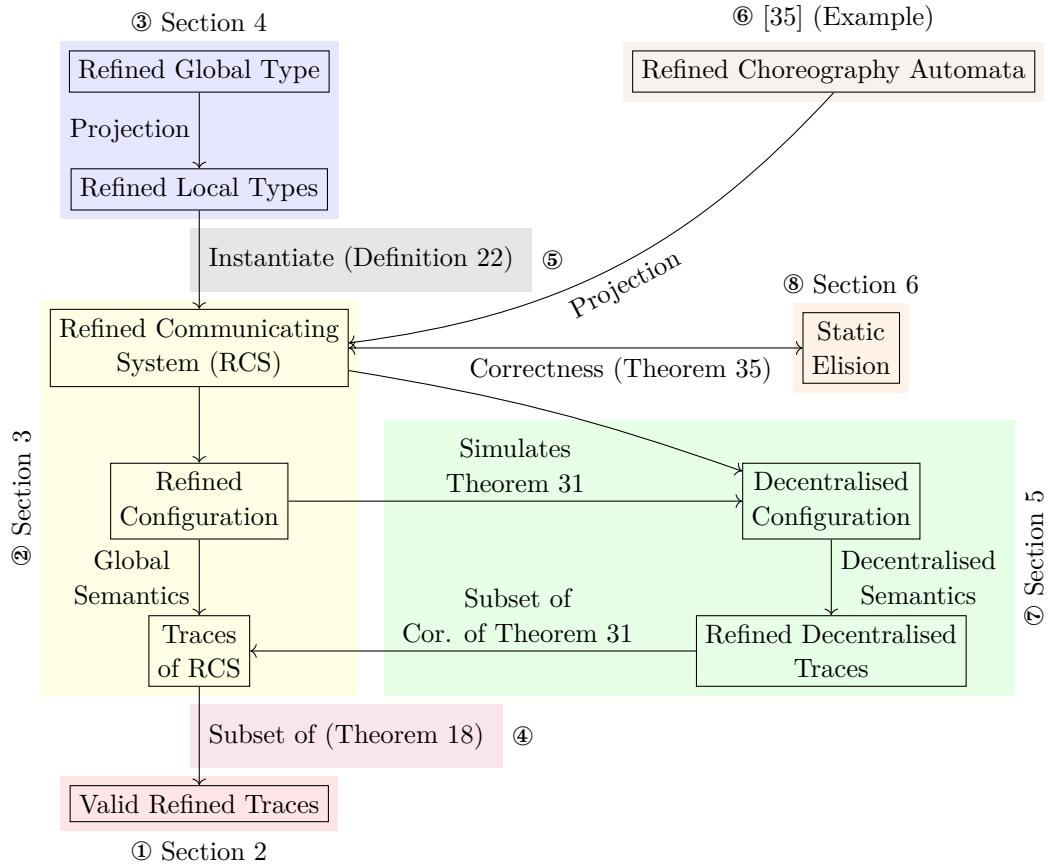

Decentralised Refinement Evaluation: The canonical semantics for RCS we present uses a single shared map of variables to provide a simple way to reason about refinements. Having this global map would not be suited for a distributed implementation. We extend our framework with an alternative semantics where each participant of a protocol has a local map of variables. We show that if variables are not duplicated, then this alternative model also produces valid refined traces.

Static Elision of Redundant Refinements: At places where refinements are redundant (e.g. where it is entailed by previous refinements), we could benefit from removing those refinements. In order to show the versatility of our framework, we show how to develop a simple static analysis technique to remove such redundant refinements.

Refined Choreography Automata: While we mostly use RMPST as an example of protocol specification language, we sketch another specification by (informally) presenting how to integrate refinements in choreography automata (in [35]).

Rust Implementation. The last objective of our work is to implement RMPST into Rust. We choose Rust for several reasons: its affine type system makes it easy to avoid unwanted reuse of values, which helps to prevent a participant from duplicating actions; and thanks to its growing popularity, there are already a few existing toolchains for session types in Rust [27, 6, 26, 25]. Among them, we choose Rumpsteak [7] since it already uses CS to implement MPST participants inside its toolchain. We extend Rumpsteak with refinements using the decentralised refinement evaluation approach. We finally measure the refinement overhead in Rumpsteak.

Contributions and Outline. Our main contribution is to unify the different points presented above in a *single* framework as presented in Figure 2. We introduce a uniform framework which is agnostic to any particular specification formalism, model, semantics and language, defining the correctness of refinements as validity of traces. We then prove the safety of the framework (Theorem 18). We demonstrate the *versatility of our framework* by accommodating *multiple protocol specifications* such as (refined) multiparty session types [38, 19, 18, 42] and (refined) choreography automata [1, 16], *multiple semantics* such as (refined) communicating automata [5] with centralised and decentralised semantics, and *multiple analysis techniques* such as dynamic and static analyses. We provide an implementation of an instance of the framework in Rust. Our framework is the first, to the best of our knowledge, to achieve such versatility.

■ **Figure 2** Overview of the framework for RMPST developed in this work. The coloured backgrounds show the main steps of this paper.

The framework is composed of the following parts (circled numbers refer to Figure 2):

- ① **Valid Refined Traces:** We introduce *valid refined traces* which characterise valid executions with respect to refinements.
- ② **Refined Communicating Systems (RCS):** We extend Communicating Systems to accommodate refinements. From a configuration of RCS, we induce a set of possible traces. One of our main results is Theorem 18 (④), which states that all traces produced by RCS are valid refined traces, which in turn proves the correctness of the RCS.
- ③ **Refined Multiparty Session Types (RMPST):** In Section 4, we adapt MPST (which consists of *global types* (which describe a multiparty protocol), *local types* (which describe the behaviour of a single participant), and a *projection* from global to local types which extracts the behaviour of a single participant) to accommodate for refinements. We show how to generate a RCS from a set of local types with refinements (⑤). In addition, in [35], we sketch how to accommodate refinements in choreography automata, to illustrate the versatility of the framework (⑥).
- ⑦ **and ⑧ Optimisations:** In Section 5 (⑦), we propose a *decentralised* model as an alternative for RCS. We show trace inclusion w.r.t. RCS, which ensures refinements are correctly checked. In Section 7, we implement this improved model in Rust. In addition, in Section 6, we demonstrate how to develop analysis techniques using the framework. We show how redundant refinements can, under some conditions, be statically removed (⑧).

2 Refined Traces and their Validity

This section introduces *refined traces* which are sequences of messages *actions*. We then define their *validity*, introducing two definitions on traces, *well-queued* and *well-predicated* traces. We precede this (in Section 2.1) with preliminary definitions used throughout this paper.

2.1 Preliminaries: Predicates Language and Semantics

This first subsection introduces the basic definitions we use in this paper.

Let \mathbb{V} be a set of variables, ranged over by x, y, \dots ; and a finite set \mathbb{C} of values (in this work, we take 32-bit integers: $\mathbb{Z}/2^{32}\mathbb{Z}$).

We use associative maps from variable names to values, noted M . $\text{dom}(M)$ denotes the domain of a map, that is the set of variables that appear in the map. Maps are equipped with lookup ($M(x)$), update ($M[x \mapsto c]$) and removal ($M \setminus x$) operations. $M_1 \uplus M_2$ denotes the union of M_1 and M_2 if their domains are disjoint (see [35] for the definition of all those operators). Finally, M_\emptyset denotes an empty map.

In order to keep our work general, we do not strictly specify the language of predicates, nor their semantics rules. Instead, we suppose we are given a language to express refinements, whose terms are produced by a rule \mathcal{R} . In this paper, we intentionally leave the logic underspecified so that it can be fine tuned by the end user. In practice, in our implementation (Section 7), custom predicates can easily be added. In the following, we use a simple grammar with arithmetic and relational operators as predicates. Let \mathbb{R} be the set of refinement expressions. We assume refinements can have free variables, and that there exist a function $\text{fv} : \mathbb{R} \rightarrow \mathcal{P}(\mathbb{V})$ that gives the free variables of each refinement expression. We note \mathbb{R}_W be the set of refinements of \mathbb{R} whose set of free variables is $W \subseteq \mathbb{V}$. We assume a variable substitution function, $\mathcal{R}\{v_i/x_i\}$ that substitutes every free occurrence of each variable x_i for the value v_i . For any refinement expression r , $r\{\dots/\text{fv}(r)\}$ is a closed refinement. Since our predicates are abstract, we do not explicitly specify their semantics, nor their well-formedness. Instead, we assume each closed refinement formula evaluates to \top or \perp . We assume there exists a function $\text{eval}(r)$ that evaluates the refinement r , provided that r is closed¹. Finally, we assume the existence of a closed formula \top that is a tautology, i.e. $\text{eval}(\top) = \top$.

Given a map M and a refinement r , we note $M \models r$ if and only if the refinement r is closed under the map M : $\text{fv}(r) \subseteq \text{dom}(M)$, and evaluates to \top after substitution: $\text{eval}(r\{M(\text{fv}(r))/\text{fv}(r)\}) = \top$.

In a protocol with multiple participants, let \mathbb{P} be a set of participants ranged over by A, B, \dots and p, q, \dots being meta-variables over participant names. In this work, messages contain a label, a variable, and a value. Let \mathbb{L} be a set of labels; ℓ and its decorated variants range over labels in \mathbb{L} . We define $\mathbb{M} = \mathbb{L} \times (\mathbb{V} \times \mathbb{C})$ for the set of messages (as a reminder: \mathbb{L} is the set of labels, \mathbb{V} the set of variables, and \mathbb{C} the set of values).

2.2 Traces

Let us denote $\vec{e} = e_1 :: \dots :: e_n$ ($n \geq 0$) as a *FIFO*, i.e., a finite sequence of elements e_i (messages exchanged in this paper). We use ε for an empty FIFO ($n = 0$). We define: $\text{enq}(\vec{e}, e) \stackrel{\text{def}}{=} e :: \vec{e}$; $\text{deq}(\vec{e} :: e) \stackrel{\text{def}}{=} \vec{e}$ ($\text{deq}(\varepsilon)$ is undefined); and $\text{next}(\vec{e} :: e) \stackrel{\text{def}}{=} e$ ($\text{next}(\varepsilon)$ is undefined). Notice

¹ We do not discuss the decidability of the actual chosen logic of refinements here. For undecidable logics, providing such function is, of course, not possible; however this is not in the scope of this work.

that $\text{deq}(\vec{e})$ is defined if and only if $\text{next}(\vec{e})$ is defined. In this paper, we consider one FIFO channel per pair of participant. We call *queues* a map of all pairs of distinct participants to their communication FIFO of a system. We note $\text{enq}_{(p,q)}(w, e)$, $\text{deq}_{(p,q)}(w)$, $\text{next}_{(p,q)}(w)$, where the indices indicates which FIFO of the set is affected (see [35] for the formal definition). We write w_\emptyset for the empty queue, which is the queue where $w_{(p,q)} = \varepsilon$ for all p and q .

Actions are tuples consisting of a sending participant p , a direction of communication $\dagger \in \{!, ?\}$ (! stands for sending, and ? stands for receiving), a receiving participant q , a message m and a predicate r associated to the action (as a reminder: \mathbb{R} is the set of refinements). We require participants to be distinct (i.e. $p \neq q$).

► **Definition 1** (Action and Trace). *An action is an element of \mathbb{A} defined as follows: $\mathbb{A} = \mathbb{P} \times \{!, ?\} \times \mathbb{P} \times \mathbb{M} \times \mathbb{R}$. We write $\alpha = p\dagger q(m) : r$ ($p \neq q$) when $\langle p, \dagger, q, m, r \rangle \in \mathbb{A}$.*

Traces (denoted by τ and its decorated variants) are finite sequences of actions, defined inductively from the rule $\tau ::= \alpha \cdot \tau' \mid \epsilon$, where α is an action. We write \mathbb{A}^ for the set of traces.*

► **Example 2** (Trace). We presented a trace in Section 1.

We denote $\tau_1 \cdot \tau_2$ for the concatenation of two traces. We assume an intuitive notion of the size of trace, as well as lemmas that allow us to infer that, if the size is 0, then the trace is ϵ .

2.3 Properties of Refined Traces

In this subsection, we characterise the *correctness* of traces w.r.t. refinements.

There are two conditions valid traces should verify. First, the sending/reception of messages should be consistent (as with normal MPST). Second, for every action of the trace, predicates that guard the action should hold. We call traces that satisfy message consistency *well-queued traces*, and the traces that satisfy the predicates *well-predicated traces*. In the end, we consider traces that satisfy both conditions: we call those traces *valid refined traces*.

To start with well-queued traces, we first evaluate the impact of a trace on a queue, by looking at the effect of each action on that queue (Definition 3).

► **Definition 3** (Trace Ending Up with Queues, well-queued traces). *A trace τ ends up with the queue w_f w.r.t. a queue w_i if:*

1. *If $\tau = \epsilon$, $w_i = w_f$; and*
 2. *If $\tau = p!q(m) : r \cdot \tau'$, then τ' ends up with w_f w.r.t. $\text{enq}_{(p,q)}(w_i, m)$; and*
 3. *If $\tau = p?q(m) : r \cdot \tau'$, then τ' ends up with w_f w.r.t. $\text{deq}_{(p,q)}(w_i)$ and $\text{next}_{(p,q)}(w_i) = m$.*
- A trace τ is well-queued with regards to the queue w if τ ends up with the empty queue w_\emptyset with respect to an initial queue w .*

A trace τ is valid if τ is well-queued with respect to the empty queue w_\emptyset .

► **Remark 4.** In Definition 3, we say w_i is the *initial* queue.

Regarding well-predicated traces, the idea is to record the latest value of each variable in a map; and to use that map to evaluate refinements (Definition 5).

► **Definition 5** (Well-Predicated Traces). *A trace τ is well-predicated under a map M , if either*

- (i) $\tau = \epsilon$; or
- (ii) $\tau = p\dagger q(l, (x, c)) : r \cdot \tau'$ and $M[x \mapsto c] \models r$ and τ' is well-predicated under $M[x \mapsto c]$.

► **Example 6** (Well-Predicated Traces). In Section 1, we presented the trace τ :

$$\text{A!B}\langle secret, \langle n, 5 \rangle \rangle : \top \cdot \text{A?B}\langle secret, \langle n, 5 \rangle \rangle : \top \cdot \text{C!B}\langle guess, \langle x, 5 \rangle \rangle : \top \cdot \text{C?B}\langle guess, \langle x, 5 \rangle \rangle : \top$$

To illustrate Definition 5, we propose two actions after τ :

- (i) $\tau_1 = \text{B!C}\langle more, \langle _, _ \rangle \rangle : x > n$; and
- (ii) $\tau_2 = \text{B!C}\langle correct, \langle _, _ \rangle \rangle : x = n$.

We can investigate whether $\tau \cdot \tau_1$ (resp. $\tau \cdot \tau_2$) is a well-predicated trace under M_\emptyset . According to Definition 5, we have to investigate whether τ_1 (resp. τ_2) is well predicated under $M = \{\langle n, 5 \rangle, \langle x, 5 \rangle\}$.

For τ_1 , according to Item ii in Definition 5, then $x > n$ must hold under M , which is not the case, therefore $\tau \cdot \tau_1$ is not well-predicated.

Regarding τ_2 , according to Item ii in Definition 5, then $x = n$ must hold under M , which is the case.

Finally, we consider traces that are both valid with respect to predicates and to messages. We call those *Valid Refined Traces*. Our overall goal is to show that our framework only produces such valid refined traces.

► **Definition 7** (Valid Refined Traces). A refined trace τ is valid if

- (i) τ is well-queued with respect to the empty queue w_\emptyset ; and
- (ii) τ is well-predicated under the empty map M_\emptyset .

3 Refined Communicating Automata

In this section, we model message-passing concurrent systems with refinements. We ensure that this model only generates valid refined traces (c.f. Definition 7). Our model of computation is an extension of *communicating systems* (CS) [5, 8], which are sets of Finite State Machines communicating using queues. We introduce *refined communicating systems* (RCS), a variant of CS which accounts for refinements and we show that all traces produced by RCS are valid refined traces (Theorem 18).

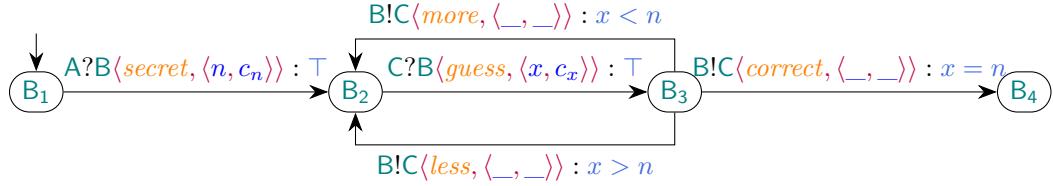

Refined Communicating Finite State Machines. *Communicating systems* [5] are a concurrent model of computation composed of a set of *communicating finite state machines* (CFSM) that interact with exchanges of messages. CFSM are standard finite state machines, where labels represent actions (i.e. sending or receiving messages). Individual FSM are then given a concurrent semantics, which performs messages exchanges. The state of the system is called a *configuration*, which records the state of the individual CFSMs as well as the content of the message queues. In this section, we adapt communicating systems for refinements.

First, we add refinements to the transitions of CFSM, which we call *refined CFSM*. This appears in the additional \mathbb{R} in Definition 8 (we recall \mathbb{R} is the set of refinements).

► **Definition 8** (Refined Communicating Finite State Machine (RCFSM)). An RCFSM is a finite transition system given by $M = \langle Q, C, q_0, \mathbb{M}, \delta \rangle$, where Q is a set of states; $C = \{pq \in \mathbb{P}^2 \mid p \neq q\}$ is a set of channels²; $q_0 \in Q$ is an initial state; \mathbb{M} is a finite alphabet of messages; and $\delta \subseteq Q \times (C \times \{!, ?\} \times \mathbb{A} \times \mathbb{R}) \times Q$ is a finite set of transitions.

We write $s \xrightarrow{\text{itj}(m):r} s'$ for $\langle s, \langle \text{j}, \text{i}, m, r \rangle, s' \rangle \in \delta$. *Refined communicating systems* (RCS) are analogous to their non-refined counterparts and simply consist of a tuple of RCFSM, with one RCFSM per participant. For *refined configurations*, as with (non-refined) configurations,

² The original definition uses *channels*, which we do not use. We keep them for the sake of consistency.

■ **Figure 3** RCFSM of **B** in the G_{\pm} protocol.

we store the states of the individual CFSM and the content of queues. In addition, contrary to non-refined configurations, refined configurations also contain a map in order to keep track of the values of the variables in order to be able to evaluate refinements.

► **Definition 9** (Refined Communicating System (RCS)). *A refined communicating system is a tuple $R = \langle M_p \rangle_{p \in \mathbb{P}}$ of RCFSMs such that $M_p = \langle Q_p, C, q_0 p, \mathbb{M}, \delta_p \rangle$.*

An RCS uses one RCFSM per participant $i \in \mathbb{P}$. A *configuration* represents the state of such RCS, where each participant i is in a local state s_i .

► **Definition 10** (Refined Configuration). *A refined configuration of an RCS R is a tuple S as follows: $S \stackrel{\text{def}}{=} \langle \langle s_1, \dots, s_n \rangle, w, \mathbb{M} \rangle_R$ where each $s_i \in Q_i$, w is a queue of messages, and \mathbb{M} is a map from variables names to values. Let \mathbb{S} be the set of refined configurations.*

► **Remark 11.** Refined configurations are indexed by their RCS. This allows the configuration to store the automaton of the participant. The semantics developed below uses those (local) transitions to infer the global semantics. When the context is clear, we omit this index.

From that, we characterise *initial* and *final* configurations. We call a configuration *initial* when it is a possible configuration where no actions have been taken yet. This means that there is no pending messages (which would imply a previous *send* action), nor known variables (which would imply a previous action initialised the variable). We say a configuration is *final* when there are no pending messages (otherwise, we would expect a *receive* action to take place). Notice that it does not mean the system cannot take action at all.

► **Definition 12** (Initial and Final Refined Configuration). *A refined configuration*

$\langle \langle s_1, \dots, s_n \rangle, w, \mathbb{M} \rangle \in \mathbb{S}$ *is initial if and only if*

- (i) $w = w_{\emptyset}$;
- (ii) $\mathbb{M} = \mathbb{M}_{\emptyset}$; and
- (iii) each s_i is initial in the RCFSM.

A refined configuration $S = \langle \langle s_1, \dots, s_n \rangle, w, \mathbb{M} \rangle \in \mathbb{S}$ is final if and only if $w = w_{\emptyset}$.

► **Example 13** (RCS). The RCFSM of participant **B** in the guessing game is shown in Figure 3. See [35] for the RCFSM of **A** and **C**. Together, they form a RCS, which initial configuration is $\langle \langle A_1, B_1, C_1 \rangle, w_{\emptyset}, \mathbb{M}_{\emptyset} \rangle$.

Refined Semantics. We now define the semantics of RCS in Definition 14 with two reduction rules GRREC and GRSND (the initial GR stands for *global refined*, to distinguish the rules from variants in the following parts of this work), which are respectively used for receiving and sending messages. To avoid confusion with RCFSM reductions, we use a double arrow (\Rightarrow) to represent reductions at the refined communicating system level.

Rule GRSND specifies that, if a participant i reduces from state s_i to state s'_i while sending a message m and if the refinement predicate r attached to the action holds, then the transition is taken at the global level. In the resulting refined configuration, the message is enqueued in the relevant queue and the map of known variables M is updated to take into account the new value of the carried variable c .

Rule GRREC is similar, with the additional requirement that the message received must be the next in the participant's queue (the third premise).

Notice that the verification of refinements is *dynamic*, as it is performed by the corresponding premise in each of the rules, i.e. at execution time.

► **Definition 14** (Refined Global Semantics). *Given a RCS $R = \langle M_p \rangle_{p \in \mathbb{P}}$, we define:*

$$\begin{array}{c} \text{GRREC} \frac{t = s_i \xrightarrow{j?i(\ell, \langle x, c \rangle):r} s'_i \in \delta_i \quad M[x \mapsto c] \models r \quad \text{next}_{(j,i)}(w) = \langle \ell, \langle x, c \rangle \rangle}{\langle \dots, s_i, \dots \rangle, w, M \rangle_R \xrightarrow{t} \langle \dots, s'_i, \dots \rangle, \text{deq}_{(j,i)}(w), M[x \mapsto c] \rangle_R} \\ \\ \text{GRSND} \frac{}{\langle \dots, s_i, \dots \rangle, w, M \rangle_R \xrightarrow{t} \langle \dots, s'_i, \dots \rangle, \text{enq}_{(i,j)}(w, \langle \ell, \langle x, c \rangle \rangle), M[x \mapsto c] \rangle_R} \end{array}$$

► Remark 15. Global transitions are labelled with the underlying local transition. When the local transition is not relevant, we do not show it.

► **Example 16** (Transitions of a RCS). Considering the RCS of G_{\pm} (Figure 3) in its initial configuration $C_i = \langle \langle A_1, B_1, C_1 \rangle, w_{\emptyset}, M_{\emptyset} \rangle$, we have that the automaton of A can fire a transition $A_1 \xrightarrow{A!B(\text{secret}, \langle n, 5 \rangle):T} A_2$, and $M_{\emptyset}[n \mapsto 5] \models T$, by definition of T . Therefore, C_i can take a GRSND transition and reduce to $\langle \langle A_2, B_1, C_1 \rangle, w, \{ \langle n, 5 \rangle \} \rangle$, where w contains a single message $\langle \text{secret}, \langle n, 5 \rangle \rangle$ in $w_{(A,B)}$.

If the RCS is in the configuration $C = \langle \langle A_2, B_3, C_2 \rangle, w_{\emptyset}, M \rangle$ with $M = \{ \langle x, 5 \rangle, \langle n, 5 \rangle \}$, the RCFSM of participant B offers three possible transitions:

- (i) $B_3 \xrightarrow{B!C(\text{more}, \langle _, _ \rangle):x < n} B_2$;
- (ii) $B_3 \xrightarrow{B!C(\text{less}, \langle _, _ \rangle):x > n} B_2$; and
- (iii) $B_3 \xrightarrow{B!C(\text{correct}, \langle _, _ \rangle):x = n} B_4$.

The predicates carried in first two do not hold under M : $M \not\models x < n$ (resp. for $x > n$). Therefore, only $B_3 \xrightarrow{B!C(\text{correct}, \langle _, _ \rangle):x = n} B_4$ is feasible as a GRSND transition in the RCS. As we will see below (Theorem 18), this semantics prevents invalid traces.

Trace of Refined Communicating Systems. In order to show that the semantics of RCS captures the intuition of refinements, we study the traces formed by sequences of reductions (see [35] for the formal definition of traces of RCS).

► **Example 17** (Trace of an RCS). The trace $\tau \cdot \tau_2$ (Example 6) is a trace of the RCS of G_{\pm} .

We conclude this section with our main result, which is that all traces produced by $\mathcal{S}(G)$ are valid refined traces. A trace is *initial* (resp. *final*) if it is obtained from a run whose first (resp. last) state is initial (resp. final).

► **Theorem 18** (Traces of Refined Communicating Systems are Valid Refined Traces). *For all RCS R , for all initial and final traces τ of R , τ is a valid refined trace.*

The proof is in [35].

\mathcal{G}	$\mathbf{p} \rightarrow \mathbf{q}\{\mathbf{l}_i(\mathbf{x}_i : \mathcal{S} \models \mathcal{R}).\mathcal{G}\}_{i \in I} \mid \mu \mathbf{t}.\mathcal{G}$	communication, recursive type

4 Refined Multiparty Session Types (RMPST)

In the two previous sections, we introduced refinement validity and a variant of CS which is correct with respect to our validity criterion. However, working with RCS is cumbersome, in particular if we intend to prove additional properties (e.g. deadlock freedom). Fortunately, various models for message-passing concurrent computation have been developed in the literature, many of which can be encoded into CS. Multiparty session types (MPST) [38, 19, 18] is an example of such model. We focus on MPST as they have proved successful for many applications and the theory enjoy many useful properties (e.g. session fidelity, deadlock freedom, liveness etc). However, MPST is not the only possible choice, and we sketch different input models in [35]. In this section, we introduce *refined multiparty session types* (RMPST), which are an extension of MPST annotated with refinement predicates and we show how one can extend existing models to easily obtain refinements.

In Section 4.1, we first present the syntax of *global* and *local* refined multiparty session types, adapted for refinements. In Section 4.2, we present how to obtain RCS from local RMPST, extending a standard approach to implement MPST in CS [12] with refinements.

4.1 Syntax of RMPST

We define the syntax of RMPST. First we assume that messages carry different sorts of payload. As a reminder, for simplicity, in our examples, we only consider `int` payloads. Also, we recall the conventions from Section 2.1: \mathbb{P} is the set of participants and \mathbb{L} is the set of labels. For recursion, we introduce type variables that range over $\{\mathbf{T}, \mathbf{U}, \dots\}$; \mathbf{t} is a meta-variable taken over the set of type variables. We assume all type variables appearing in a type are distinct and we do not (syntactically) distinguish global and local type variables. Finally, \mathbf{x}_i are meta-variables over payload variables taken from the set \mathbb{V} .

We first define *global refined multiparty session types*, which are inductive data types generated by the production \mathcal{G} in Figure 4. The type $\mathbf{A} \rightarrow \mathbf{B}\{\mathbf{l}_i(\mathbf{x}_i : \mathcal{S}_i \models r_i).\mathcal{G}_i\}_{i \in I}$ describes a protocol where \mathbf{A} chooses a label \mathbf{l}_i amongst possible I and sends a message to \mathbf{B} . The message contains a payload of type \mathcal{S}_i , which is bound to \mathbf{x}_i when sent. *Refinement predicates* we introduce guard the communication they are attached to, meaning the system can select a choice with predicate r_i only if r_i holds. In that case, the message is sent and the protocol continues with its continuation of type \mathcal{G}_i . $\mu \mathbf{T}.\mathcal{G}$ binds \mathbf{T} in \mathcal{G} , and a bound type variable \mathbf{T} in a type denotes a protocol recursion. Let $\text{frv}(\mathcal{G})$ denotes the free recursion variables occurring in \mathcal{G} . Finally `end` describes a terminated protocol. Let $\text{parts}(\mathcal{G})$ be the set of participants that appear in \mathcal{G} (c.f. [35] for the definition of $\text{parts}(\mathcal{G})$). We write $\mathbf{p} \in \mathcal{G}$ for $\mathbf{p} \in \text{parts}(\mathcal{G})$.

► **Example 19** (Refined Global Multiparty Session Type). The type \mathcal{G}_\pm presented in Section 1 is a refined global type; we have $\text{parts}(\mathcal{G}_\pm) = \{\mathbf{A}, \mathbf{B}, \mathbf{C}\}$.

To characterise the behaviour of individual participants, we define *refined local multiparty session types*, which are inductive datatypes generated by \mathcal{L} in Figure 4. Recursion, type variables and termination are similar in local and global types. Only the communication specifications differs: in a local type $p \oplus \{l_i(x_i : s_i \models r_i).L_i\}_{i \in I}$ describes an *internal choice*, i.e. the participant chooses a label l_i and sends it to p . Conversely, $p \& \{l_i(x_i : s_i \models r_i).L_i\}_{i \in I}$ describes an *external choice*: p makes a choice amongst the possible l_i and the local participant receives this choice.

Global and local MPST are related: we can *project* a global type onto the local types of its participants. Below, we define a *projection* (partial) operator $G \upharpoonright_p$, which returns the local type of p with respect to the global type G .

We define a projection with a *merge* (partial) operator, which merges multiple local types of a participant into a single local type. This is used to merge the (possibly different) types of the continuations present in the communication branches. The study of different variants of merge operators is an active field (e.g. [32, Section 3]). For the sake of simplicity, in this paper we use a naïve merge operator, which simply ensures that all types are the same.

► **Definition 20** (Projection). *Given p , q and r three distinct participants:*

$$p \rightarrow q \{l_i(x_i : s_i \models R_i).G_i\}_{i \in I} \upharpoonright_p = q \oplus \{l_i(x_i : s_i \models R_i).G_i \upharpoonright_p\}_{i \in I}$$

$$q \rightarrow p \{l_i(x_i : s_i \models R_i).G_i\}_{i \in I} \upharpoonright_p = q \& \{l_i(x_i : s_i \models \top).G_i \upharpoonright_p\}_{i \in I}$$

$$q \rightarrow r \{l_i(x_i : s_i \models R_i).G_i\}_{i \in I} \upharpoonright_p = \sqcap_{i \in I} (G_i \upharpoonright_p)$$

$$\mu t. G' \upharpoonright_p = \begin{cases} \mu t. (G' \upharpoonright_p) & \text{if } p \in G' \text{ or } \text{frv}(G') \neq \emptyset \\ \text{end} & \text{otherwise} \end{cases} \quad t \upharpoonright_p = \text{tend} \upharpoonright_p = \text{end}$$

where a merge operator is defined as: $\sqcap_{i \in I} L_i \stackrel{\text{def}}{=} L$ if $\forall i \in I \cdot L = L_i$, undefined otherwise.

Notice that our local RMPST accept refinements on both receiving and sending, and the semantics developed in Section 3 accept any position for verification. When projecting a global type $G = A \rightarrow B \{l(x : \text{int} \models r).\text{end}\}$ onto local types, we therefore have a choice to project the refinement:

- on the send side: $G \upharpoonright_A = B \oplus \{l(x : \text{int} \models r).\text{end}\}$ and $G \upharpoonright_B = A \& \{l(x : \text{int} \models \top).\text{end}\}$
- on the receive side: $G \upharpoonright_A = B \oplus \{l(x : \text{int} \models \top).\text{end}\}$ and $G \upharpoonright_B = A \& \{l(x : \text{int} \models r).\text{end}\}$
- or a combination of both³.

Our projection takes the first option, i.e. refinements are checked when the message is emitted, but with any of these choices, our developments would not substantially change.

► **Example 21** (Projection). We project G_\pm (Section 1) onto participants A and B ⁴:

$$G_\pm \upharpoonright_A = B \oplus \{\text{secret}(n : \text{int} \models \top).\text{end}\}$$

$$G_\pm \upharpoonright_B =$$

$$A \& \left\{ \text{secret}(n : \text{int} \models \top).\mu T.C \& \left\{ \text{guess}(x : \text{int} \models \top).C \oplus \left\{ \begin{array}{l} \text{more}(\models x < n).T, \\ \text{less}(\models x > n).T, \\ \text{correct}(\models x = n).\text{end} \end{array} \right\} \right\} \right\}$$

³ For instance, if we want to implement a centralised server that communicates with (isolated) clients, we may want all refinements to be asserted by the server, independently of the direction.

⁴ The projection onto C is similar to the recursive part of the projection onto B , with $!$ and $?$ swapped.

4.2 From Refined MPST to Refined Communicating System

In this subsection, we show how to generate an RCS from local RMPSTs. As shown in Definition 20, local types are projected from global multiparty session types. Therefore, this step allows us to complete the conversion from a global RMPST into an RCS. We adapt the translation from local type to CFSMs presented in [13] to accommodate refinements in types.

The intuition behind the translation is to decompose a local type into the individual steps it specifies. For this, we first need to retrieve all those steps. We define the set of types that occur nested in another type: a type T' occurs in a type T (noted $T' \in T$) if it appears in the continuations of T after one or multiple steps (see [35]).

Given this, we can proceed to the translation itself, in Definition 22. This definition says that the states of the RCFSM of a local type T_0 are composed of the (sub)types that appear in T_0 , stripped of the leading μt . (the function `strip` removes the leading recursions variables; this formalises [13, Item (2) in Definition 3.4]) and of recursive variables t . We define the set of transitions of this RCFSM by taking the action each type (i.e. each state) can take, and adding a transition with this action from the initial state to the continuation (stripped of leading μt). In the case that the continuation is a recursion variable t , we have to search in the original type the continuation. Compared to [13, Item (2) in Definition 3.4], we simply add the support for the refinements predicates, which appear both in the types (i.e. in the states) and in the actions (i.e. in the transitions).

► **Definition 22** (RCFSM of Refined Local Types (extends Definition 3.5 in [13])). *Given a global type G , the RCFSM of participant p (with local type $T_0 = G|_p$) is the automaton $\mathcal{A}(T_0) = \langle Q, C, \text{strip}(T_0), \mathbb{M}, \delta \rangle$ where:*

- $Q = \{T' \mid T' \in T_0 \wedge T' \neq t \wedge T' \neq \mu t.T_\mu\}$;
- $C = \{\mathbf{pq} \mid p, q \in G, p \neq q\}$; and
- δ is the smallest set of transitions such that: for all $T \in T_0$ in Q , for all $c \in \mathbb{C}$:
 - if T is $q \oplus \{\ell_i(x_i : S_i \models r_i).T_i\}_{i \in I}$, for all T_i :
 - * if $T_i \neq t$, then $\langle T, p!q(\ell_i, \langle x, c \rangle) : r, \text{strip}(T_i) \rangle \in \delta$
 - * if $T_i = t$ with $\mu t.T' \in T_0$, then $\langle T, p!q(\ell_i, \langle x, c \rangle) : r, \text{strip}(T') \rangle \in \delta$
 - if T is $q \& \{\ell_i(x_i : S_i \models r_i).T_i\}_{i \in I}$, for all T_i :
 - * if $T_i \neq t$, then $\langle T, q?p(\ell_i, \langle x, c \rangle) : r, \text{strip}(T_i) \rangle \in \delta$
 - * if $T_i = t$ with $\mu t.T' \in T_0$, then $\langle T, q?p(\ell_i, \langle x, c \rangle) : r, \text{strip}(T') \rangle \in \delta$

where $\text{strip}(T) \stackrel{\text{def}}{=} \text{strip}(T')$ if $T = \mu t.T'$; and $\text{strip}(T) \stackrel{\text{def}}{=} T$ otherwise.

Finally, we define the *RCS of a type*.

► **Definition 23** (Refined Communicating System of a Type). *The RCS of a type G , noted $\mathcal{S}(G)$, is a tuple composed of the RCFSM of all participants $\mathcal{S}(G) \stackrel{\text{def}}{=} \langle \mathcal{A}(G|_p) \rangle_{p \in \text{parts}(G)}$. We note $\mathcal{C}(G)$ the initial configuration of $\mathcal{S}(G)$.*

► **Example 24** (Refined Communicating System of G_\pm). The communicating system of G_\pm is $\mathcal{S}(G_\pm) = \langle \mathcal{A}(G_\pm|_A), \mathcal{A}(G_\pm|_B), \mathcal{A}(G_\pm|_C) \rangle$.

The initial configuration $\mathcal{C}(G_\pm)$ of this RCS $\mathcal{S}(G_\pm)$ is $\langle \langle A_1, B_1, C_1 \rangle, w_\emptyset, M_\emptyset \rangle$.

Theorem 18 applies to RCS obtained from RMPST: RCS generated from Definition 23 only produce valid refined traces, with the refined global semantics presented in Definition 14. Notice also that, if refinements always hold, RMPST and their semantics coincide with the semantics presented in [12].

5 Decentralised Refined Multiparty Session Types

In the previous section, we presented RCS and we showed that every trace of an RCS is a valid refined trace. However, RCS are theoretical constructions and are not intended to be implemented directly, as they use a global shared map of variables. In practice, a user may want to develop more precise analysis techniques on specific classes of RCS to remove this global map, which allows a decentralised verification of refinements, while keeping the validity of refined traces.

The goal of this section is twofold: on the one hand, the decentralised semantics we develop serves as a theoretical background for our implementation (Section 7). On the other hand, it illustrates the modularity of our framework. We show that the decentralised approach produces valid refined traces by showing refined configurations we developed in Section 3 simulate decentralised systems. This approach is not specific to our variant: we expect other optimisations presented in the literature could be integrated similarly.

This section is divided in the following steps: first, we define what we mean by *decentralised verification of the refinements*, by adapting the semantics of RCS (Definitions 25 and 28). We split the global map of variables' values into local maps (one per participant). Then, we show that despite being modified, the new variant still produces valid refined traces (Definition 7). We justify this claim by proving that under some conditions, the original RCS *simulates* (c.f. [30, Exercise 1.4.17, p. 26]) the decentralised variant (Theorem 31). Since trace equivalence is coarser than simulation, this is sufficient to prove that decentralised configurations that meet the said conditions produce valid refined traces.

The conditions we mentioned above are:

- (i) variables should not be duplicated; and
- (ii) when evaluating a predicate, the free variables of the predicate must be in the local map.

Without the first condition, we can possibly have two distinct values assigned to the same variable without being able to distinguish which is the most recent. The second condition is required to verify the refinements locally (e.g. predicates that constraint an action of A should be checked by A itself). To illustrate the importance of the first condition, consider the type $\text{A} \rightarrow \text{B} \{ \ell_1(x : \text{int}).\text{C} \rightarrow \text{D} \{ \ell_2(x : \text{int}).\text{end} \} \}$. In the centralised approach, x is aliased, while in the decentralised approach, the x exchanged between A and B is stored in a local map, and the x exchanged between C and D is stored in another local map; both are not aliased. To prevent different semantics, we need to prevent such difference, which is the goal of the first condition.

Decentralised Configurations and Decentralised Semantics. First, we define *decentralised* configurations in Definition 25. Compared to Definition 10, instead of a global map in the tuple, we associate a local map to each automata state. Those maps store the variables each participant has access to.

► **Definition 25** (Decentralised Configuration). A Decentralised Configuration of an RCS $\mathcal{S}(\text{G}) = \langle\langle Q_i, C_i, q_{0,i}, \mathbb{A}, \delta_i \rangle\rangle_{i \in \text{parts}(\text{G})}$ is a tuple $\langle\langle \langle s_1, M_1 \rangle, \dots, \langle s_n, M_n \rangle \rangle, w \rangle_{\mathcal{S}(\text{G})}$ where each $s_i \in Q_i$, each M_i is a local map of variables to values, and w is a queue of messages.

Let \mathbb{S}_D be the set of decentralised configurations. We note $\mathcal{D}(\text{G})$ the initial decentralised configuration of $\mathcal{S}(\text{G})$.

Remark 11 also applies for decentralised configurations.

► **Example 26** (Initial decentralised configuration of G_{\pm}). In Example 13, we presented the refined communicating system of G_{\pm} and its associated refined configuration. The *initial decentralised configuration* of this system is $\langle \langle A_1, M_{\emptyset} \rangle, \langle B_1, M_{\emptyset} \rangle, \langle C_1, M_{\emptyset} \rangle, w_{\emptyset} \rangle$. In particular, notice that it uses the same set of refined CFSM than the refined configuration.

The global reduction rules are adapted accordingly: in the rules DREC and DSND (“D” stands for “decentralised”), when a message is sent or received, the corresponding local map is updated, instead of a global map as in GRREC and GRSND.

► **Remark 27.** Contrary to Definition 14, when a variable is sent, it is removed from the local map of variables. Intuitively, when a participant sends a variable, it erases its knowledge of it, to prevent aliasing issues. A direct consequence of this is that, in the centralised implementation, the global map of variables is a *superset* of the local maps in the corresponding decentralised implementation. Indeed, while a variable is in transit, it appears neither in the sender’s map, nor in the receiver’s one. This observation will be proved together with the simulation proof (Theorem 31).

► **Definition 28** (Decentralised Global Semantics). *Given an RCS $R = \langle M_p \rangle_{p \in \mathbb{P}}$*

$$\begin{array}{c} DREC \quad \frac{t = s_i \xrightarrow{j?i(\ell, \langle x, c \rangle):r} s'_i \in \delta_i \quad \text{next}_{(j,i)}(w) = \langle \ell, \langle x, c \rangle \rangle \quad M_i[x \mapsto c] \models r}{\langle \langle \dots, \langle s_i, M_i \rangle, \dots \rangle, w \rangle_R \xrightarrow{t} \langle \langle \dots, \langle s_i, M_i[x \mapsto c] \rangle, \dots \rangle, \text{deq}_{(j,i)}(w) \rangle_R} \\ DSND \quad \frac{}{\langle \langle \dots, \langle s_i, M_i \rangle, \dots \rangle, w \rangle_R \xrightarrow{t} \langle \langle \dots, \langle s_i, M_i \setminus x \rangle, \dots \rangle, \text{enq}_{(i,j)}(w, \langle \ell, \langle x, c \rangle \rangle) \rangle_R} \end{array}$$

Conditions for Decentralised Verification and Correctness Proofs. We now focus on proving that this decentralised semantics produces valid refined traces. As we mentioned above, this holds under two conditions, which we define first:

► **Definition 29** (Conditions for Decentralised Verification Simulation). *Given a decentralised configuration $\langle \langle s_i, M_i \rangle, \dots \rangle, w \rangle$, the conditions for simulation are:*

1. *No duplication:*
 - a. if $\exists M_i \cdot x \in \text{dom}(M_i)$, then $\forall i, j \cdot x \notin w_{(i,j)}$ and $\forall j \neq i \cdot x \notin \text{dom}(M_j)$.
 - b. if $\exists \langle i, j \rangle \cdot x \in w_{(i,j)}$, then $\forall i \cdot x \notin \text{dom}(M_i)$ and $\forall \langle i', j' \rangle \neq \langle i, j \rangle \cdot x \notin w_{(i',j')}$.
2. *Free variables are in the map:* $\forall i \cdot \forall s'_i \cdot s_i \xrightarrow{i?j(\ell, \langle x, c \rangle):r} s'_i \cdot \text{fv}(r) \subseteq \text{dom}(M_i[x \mapsto c])$

► **Definition 30** (Decentralisable Type). *A type G is decentralisable if the two conditions hold for all reachable decentralised configurations from $\mathcal{D}(G)$.*

Notice that the second condition is redundant, as the condition $M_i[x \mapsto c] \models r$ (in the premises of the reduction rules) already requires that $\text{fv}(r)$ is a subset of the variables in $M_i[x \mapsto c]$. Even without making this condition explicit, the system would stall if a predicate cannot be verified. For the sake of clarity, we keep it explicit in the two required conditions.

We now observe a correspondence between the (centralised) refined configuration and the decentralised configuration of a global type G . To characterise the correspondence between centralised and decentralised configuration, we establish a *simulation* relation between the two (see [35] and [30]). Intuitively, a simulation captures the fact that one system (the centralised configuration in our case) can mimic all transitions of another system (the decentralised one here).

We can now prove the main result of this section, which is that the decentralised semantics does not induce new (unwanted) behaviours, i.e. all decentralised transitions can be mimicked by centralised transitions, i.e. the centralised approach simulates the decentralised one.

► **Theorem 31** (Centralised simulates Decentralised). *For all decentralisable RMPST G (Definition 30), $\mathcal{C}(G)$ simulates $\mathcal{D}(G)$.*

Proof. The proof is available in [35]. ◀

This result shows that any type that verifies the conditions stated in Definition 29 can be verified in a decentralised way. The difficulty is that the conditions are about the execution: we do not know whether a predicate will have a missing variable during the execution. With a knowledge flow algorithm, we can infer (from the communication specifications in the global type) which participant has access to which variables at any point in the execution of the protocol, i.e. we can *localise* each variable throughout the execution of the protocol. This algorithm (which we present in [35]) does not present major challenges.

Notice that the reverse simulation does not hold: $\mathcal{D}(G)$ does not simulate $\mathcal{C}(G)$. Indeed, $\mathcal{C}(G)$ can verify a predicate whose variables are spread over different participants, i.e. where variables would be spread across multiple M_i in the decentralised variant.

6 Static Elision of Redundant Refinements

In this section, we present a second optimisation, which is complimentary from the first one. The main idea is to statically analyse a given protocol to find and remove redundant refinements. Our approach is to consider a *target* transition, which we aim to remove the refinement, if possible. Our optimisation can then be applied successively to different target transitions one after each other. For instance, consider the following protocol G_s . We target the second refinement, $x < 10$, which necessarily holds if the first one does (since x does not change). Therefore it is redundant and can be removed.

$$G_s = A \rightarrow B \{\ell_1(x : \text{int} \models x < 0).A \rightarrow B \{\ell_2(y : \text{int} \models x < 10).\text{end}\}\}$$

However, removing refinements is not always trivial, since the communication semantics is asynchronous. Consider for instance the following type:

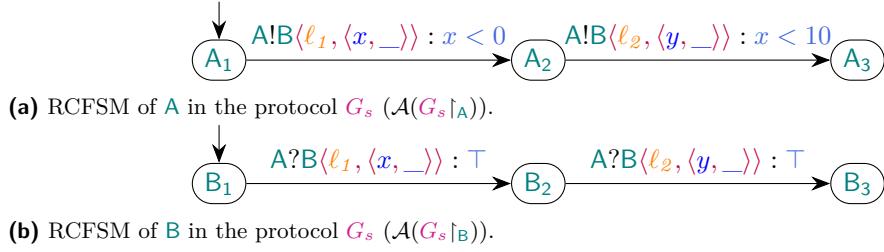

$$A \rightarrow C \{\ell_1(x : \text{int} \models x > 20).A \rightarrow B \{\ell_2(x : \text{int} \models x < 0).C \rightarrow B \{\ell_3(y : \text{int} \models x < 10).\text{end}\}\}\}$$

A naïve approach would be to remove the refinement of the last communication ($x < 10$), since the previous communication has a stronger guarantee ($x < 0$). However, due to the asynchrony of communications, the second and third communications could be swapped at runtime, but the refinement ($x < 10$) does not hold before the action $A \rightarrow B \{\ell_2(x : \text{int} \models x < 0)\dots\}$ occurs. Therefore, in this case, removing the last refinement is incorrect. The optimisation we present takes into account those cases, by keeping track of causal relations between actions.

This section is independent of the previous one, although this second optimisation can help to make some protocols localisable: for instance, G_s above is not localisable. Since the second step $A \rightarrow B \{\ell_2(y : \text{int} \models x < 10).\text{end}\}$ requires A to access x , which is at B . However, once removed, the protocol becomes localisable, and can therefore be decentralised, helping the first optimisation introduced in Section 5.

As with the previous section, the optimisation we present could easily be further improved. Here, we focus on a simple case, as our goal is not to discuss the optimisation itself, but rather to show the versatility of the framework.

We present this section in two steps: first, in Section 6.1, we focus on RCS, which form the core of our framework; then, in Section 6.2, we apply the above result to RMPST.

■ **Figure 5** RCFSM of the RCS of G_s , the running example of Section 6.

6.1 Static Elision of Refinements in RCS

In a first step, we develop and prove the correctness of our analysis in RCS. The question is therefore whether, given a RCS R with one CFSM containing a transition with refinement r , this RCS R is equivalent (bisimilar) to an RCS where r is replaced with T .

For the sake of simplicity, in this subsection, we'll explain the static elision of refinements in RCS using examples. Formal definitions, lemmas and their proofs are available in [35]. We use the RCS of G_s shown in Figure 5.

If we aim to i.e. transitions which payload modify variables that do not appear free in the refinement of the considered transition.

► **Example 32** (Independent transitions). In $S(G_s)$, $A_2 \xrightarrow{A!B<ell_2, <y, __> : x < 10} A_3$ depends on the variable $x \in \text{fv}(x < 10)$. This transition is self-independent. Since the payload of $A_1 \xrightarrow{A!B<ell_1, <x, __> : x < 0} A_2$ is x , the former transition depends on the later.

► **Remark 33.** We note \mathbb{T}_x the set of transitions $\sigma \xrightarrow{\dagger \langle __, <x, __> \rangle} \sigma'$. Given a transition t with refinement r , if $x \in \text{fv}(r)$, then t depends on all transitions of \mathbb{T}_x .

Essentially, when attempting to remove a refinement from a target transition t , we can disregard all transitions t is independent of.

The second definition we will need is about transitions being *well-defined*. So far, nothing prevents us to use refinements with undefined free variables, we simply consider the refinement does not hold (c.f. Definition 14). In this section, we specifically focus on systems where free variables of refinements are in the map when the refinement is evaluated. When it is the case, we call transitions with such refinements *well-defined*.

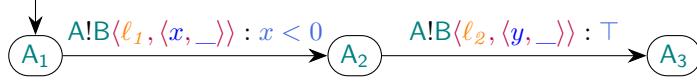

► **Example 34** (Well-defined transition). Considering the RCS in Figure 5. In the RCFSM of A , the (local) state A_2 is only accessible with a transition $A_1 \xrightarrow{A!B<ell_1, <x, __> : x < 0} A_2$. Therefore, any global state $\langle\langle A_2, B_{\{1,2,3\}}, __, M\rangle\rangle$ necessarily contains a preceding transition $A_1 \xrightarrow{A!B<ell_1, <x, __> : x < 0} A_2$. Therefore, x is always in the map M of that state. Therefore, the transition $A_2 \xrightarrow{A!B<ell_2, <y, __> : x < 10} A_3$ is well-defined.

We can now conclude our analysis technique: consider a target transition t with refinement r that is self-independent (it does not modify the variables of its refinement) and well-defined. If all transitions that modify the free variables of r can guarantee (via their refinement) that the modification they do is correct with respect to r , then we can safely remove r .

► **Theorem 35** (Correctness of refinement elision). *Given an RCS R containing an RCFSM $M = \langle Q, C, q_0, \mathbb{A}, \delta \rangle$, and $t = s_i \xrightarrow{p \dagger q(m):r} s'_i \in \delta$, a well-defined self-independent transition. Let $t' = s_i \xrightarrow{p \dagger q(m):T} s'_i$; $\delta' = \delta \setminus \{t\} \cup t'$; $M' = \langle Q, C, q_0, \mathbb{A}, \delta' \rangle$; and R' be R where M is replaced with M' . If, for each transition $t_w = _ \xrightarrow{_! \langle _ \rangle : r_w} _$ in $\bigcup_{x \in \text{fv}(r)} \mathbb{T}_x$, for all map M , $M \models r_w$ entails $M \models r$, then there exists a bisimulation relating the states of R' and R .*

Proof. Proving each direction of the bisimulation is direct (see the proof in [35]). \blacktriangleleft

► **Example 36** (Application of Theorem 35). The following RCFSM, where $x < 10$ is removed, is a valid replacement for $\mathcal{A}(G_s \upharpoonright_A)$ in $\mathcal{S}(G_s)$.

6.2 Application to RMPST Protocols

The above subsection explains how to remove some redundant refinements in RCS. In this subsection, we intend to do the same, focusing on RMPST instead of RCS.

Our goal is the following: we are given an RMPST G , and we would like to remove one of its refinement (which we call the *target* refinement r). For the sake of simplicity, in this section, we assume all labels are uniquely used. For the general case, we can simply uniquely rename redundant labels. Overall, the roadmap for this subsection is to show that given the type G' , which is G where r is replaced by T , G and G' behave similarly, i.e. the RCS they generate are bisimilar. To achieve this, we show that Theorem 35 applies to $\mathcal{S}(G)$ and $\mathcal{S}(G')$. Therefore, the main point is finding conditions on RMPST that ensures hypothesis of Theorem 35 holds; we have to verify the following items:

1. all transitions our refinement depends on should entail the refinement itself;
2. the transition that carries the refinement must be well-defined. Since variables cannot be removed from the map, the first occurrence of the target transition must respect the domain condition. Therefore, for this step, we can ignore recursion.

The main difference with automata is that, in types, we have *communications*, which possibly contains choices with multiple branches; and we our goal is to remove the refinement of one of those branches. Therefore, we first introduce *steps* of a communication, i.e. given a choice, what are the possible choices it can take. We then extend this to types. We show that steps in a type correspond to transitions in the automata of that type.

► **Example 37** (Step). The type $G_y = A \rightarrow B \{l_2(y : \text{int} \models x < 10).\text{end}\}$ has the step $A \rightarrow B(l_2, y) \models x < 10$. Since G_y occurs in one of the branches of G_s (from the introduction of this section), this step *occurs* in G_s .

Given this notion of steps occurring in a type that is analogous to transitions in the RCFSM of that type, we can now focus on the conditions of Theorem 35. Therefore, we have to characterise what corresponds to *well-defined transitions* in a type. Since transitions (in RCS) and steps (in types) are analogous, we introduce *well-defined steps* in a type. We recall that, in a RCS, a transition is well-defined if the free variables of the refinement it carries are always known when the transition is fired. Since variables are never removed from the map, we can focus on the first occurrence of the transition. So far, we do not have a notion of *run* for a type. Therefore, we first define an *happens-before* relation in RMPST, and we use this relation to define *well-defined steps* as steps that contain a refinement which free variable are all exchanged in a communication that *happens-before* the step we consider. With those two definitions, we can finally prove that a well-defined step in a type corresponds to a well-defined transition in the corresponding RCS.

► **Example 38** (Well-defined step in a type). Consider G_s and G_y as in Example 37. The step $A \rightarrow B(l_2, y) \models x < 10$ is well-defined. Indeed, $\text{fv}(x < 10) = \{x\}$, $G_s < G_y$, and G_s contains a branch that sends x and which continuation contains G_y .

We can finally proceed to the overall goal of this section: showing that the type with and without the target refinement behave similarly. Thanks to the above lemmata, we simply have to target a refinement with the appropriate conditions and apply Theorem 35.

► **Theorem 39** (Static elision of redundant refinements in types). *Given two a global types G and $G_s = p \rightarrow q\{\ell_i(x_i : S_i \models r_i).G_i\}_{i \in I} \in G$, such that, for one $t \in I$, $p \rightarrow q(\ell_t, x_t) \models r_t$ is a well-defined step with $x_t \notin \text{fv}(r_t)$. Let $\ell_{t'} = \ell_t$, $x_{t'} = x_t$, $S_{t'} = S_t$, $r'_{t'} = \top$, $G_{t'} = G_t$, $G_{s'} = p \rightarrow q\{\ell_i(x_i : S_i \models r_i).G_i\}_{i \in I \setminus \{t\} \cup \{t'\}}$; and G' be G where G_s is replaced with $G_{s'}$. If, for all steps, $r \rightarrow s(_, x_w) \models r_w$ occurring in G (for each $x \in \text{fv}(r)$), $M \models r_w$ entails $M \models r$ (for all M), there exists a bisimulation between the states of $\mathcal{S}(G)$ and those of $\mathcal{S}(G')$.*

Proof. We prove this by showing that Theorem 35 applies to $\mathcal{S}(G)$ and $\mathcal{S}(G')$. The proof is provided [35]. ◀

► **Example 40** (Application of Theorem 39). Given G_s as in Example 37 and G'_s as follows (notice the second refinement is replaced by \top), G_s and the following G'_s have the same behaviour:

$$G'_s = A \rightarrow B \{\ell_1(x : \text{int} \models x < 0).A \rightarrow B \{\ell_2(y : \text{int} \models \top).\text{end}\}\}$$

7 Implementation

In the previous section, we introduced an instance of our framework: a system that accommodates refinements using a decentralised verification mechanism. In this section, we follow up on this example with an implementation, based on Rumpsteak, of this system.

Rumpsteak [7] is a framework to write Rust programs according to an MPST specification. The framework is divided into two parts:

- (i) a runtime library that provides primitives to write asynchronous programs in Rust; and
- (ii) a tool (`rumpsteak-generate`) to generate skeleton Rust files from specification files (i.e. from global types), in two steps.

Working with Rumpsteak takes two manual steps. The user specifies (step 1) the protocol in a global type (written as Scribble files [39], see Figure 6a). This global type is automatically projected using ν Scr [15] and the projected types are used to generate skeleton Rust files (see Figure 6b). The generated Rust code contains Rust types that encode local types (e.g. the type for A is shown in Line 1 in Figure 6b). The user then manually implements (step 2) the process of each participant, following their type (Line 7), using provided communication primitives (Line 13). Rumpsteak relies on Rust’s typechecker to ensure the consistency of the implementation. For the sake of clarification where needed, we call *Vanilla Rumpsteak* the framework without refinements (i.e. as presented in [7]), and *Refined Rumpsteak* the framework modified to accommodate refinements.

In this section, we explain the main differences between Vanilla and Refined Rumpsteak: we introduce refinements in the types used in the runtime library, we modify the program generation step accordingly, and we introduce tools that ensure the localisation conditions are met (Definition 29 in Section 5). The overall workflow is presented in Figure 7. We conclude this section by measuring the overhead induced by the refinement w.r.t. Vanilla Rumpsteak and the time needed for asserting the localisation conditions.

```

1 (*# RefinementTypes #*)
2
3 global protocol PlusMinus
4 (role A, role B, role C)
5 {
6   Secret(n: int) from A to B;
7   rec Loop {
8     Guess(x: int) from C to B;
9     choice at B {
10       More(x: int {x < n}) from B to C;
11       continue Loop;
12     } or {
13       Less(x: int {x > n}) from B to C;
14       continue Loop;
15     } or {
16       Correct(x: int {x = n}) from B to C;
17     }}}

```

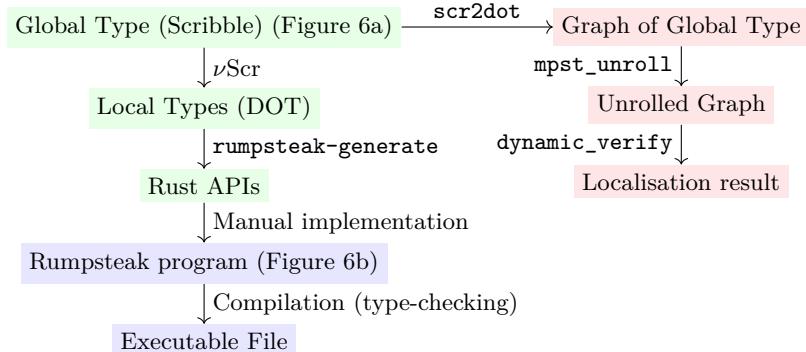

(a) ν Scr description of the guessing game protocol.

```

1 type PlusMinusA =
2 Send<B, 'n',
3 Secret,
4 Tautology::<Name, Value, Secret>,
5 Constant<Name, Value>, End>;
6 // ...
7 async fn a(role: &mut A)
8 -> Result<(), Box<dyn Error>> {
9   try_session(role,
10   HashMap::new(),
11   |s: PlusMinusA<'_, _>| async {
12     let s =
13     s.send(Secret(10)).await?;
14     return Ok((((), s))
15   })
16   .await
17 }

```

(b) Rust type and implementation of participant A of the guessing game protocol. The handwritten code (Line 7 to Line 17) is the same than with Vanilla Rumpsteak.

Figure 6 Implementation of the guessing game using Rumpsteak.**Figure 7** Workflow of Rumpsteak. Green nodes represent steps that already existed in Vanilla Rumpsteak and that have been adapted to accommodate for refinements, red nodes represent new steps, and blue nodes represent unmodified steps. The three new steps (`scr2dot`, `mpst_unroll`, and `dynamic_verify`) verify the conditions mentioned in Definition 29.

7.1 Refinement Implementation

Modifications to the Rumpsteak Library. In order to accommodate for refinements, we have to introduce new elements in to the Rumpsteak's encoding of local types. Consider the local type of participant A introduced in Example 21 $B \oplus \{secret(n : int \models \top).end\}$: Rumpsteak now has to take into account the name of the variable sent (`n`), and the refinement attached to the transition (`T`). Consider the type declaration in Line 1 to Line 5, Figure 6b. Compared to Vanilla Rumpsteak, we introduce '`n`', a const generic⁵, that carries the name of the variable sent (Line 4). Regarding the refinement, we introduce `Tautology::<Name, Value, Secret>`,

⁵ <https://github.com/rust-lang/rfcs/blob/master/text/2000-const-generics.md>

which represent the refinement T . The generic parameters are used to specify the type of variable names (`chars` in our case) and values (`i32`) as well as the label of the message (`Secret`). We modified `vScr` and `rumpsteak-generate` to generate skeleton files (the content of the file up to Line 5). Rumpsteak provides a set of available refinements, and additional ones can be written ad-hoc (for specific needs). To add an ad-hoc refinement, the user simply implements the trait `Predicate` (which extends `Default`), which requires a method `check` that asserts whether the predicate holds. For instance, the `check` function of `Tautology` simply returns `true`.

Verification of the Conditions for Decentralised Refinement Assertion. As we explained in Section 5, to make sure that refinements can be verified in a decentralised way, we require to check that variables needed for the refinements are located correctly (Definition 29). To perform this verification, we implemented new tools for the Rumpsteak framework (in red in Figure 7).

Our tools:

- (i) convert the global type into a graph (`scr2dot`);
- (ii) unroll the loops once to precisely capture variables initialisations (`unroll_mpst`); and
- (iii) localise variables on the unrolled graph (`dynamic_verify`).

The core part of this verification, `dynamic_verify`, finds variables locations with simple inference rules written in Datalog. We use the `crepe` library [40] which provides a Datalog DSL for Rust. We provide more details on the algorithm in [35].

Limitations. The current implementation makes extensive use of the Rust feature *const generics*⁹ which introduces a limited form of dependent types in Rust. It allows to use constant values in types. As of today, only some *basic types* can be used as const generics, in particular `chars` and the various integer types. We use such const generics to encode informations about the variables into the types: for instance, the predicate `x < 5` would have the type `LTnConst<L, 'x', 5>`, where the '`x`' and the 5 are const generics.

For readability, we choose to set variables to `chars`, meaning that in the current implementation, we can only accommodate a limited number of distinct variables. Should more be needed, one could easily modify our implementation to replace them with `u64`, which allows 2^{64} variables names. Similarly, we only consider `i32` as message payloads. Should different types of messages be needed, they could be encoded in an `enum`.

Finally, the static elision optimisation (Section 6) is not implemented.

7.2 Runtime and Localisation Benchmarks

We evaluate how Rumpsteak with refinements performs with respect to Rumpsteak without refinements. First, we measure the runtime of our analysis tool which verifies the two conditions in Definition 29 (`scr2dot`, `unroll_mpst` and `dynamic_verify`). Although not a runtime cost, and while we expect this analysis to be possibly expensive, we would like to ensure that it is still practical for test cases from the literature. Secondly, we evaluate the runtime overhead of adding refinements with respect to Rumpsteak without refinements.

Setup and Benchmark Programs. We evaluate the performance of Rumpsteak with refinement with benchmarks. Most of them are taken from the literature (Table 1). This set of program contains various micro-benchmarks with a variety of combination of properties (whether the protocol is binary or multiparty, contains recursivity or choice). Notice that protocols that contain recursivity with no choice (e.g. *simple auth* are infinite). Therefore,

Table 1 The set of micro benchmarks together with their characteristics. “MP” denotes a multiparty protocol, “Rec” the presence of recursion, and “Choice” the presence of choice.

Name	MP	Rec	Choice
① simple adder [21]	no	no	no
② travel_agency [23]	no	no	yes
③ ping pong [42]	no	yes	no
④ simple auth.	no	yes	yes
⑤ ring max	yes	no	no
⑥ three_buyers [19]	yes	no	yes
⑦ plus or minus	yes	yes	yes

such protocols are only measured in the variable localisation paragraph. Also, where it applies, protocols were modified in order to add relevant refinements; such modifications are listed below. By default, we add **Tautology** predicates (Section 7.1). The tests were performed on a machine running Ubuntu 22.04.1 LTS x86_64 (kernel 5.15.0-60) with an Intel i7-6700 processor (4 cores, 8 threads running at 4GHz maximum) and 16GB of memory⁶. We compare Rumpsteak with refinement vs. Vanilla Rumpsteak. For a comparison between Vanilla Rumpsteak and other libraries, see [7, Figure 6].

Added Refinements & Protocol Modifications. Some benchmarks from the literature were adapted in order to accommodate refinements. In addition, we introduce three benchmarks. Those benchmarks are close to examples from the literature, adapted to better highlight refinements.

simple adder: This example is adjusted from the *Adder* ([21]) protocol, but we remove the choice of operation in order to increase the benchmark diversity;

ping pong: In [42], some of the loops were statically unrolled, and the protocol contained a choice to exit. Ours is equivalent to an infinite *PingPong*₁ in [42].

simple authentication: This example is a binary example of an authentication protocol (e.g. OAuth [31]). The added refinements enforce that access is granted if and only if the given password is correct.

ring max: A multiparty protocol where participants receive a value from their predecessor (except for the initial participant), and forward an other value to their successor (the final participant forwards it to the initial one). Refinements ensure that the value forwarded is greater than or equal to the value received.

plus or minus: An implementation of our running example.

Static Analysis of Variable Locations. Table 2 shows the decentralised verification time cost for each refined global label. As shown in Figure 7, this static analysis is performed with three tools. The results shown account for the whole pipeline, and were measured over 50 samples, with 10 warmup runs (excluded from the measurements). Overall, the runtime for variable localisation is stable (around 5.6ms). We suspect that, for graphs with a low number of states, the runtime is dominated by the accesses to the file.

⁶ The micro-benchmarks are not memory intensive. The memory size is not a limiting factor. However, the benchmarks seem to be dominated by the startup time, which includes memory access time.

Table 2 Benchmark of the localisation analysis (Red branch in Figure 7). $|S|$ denotes the number of states of the graph of the protocol; $|U|$ denotes the number of states after unrolling the recursion loops once; and $|V|$ denotes the number of variables in the protocol. $|S|$, $|U|$ and $|V|$ are computed manually to give an insight on how protocols compare. et is the execution time, measured by the benchmark (in ms).

	$ S $	$ U $	$ V $	$et (\mu \pm \sigma)$
①	4	4	3	5.5 ± 0.2
②	7	7	6	5.5 ± 0.2
③	2	4	1	5.5 ± 0.2
④	6	11	3	5.6 ± 0.2
⑤	8	8	7	5.7 ± 0.2
⑥	10	10	7	5.6 ± 0.2
⑦	4	19	2	5.6 ± 0.2

Table 3 Evaluation of the runtime overhead due to the addition of refinements in Rumpsteak. p is the MWU p -value, m is the baseline median runtime and m_r is the median runtime with refinements when applicable ($p < 0.05$). All times are in ms.

	p	m	m_r
①	0.00	0.7	0.8
②	0.11	0.8	N/A
④	0.29	0.8	N/A
⑤	0.17	0.8	N/A
⑥	0.68	0.7	N/A
⑦	0.04	0.7	0.8

Runtime Overhead of Refinement Feature. Our second set of benchmarks aims to measure the overhead of runtime refinement verification with respect to the original Rumpsteak framework. We are expecting Rumpsteak with refinements to be slower than the original Rumpsteak, due to the additional cost of evaluating refinements. This benchmark has two objectives: first, to find out whether there is an actual, statistically significant, overhead; and second, if so, estimate this overhead. To measure this overhead, we only consider the protocols that terminate from the benchmark set.

To fulfil the first objective, we use a Mann-Whitney U test (MWU). We used MWU as it is a non-parametric test, and our runtime distributions do not follow a normal distribution, which prevents us to do simpler analysis. As MWU is sensitive to the number of samples, we run each benchmark 30 times, on both the original Rumpsteak and Rumpsteak with refinements. We perform the MWU test on the collected 30 samples, preceded by 10 iterations to warm the system up. Our hypothesis for the MWU test are the following:

$$\begin{aligned} H_0: & \text{The distributions of runtimes with and without refinements are identical.} \\ H_1: & \text{The distributions of runtimes with and without refinements are distincts.} \end{aligned}$$

The p -values obtained from the MWU test are reported in the first column of Table 3. We also report the baseline (Rumpsteak without refinements) median run time (over the 30 runs) in the second column of the table. Most often, the overhead is not significant ($p \geq 0.05$) and H_0 can not be rejected. When the overhead is statistically significant, we also report the median runtime (over the 30 runs) of Rumpsteak with refinements in the third column. With our set of microbenchmarks, in most cases we cannot distinguish Rumpsteak with refinement from Rumpsteak without refinements. We suspect Rumpsteak runtime is dominated by communications and context switching. However, as our refinements can be arbitrarily complex, specific instances could show real slowdown due to refinement evaluation.

8 Related Work and Conclusion

Design-by-Contract for (Multiparty) Session Types. In binary session types, [37] introduces contracts for binary sessions, and provides an analysis tool which verifies whether a given program complies with its associated contract. The verification is done with symbolic execution. Compared to this paper, we address multiparty sessions. Besides, our framework is more generic (specific instances could be based on symbolic execution, but we can also accommodate other verification methods). Bocchi et al. [4] present a variant of MPST that allows predicates on exchanges, that must hold for a typed process to take transitions. The main difference with our work is that their approach focuses on *correctness by construction*, i.e. they accept only correct protocols, while we can accept protocols that fail, and we simply prevent them to generate incorrect traces. More precisely, the authors statically ensure that there is a satisfiable path, which prevents some valid runs to be accepted. For instance, consider the following type:

$$\text{A} \rightarrow \text{B} \{ \ell_1(x : \text{int} \models x < 10). \text{B} \rightarrow \text{A} \{ \ell_2(y : \text{int} \models x > y \wedge y > 6). \text{end} \} \}$$

This type would be rejected in [4] since if **A** sends $x = 5$ (which is allowed by $x < 10$), then there is no y that satisfies $5 > y \wedge y > 6$. By rejecting this, they also reject all possibly valid runs (e.g. if **A** sends $x = 9$ and **B** replies with $y = 7$). A follow-up on this work is [3] which introduces local states, i.e. the authors allow participants to have local variables, which can be updated during process execution. The session types reflect those elements and contain predicates on exchanged variables and local variables.

With respect to these two papers, our criteria for the validity of refinements (expressed as a property of the generated trace) is decoupled from the semantics of the model. This approach allows us to be more flexible than enforcing statically the refinements, and to lower the cost of adopting refinements, in particular to retrofit refinements into existing systems. For instance, using our framework, one can simply use the centralised semantics at first, which is very expressive, without having to prove the correctness of the implementation. In a second step, users can then develop different verification or analysis techniques which can be plugged-in transparently. For instance, switching from Vanilla Rumpsteak to Refined Rumpsteak does not involve changes in the implementation, as the modifications do not happen in the programming interface. Also, compared to these papers, our framework is not bound to MPST only, and provide an actual implementation of our framework.

Design-by-Contract in Choreography Automata. Choreography Automata (CA) are graphs that represent the global behaviour of a concurrent system. The behaviour of individual participants is obtained by *projecting* well-formed CA, i.e. erasing all actions that do not concern a given participant. The result is a FSM which, after determinising and minimising, is used as a CFSM. The projection of all participants leads to a CS. Notice that CA accept some protocols that would be rejected by MPST, and vice-versa.

Gheri et al. [16] study the verification of CA with assertions. Their work and ours are distinct with respect to the following aspects:

- (i) the communication semantics;
- (ii) the choices;
- (iii) the logic for predicates; and
- (iv) the implementation presented in [16] is limited to CA without assertions (i.e., the design-by-contract approach was not implemented and left as their future work).

Regarding Item i, Gheri et al. [16] defines choreography automata with *synchronous* communication semantics, while the one we developed in this work is asynchronous. Gheri et al. [16, Section 7] discusses asynchronous semantics but it remains future works.

Regarding Item ii, we are constrained by the syntax of RMPST, in which choices can only happen between two selected participants, while choreography automata accept protocols with choices where a (single) participant **A** sends to multiple receivers (**B** and **C**) [16, Definition 4.15]. Explicit connections [22] is an extension of MPST that accommodates with choices with multiple receivers.

Regarding Item iii, we kept our refinement logic abstract, while it is fixed in choreography automata, with a form of first order logic. Besides, predicates are handled differently in both frameworks as well: Gheri et al. [16] require choreography automata to be *history-sensitive* [4], a definition which serves a similar purpose to our definition of *variable localisation* (Section 5 and [35]), which constrains our decentralised semantics. Our centralised semantics (Definition 10) is not constrained by variable localisation. For instance, the RMPST $A \rightarrow B \{ \ell_1(x : \text{int} \models T). C \rightarrow D \{ \ell_2(y : \text{int} \models x = y). \text{end} \} \}$ produces valid traces with our centralised semantics, while the corresponding choreography automata would be rejected.

Besides, our work introduces a general framework that can accommodate refined CA in addition to RMPST. We show [35] a possible way to do so.

Implementations of Refinements in MPST. Neykova et al. [29] develop an F# library for static verification of MPST with refinements. They present a compiler plugin which uses an SMT solver (Z3) to statically verify some refinements. They use a notion of similar to our variable localisation criterion (which they call *variable knowledge*), and a variant of CFSM with refinements that is similar to ours. In their work, refinements that are statically asserted by the SMT solver are pruned in the CFSM, while the rest of refinements are kept in the CFSM and are dynamically checked. Similarly, [41, 42] develop a framework for multiparty session types with refinements in F*. They delegate the management of refinements to F* type system (which internally uses an SMT solver). They define refinements on global types, which are then projected onto local types. They show that a global type and its projection are trace equivalent. Those two works focus on the *implementation* of MPST with refinements. [29] does not focus on the theory of refinements and the theory developed in [42] is tightly coupled to F*. For instance, they do not present a *correctness* criterion such as *valid refined traces* we present. Contrary to both works, our correctness criteria (based on valid refined traces) is *decoupled from* (i.e. independent of) any target type theory, programming language or model of computation: we only require an LTS labelled with actions. Besides, the logic used for refinements is also a parameter of our framework, and users could use alternatives, leading to a greater expressivity of our framework.

The main syntactical difference between our RMPST and those developed in [42] is that we attach refinements to the messages of the protocol, while [42] attach refinements to the payload value. This is due to a different approach: correctness in [42] is related to payload types being inhabited while our criteria of correctness (developed in Definition 7) relies on actions being allowed. In binary linear logic-based session types, [9] study the metatheory of binary session types with arithmetic refinements. In particular, they focus on the type equality, showing that added refinements make the type equality undecidable (they provide a sound but incomplete algorithm for type equality). [10] also implement a library for session types with refinements, although it only accounts for arithmetic refinements.

Other Related Works. There are various papers on the dynamic verification of MPST. For instance [2] present a framework that allows for both static and dynamic verification of MPST. This paper introduces a theory for (dynamically) monitoring assertions on messages (i.e. the equivalent of our refinements). Furthermore, the authors introduce theoretical tools (bisimulations) to relate monitored processes with correct unmonitored processes. This paper, however, suffers a few limitations. First, it focuses on *monitorable* types (which intuitively correspond to types satisfying our conditions for decentralised verification Definition 29). Second, it focuses on dynamic verification of assertions. The paper is compatible with statically verified processes (which allows turning off the dynamic monitoring), but it does not present techniques for static verification in itself.

On the other hand, our paper takes a different approach, by decoupling the correctness criterion from the verification technique. This allows us to have a more general framework (our framework accept types that are not localisable/monitorable, although not all semantics can accommodate those), as well as to develop static verification techniques.

In Rust, the `refinement` crate [11] provides refinement data types. Their approach of refinements is similar to ours, with a `Predicate` trait that provides a method to perform the predicate verification (at runtime). Refinement data types have also been implemented in multiple languages (e.g. F^{*}, Haskell [36], etc.). On the practical side, we can note the similarities between typestates and session types [20]. [14] implements typestates in Rust with a DSL to verify protocol conformance. While Rumpsteak does not use their library, it internally uses similar constructs.

Regarding implementations of session types in Rust, there are several frameworks beside Rumpsteak. [25] first integrate binary session types in Rust, but their implementation suffers a few drawbacks (see [26, Section 3] for a detailed explanation). Sesh [26] and Ferrite [6] are two Rust libraries for *binary* session types, and they implement synchronous and asynchronous ones, respectively. MultiCrusty [27] implements synchronous MPST on top of Sesh, with a mesh of binary sessions. Compared to MultiCrusty, Rumpsteak implements directly MPST instead of wrapping them into binary sessions, and focuses on asynchronous MPST. None of the aforementioned tools develops refinements. It would be an interesting future work to apply our criteria to extend their tools with refinements.

Finally, we note the proximity between (MP)ST with refinements and dependent (MP)ST. For instance, [33] introduce a session type calculus with label-dependency (their approach does not explicitly account for payload value refinement). Other approaches exist, for instance, an intuitionistic linear logic-based type theory for building value-dependent session types [34], and separation logic-based work for reasoning about session types [17].

Future Work While, in our work, we consider MPST with payloads (some variants only consider messages with labels), we restrict our MPST with a single payload (i.e. *monadic* MPST, where each message carries a single value). The extension to polyadic MPST, where a message can carry multiple values, is straightforward, by adapting the RCS rules (GRSND and GRREC, Definition 14).

We presented two optimisations, in order to illustrate the flexibility of our theoretical framework. Regarding the decentralised verification (Section 5), there is room for an extension, e.g. with specific domains (i.e. some class of protocols with specific refinements). Regarding the static elision of redundant refinements, we envision improving the technique with use of SMT solvers could be promising. The main difficulty lies in asynchronous communications: one would need to consider all possible message orderings before solving constraints.

Abstract

Failure transparency enables users to reason about distributed systems at a higher level of abstraction, where complex failure-handling logic is hidden. This is especially true for stateful dataflow systems, which are the backbone of many cloud applications. In particular, this paper focuses on proving failure transparency in Apache Flink, a popular stateful dataflow system. Even though failure transparency is a critical aspect of Apache Flink, to date it has not been formally proven. Showing that the failure transparency mechanism is correct, however, is challenging due to the complexity of the mechanism itself. Nevertheless, this complexity can be effectively hidden behind a failure transparent programming interface. To show that Apache Flink is failure transparent, we model it in small-step operational semantics. Next, we provide a novel definition of failure transparency based on observational explainability, a concept which relates executions according to their observations. Finally, we provide a formal proof of failure transparency for the implementation model; i.e., we prove that the failure-free model correctly abstracts from the failure-related details of the implementation model. We also show liveness of the implementation model under a fair execution assumption. These results are a first step towards a verified stack for stateful dataflow systems.

1 Introduction

Stateful dataflow systems have seen wide adoption in the modern cloud infrastructure due to their ability to process large amounts of event-based data at ingestion time [24]. Apache Flink [13], for example, is used to power tens-of-thousands of streaming jobs with up to nine billion events per second at ByteDance [48], and several thousand streaming jobs at Uber [25]. An essential aspect of stateful dataflow systems is the recovery from failures, as failures are to be expected in any long-running streaming job [19]. However, failure recovery is non-trivial. For example, simply recovering from a failure by restarting a job from the

¹ Both authors contributed equally to this research.

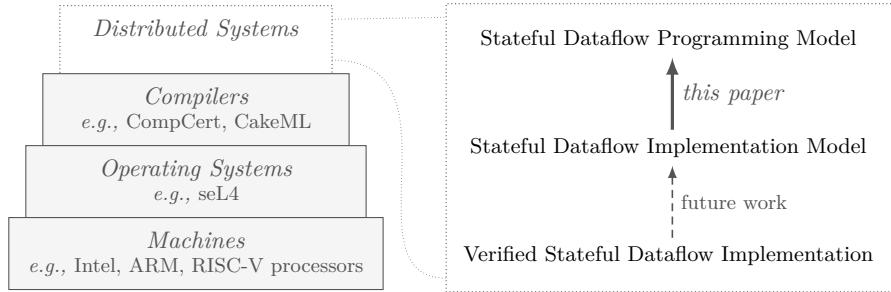

Figure 1 This work in the context of a fully verified stack for distributed programming.

very beginning would discard all progress up to that point, making the recovery prohibitively expensive. To balance the need for efficiency and reliability, stateful dataflow systems have to embrace complex failure recovery protocols. Because of their complexity, the correctness of these recovery protocols is a crucial problem for the reliability of stateful dataflow systems.

In previous work [21, 44, 26], a failure-masking recovery protocol is considered to be correct, if failures can be masked such that the user cannot observe the failures. This property is also known as *failure transparency*, *i.e.*, a user should be able to ignore failures as if they do not occur. Failure transparency has been shown for some distributed systems, such as Durable Functions [8], Reliable State Machines [51], reliable actors (KAR) [61], and serverless microservices (μ 2sls) [30]. As for stateful dataflow, the core mechanism used in Apache Flink’s [13] recovery protocol, namely Asynchronous Barrier Snapshotting (ABS) [11, 12], has been shown to be a correct snapshotting protocol [10]. However, the proof does not reason about failure transparency and its related aspects, such as modelling failures and the recovery from failures, as well as about the equivalence of observed executions. That is, there has been no formal proof that Apache Flink’s entire failure recovery protocol provides failure transparency. Furthermore, the literature lacks a formal definition of failure transparency for systems described with distinct failure-related rules using small-step operational semantics, a widely-used method for defining program execution in programming languages theory.

An important approach for ensuring reliability and correctness is machine-checked formal verification, *i.e.*, proving that a system implements its specification. There is well-known prior work on verified compilers [41, 33, 53], operating systems [31], as well as processors [16, 29, 55] (Figure 1, left). However, there is an apparent lack of verified distributed systems, particularly, there is no verified stateful dataflow system. We believe that it is essential to address this gap in order to prevent disastrous outages of distributed infrastructure as known today.

This work is a first step towards the grand goal of providing a fully verified reliable stack for distributed programming, as shown in Figure 1. It addresses the highlighted gap by: (1) providing a definition of failure transparency, (2) formalizing a stateful dataflow system as a model in small-step operational semantics, under the assumptions of crash-recovery failures and FIFO-ordered channels, and (3) formally proving that the model permits abstracting from failures, *i.e.*, that it is failure transparent. Our definition of failure transparency is based on *observational explainability*, a property which, informally, says that the *explainable* implementation model generates the same observable output as is possible in the *explaining* abstract model. Using this property, a system is defined as failure transparent if the whole system is observationally explainable by its explicitly separated failure-free part. Finally, we prove that our formal model of a stateful dataflow system based on Asynchronous Barrier Snapshotting [13, 10] is failure transparent. This abstraction from failures is designed to serve the end users of the modelled system with less interest in its implementation details.

Contributions. In summary, this paper makes the following contributions.

- We provide the first small-step operational semantics of the *Asynchronous Barrier Snapshotting* protocol within a stateful dataflow system, as used in Apache Flink (Section 4).
- We provide a novel definition of *failure transparency* for programming models expressed in small-step operational semantics with explicit failure rules and the intuitions behind it (Section 5). It is the first attempt to define failure transparency in the context of stateful dataflow systems.
- We prove that the provided implementation model is failure transparent and guarantees liveness (Section 6).
- We provide a mechanization of the definitions, theorems, and models in Coq.²

Outline. Section 2 introduces background on failures, distributed systems, stateful dataflow, as well as some basic notation used throughout this paper. Section 3 informally introduces the stateful dataflow programming model and failure recovery via the Asynchronous Barrier Snapshotting (ABS) protocol. Section 4 provides a small-step operational semantics of a stateful dataflow system based on ABS. Section 5 defines failure transparency and observational explainability for programming models expressed in small-step operational semantics. Section 6 proves that the implementation model is failure transparent. Section 7 discusses related work, and Section 8 concludes this paper.

2 Background

2.1 Failures in Distributed Systems

A distributed system is a system of many processes communicating over a network [9]. The kind of distributed systems which are related to this work are event-based processing systems such as stateful dataflow systems [19, 67, 13, 52, 69, 60]. Failures within such systems are expected to happen, due to their typical large scale and longevity [19]. However, failures are notoriously hard to deal with within distributed systems. For this reason, *failure transparency* is a necessary abstraction, as it enables the user to abstract from failures. Failure transparency as a general concept, and failure recovery protocols are both well-studied topics in distributed systems [63, 65, 40, 44, 43, 26, 21]. Moreover, failure transparency has seen an increase in interest within the programming languages community in recent years [8, 30, 51, 61]. The goal of failure recovery is to provide automatic system means to recover from system failures, in ways which the system user may or may not notice. In contrast, the goal of failure transparency is to provide an abstraction of the system, such that the abstraction hides the internals of failures and failure recovery, masking the failures from the user [26]. For this reason, failure transparency greatly simplifies the programming model to the benefit of the end user.

2.2 Stateful Dataflow and Apache Flink

Stateful dataflow systems, sometimes also called stream processing or dataflow streaming systems, such as Apache Flink [13], have become ubiquitous for real-time processing of large amounts of data [48, 25]. Other well known dataflow systems include Google Dataflow [2], IBM Streams [18], Apache Spark [66] and Spark Streaming [68], Timely Dataflow [52],

² <https://github.com/aversey/abscoq>

NebulaStream [69], Portals [60], and more [7, 56]. The popularity and wide-spread use of dataflow systems [25, 48] is due to their ability to scale-out production workloads. In particular, they provide high throughput, low latency, and strong guarantees (such as failure transparency, sometimes referred to as exactly-once processing). The programming model of most stateful dataflow systems is based on acyclic dataflow graphs [24]. In these graphs, the nodes are stateful processing tasks, and the edges are streams of data. As failure transparency is an important aspect of the stateful dataflow programming model, it and its failure recovery protocol is the focus of this paper.

2.3 Asynchronous Barrier Snapshotting

The failure recovery protocol used in Apache Flink [13] is a checkpointing-based rollback recovery protocol [21], in which the system regularly takes checkpoints and, after a failure, recovers to the latest completed checkpoint. For batch execution systems, such as MapReduce [19], the general approach is to atomically execute one batch at a time, and if a failure occurs, the system restarts from the beginning of the current batch. In contrast, computation on stateful dataflow streaming systems is continuous [24], without predefined recovery points in its execution, complicating the failure recovery. The solution to recovery in continuous computations is the acquisition of causally consistent snapshots [14], which can be used for the recovery to a consistent system state after a failure [21]. The specific implementation of Apache Flink [13] and other stateful dataflow systems [60] use the Asynchronous Barrier Snapshotting (ABS) protocol [12], an extended and optimized variant for data processing graphs of the Chandy-Lamport snapshotting protocol [14], for taking causally-consistent snapshots. In contrast to the Chandy-Lamport snapshotting protocol, the ABS protocol is tailored to acyclic dataflow graphs and its snapshots do not contain any in-flight events. In contrast to batching protocols, the ABS protocol is fully asynchronous, and does not require blocking coordination. For these reasons, the ABS protocol greatly benefits the end-to-end latency and throughput of the system.

2.4 Basic Notation

Functions. We denote a function f similarly to set-builder notation as: $[k \mapsto t \mid k \in \text{dom}(f)]$. The part after the bar defines the domain of the function. The part before the bar defines the value of the function at point k by the expression t . The expression t captures all variables defined on the right side of the bar, including k . A function with only one element in its domain is represented as $[x \mapsto x']$, for example, $[3 \mapsto 7]$ is such a function that $\text{dom}([3 \mapsto 7]) = \{3\}$ and $[3 \mapsto 7](3) = 7$. We denote function update as $f g$, such that:

$$(f g)(x) = \begin{cases} g(x) & \text{if } x \in \text{dom}(g) \\ f(x) & \text{if } x \notin \text{dom}(g) \end{cases}$$

Sequences. We represent a sequence S as a function f with domain $\{i \mid i \in \mathbb{N} \wedge i < |S|\}$. The length of the sequence is represented by $|S|$ and may be infinite. The notation S_i stands for the i -th element of the sequence S and equals $f(i)$. To simplify our analysis of sequences, we use $[t]_i^n$ as a shorthand for $[i \mapsto t \mid i \in \mathbb{N} \wedge i < n]$, where t is an expression that captures i and represents the i -th element of the sequence. Therefore, for any sequence S , we have that $S = [S_i]_i^{|S|}$.

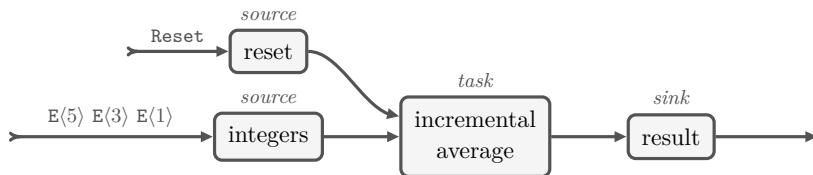

Figure 2 Example stateful dataflow program calculating the incremental average of a data stream of integers. Another stream is used to transfer control messages resetting the state of the program.

The usage of indices for variables standing for sequences may differ from other variables. If S stands for a sequence, then S_i corresponds to the i -th element of S . If, in contrast, x is not a sequence, then x_i is an independent variable and is not connected to x or any x_j . To avoid confusion, we name sets and sequences using uppercase and individual elements using lowercase.

Sequence concatenation can be used to extend or shrink existing sequences. We include a shorthand notation for sequence concatenation, concatenating S with S' as follows $S : S' \equiv [i \mapsto S_i \mid i \in \mathbb{N} \wedge i < |S|] [j + |S| \mapsto S'_j \mid j \in \mathbb{N} \wedge j < |S'|]$. To simplify extraction and addition of single elements, we denote single-element sequences $[x]_i^1$ as $[x]$, where x is the only value in the sequence. The empty sequence is represented as ε .

3 Stateful Dataflow

Stateful dataflow systems, sometimes also called *distributed dataflow*, *dataflow streaming*, or *stream processing* systems, are widely used for real-time processing of large amounts of streaming data. This section informally introduces the stateful dataflow programming model and its failure recovery mechanism, which we formalize and prove correct in later sections. It is mostly based on Apache Flink [13], a stateful dataflow system, however, the core concepts and techniques involved also apply to other similar systems [19, 66, 68, 2, 18, 52, 69, 60].

3.1 A Taste of Programming in Stateful Dataflow

Figure 2 shows a stateful dataflow example calculating the incremental average of a stream of integers. The example consists of two *sources* ingesting streams of events into the system. One source ingests a stream of integers $E\langle i \rangle$, and the other ingests a stream of `Reset` events. The term *stream* can be understood as an unbounded sequence of events, it may in general continue forever. The example also consists of a *task*, an internal processing unit, which calculates an incremental average of the integers. The incrementally computed averages are emitted to a *sink*, which is the output of the system.

A more detailed representation of the example is shown in Listing 1. Sources, tasks, and sinks are created using corresponding functions. The API enables users to: (1) create sources, tasks, and sinks; (2) specify the connections in the graph by providing input and output streams; and (3) to specify how the tasks process events by providing their processing functions. In this example, when the task receives an integer event $E\langle i \rangle$, it updates the average and emits the new average. When it receives a `Reset` event, it resets its local state, such that the average is reset to its initial state. To note is that the task is considered *stateful*, as it maintains local state for its computation of the incremental average, even though the processing function f is a pure function. Also to note is that it is possible to provide an easier-to-use API above this core API, for example an API based on higher-order functions (`map`, `flatMap`, etc.) [13, 60, 2, 52].

Listing 1 A stateful dataflow program calculating the incremental average of a data stream of integers (see Figure 2).

```
Source(input = "src_reset", output = "reset")
Source(input = "src_ints", output = "ints")
Sink(inputs = { "avgs" }, output = "sink_avgs")
Task(inputs = { "src_ints", "src_reset" }, output = "avgs",
  f = (event, state) => event match {
    case Reset =>
      val new_state = {sum = 0, count = 0}
      return (Nil, new_state)
    case E<value> =>
      val new_state = {sum = state.sum + value, count = state.count + 1}
      val average = E<value = new_state.sum / new_state.count>
      return (average : Nil, new_state) })
```

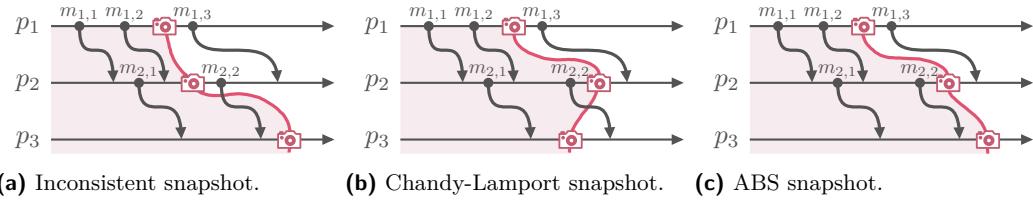

Figure 3 Examples of snapshots obtained in a distributed stateful dataflow system with three processes $p_1 \rightarrow p_2 \rightarrow p_3$.

3.2 Failure Recovery via Asynchronous Barrier Snapshotting

Failure recovery is a crucial aspect of stateful dataflow systems. In this section, we describe the failure recovery mechanism of the Asynchronous Barrier Snapshotting (ABS) protocol [12] as used in Apache Flink. More specifically, ABS is a *distributed snapshotting* protocol [14] which is used for the checkpointing-based rollback-recovery protocol [21] within Apache Flink [12]. After a failure, a checkpointing-based recovery will restart the system from the latest valid snapshot of the system [21].

Distributed Snapshotting Protocols. A distributed snapshotting protocol is considered *causally consistent* if it captures snapshots that do not violate causality [14]. Causality, here, refers to the causal order relation [35], informally: two events are causally ordered if one event was part of a causal chain leading to the other event. Consequently, a causally consistent snapshot captures the state of a system such that all events causally preceding any other event in the snapshot are included. This definition is illustrated by three example executions of different snapshotting protocols for a dataflow graph consisting of three nodes, shown in Figure 3. An incorrect implementation (Figure 3a) would be to let the processes periodically capture a snapshot of their state without coordination. A snapshot captured with this method can be inconsistent, thus not suitable for recovery, as it may violate causality. In the example, the incorrect snapshot has captured that $m_{2,2}$ was received by p_3 but never sent by p_2 , this is a violation of causality, and recovery from such a snapshot would be considered erroneous. In contrast, consistent snapshotting protocols do not violate causality. The Chandy-Lamport asynchronous snapshotting protocol [14] (Figure 3b) solves

■ **Listing 2** Representation of an event handler within a stateful dataflow system implementing failure recovery using the ABS protocol [12, 10].

```

EventHandler Def  $TK\langle f, [S_i]_i^n, o \rangle$ 
  Vars state, snapshots
  On Event Receive  $\langle S_j, \text{epoch}, \text{Event}\langle w \rangle \rangle$  If  $\exists v: \text{state} = \langle \text{epoch}, v \rangle$  Do
     $v', w' = f(v, w)$ 
    state =  $\langle \text{epoch}, v' \rangle$ 
    emit( $\langle o, \text{epoch}, \text{Event}\langle w' \rangle \rangle$ )
  On Event Receive  $\langle [S_i, \text{epoch}, \text{Border}]_i^n \rangle$  If  $\exists v: \text{state} = \langle \text{epoch}, v \rangle$  Do
    snapshots.update(epoch  $\mapsto$  v)
    state =  $\langle \text{epoch} + 1, v \rangle$ 
    emit( $\langle o, \text{epoch}, \text{Border} \rangle$ )
  On Event Fail Do
    state = Failed
  On Event Recover  $\langle \text{recoverEpoch} \rangle$  Do
    state =  $\langle \text{recoverEpoch}, \text{snapshots}(\text{recoverEpoch}) \rangle$ 

```

this issue through distributed coordination by means of disseminating markers during its regular execution, separating pre-snapshot and post-snapshot messages. However, a snapshot captured with the Chandy-Lamport protocol may capture in-flight events: as shown in the example (Figure 3b), the message $m_{2,2}$ was sent (according to p_2 's snapshot) but not yet received (according to p_3 's snapshot). The Asynchronous Barrier Snapshotting (ABS) protocol [12, 10], in contrast, captures complete distributed computations without in-flight events by modification of the marker-based Chandy-Lamport protocol. As shown in Figure 3c, the snapshot does not include any in-flight events.

The ABS Protocol. A representation of the ABS protocol [12, 10] corresponding to our formalization in Section 4 is found in Listing 2. The handler has two mutable states: the processing task's volatile **state**, and the persistent **snapshots** state. The **state** is a tuple $\langle \text{epoch}, v \rangle$ consisting of the current **epoch**'s sequence number being processed, and the state **v** of the processing task. The first event handler consumes an event **Event** $\langle w \rangle$ from a stream with stream name S_j out of the sequence of stream names S for some **epoch** if it is not currently in a failed state. It processes the event w on its current state v , which produces an output event w' and new state v' . It then updates its mutable state, and emits the output on its outgoing stream with stream name o . The second handler processes the **Border** markers from the higher-level ABS protocol. It will consume all border events from all its incoming streams in a single step. In doing so, it will take a snapshot of the local state and update the epoch number, as well as disseminate the border marker further downstream. To note is that the first handler does not consume from a stream if that stream has a border marker as its next event, instead it will block such streams until the border step (*i.e.*, the second handler) has been taken. The first and second handlers implement the ABS protocol, whereas the third and fourth handlers implement the failure recovery. The third handler models the random failures of tasks, a task can randomly fail at any time, in which case it loses its volatile state. The fourth handler implements the failure recovery, and is triggered by some external coordinating instance once it has detected the failure. Once a failure has

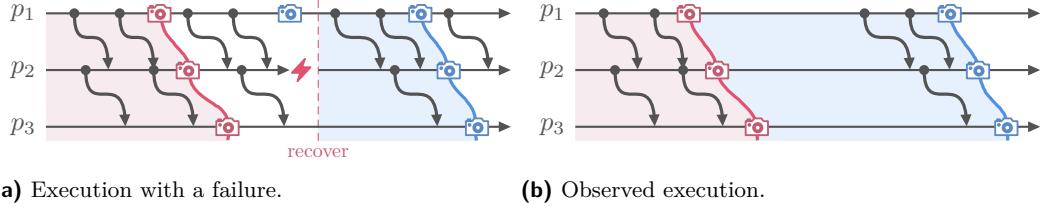

Figure 4 An execution with failures and its observed execution.

been detected, all tasks are recovered to the same epoch which corresponds to the latest snapshot of the system. When triggered, the fourth handler recovers the state back to the snapshot of the epoch found in the message.

Failure Recovery. The dataflow system can recover from failures using the ABS protocol. Figure 4a shows an execution using the ABS protocol in which \$p_2\$ fails. The coordinator (not displayed) will eventually discover the failure, and trigger a synchronous recovery step in which all processes recover to the latest completed snapshot and continue processing from there. Even though failures occur in the execution, the observer will be able to construct an idealized execution corresponding to our notion of failure transparency in which there are no failed events or incomplete epochs as shown in Figure 4b. This is, loosely speaking, achieved by ignoring the side effects from the failed epochs, and is explored in detail in Section 6.

4 Implementation Model

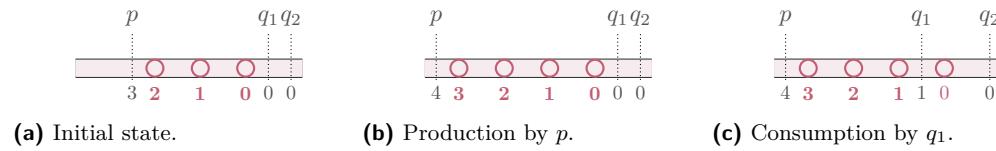

We now provide a formal model of the stateful dataflow system described above. The goal of this formalization is to capture and analyze key aspects of the implementation of the system, with focus on its failure recovery using the Asynchronous Barrier Snapshotting protocol [12, 10]. The formal model is presented in two parts: the first part presents an explicit evaluation rule for message passing, and the second part presents the evaluation rules for processing and failure recovery.

4.1 Streaming Model

The streaming model is based on processors (or tasks) that communicate via streams. A processor is a stateful entity that may consume an event from an incoming stream, process it, and produce events to its outgoing stream. Streams, in turn, transport the events between processors in a FIFO order. With this notion of processors and streams, we can execute computational graphs by means of steps. Note that, in this section, we discuss a general streaming model, leaving the implementation of processors abstract. Whereas, in the next section, we discuss concrete implementations of processors.

Syntax. Figure 5 shows the syntax of the streaming model. A configuration $c = \langle \Pi, \Sigma, N, M, D \rangle$ represents a point in an execution of a streaming program. The processors Π indexed by identifiers p represent processor definitions, for which Σ represents the states of the processors. The messages M are modeled as a sequence of all messages, for which a message m corresponds to a tuple of a sequence number n , a stream name s , and the message data d . The current sequence number from which a processor p reads from or writes to a stream s is represented by $N_p(s)$. The sequence numbers for all processors are represented by N . When

p, q	processor ID	s, o	stream name	$n \in \mathbb{N}$	sequence number
π	processor	σ	state	d	message data
$\Pi ::= [\pi]_p^{ \Pi }$	processors	$X ::= [x]_i^{ X }$			
$\Sigma ::= [\sigma]_p^{ \Pi }$	states	$x ::=$			action
$M ::= [m]_i^{ M }$	messages			$+ s d$	production
$N ::= [N_p]_p^{ \Pi }$	sequence numbers			$- s d$	consumption
$N_p ::= [s \mapsto n \mid s]$	sequence numbers of p			$m ::= n s d$	message

Figure 5 Streaming syntax.**Figure 6** Production and consumption to/from a stream with a producer p and consumers q_1 and q_2 .

a processor processes a message, it may produce and consume messages. This production and consumption is represented by a sequence of actions X . A production action producing message d to stream s has the form $+ s d$, similar to the consumption action $- s d$. The auxiliary data D is used to store global and additional execution information which is specific to the models; for example, it can be used to implicitly model the global coordinator. In the formalization here, the processor π , state σ , message data d and auxiliary global data D are seen as atomic values, that is, no information about their internal structure is provided. These limitations permit reusing the same syntax and rule for different instantiations of π , σ , d and D .

Figure 6 illustrates a stream as a sequence of messages with index numbers. When producing an event to a stream (Figure 6b), the event is appended to the stream with an incremented index number. This also increments the producer's index number for the stream from 3 to 4. Similarly, the consumer's index number points to the next event to be consumed. Figure 6c shows that the consumer q_1 has consumed the event 0, which in turn also increments its index number for the stream, pointing at the next event. Consumers and producers process the stream independently and asynchronously. The production of a message is a kind of broadcast, in the sense that all processors will have to consume it before consuming a newer message.

Step Rule. The streaming model essentially consists of a single rule (S-STEP) which describes the processing of messages. Intuitively, a streaming step from configuration (Π, Σ, N, M, D) can be taken if there is a local step with actions X , such that the actions are applicable. A local step describes how the processor Π_p changes its current state Σ_p to its next state Σ'_p using actions X . The actions X are applicable to N_p and M if all messages consumed by X are available on the input streams of the processor. The application of the actions X results in N'_p and M' , which are the incremented sequence numbers for the processor and the set of

messages M extended with the newly produced messages. In case of taking a streaming step, the configuration transitions to the new configuration $\langle \Pi, \Sigma[p \mapsto \Sigma'_p], N[p \mapsto N'_p], M', D \rangle$. In summary, the result of the streaming step is an update of the local state of the processor according to the local step, and an update of the sequence numbers and messages according to the actions X . To simplify the analysis of streaming steps, auxiliary information about the processor ID, its sequence numbers, and the actions of the step is placed on the arrow of the execution step. This information can be omitted when it is not needed by applying abstraction steps S-AbsX and S-ABSP.

$$\frac{\Pi_p \Vdash \Sigma_p \xrightarrow{X} \Sigma'_p \quad X(N_p, M) = (N'_p, M')}{\langle \Pi, \Sigma, N, M, D \rangle \xrightarrow[p]{N_p, X} \langle \Pi, \Sigma[p \mapsto \Sigma'_p], N[p \mapsto N'_p], M', D \rangle} \text{S-STEP}$$

$$\frac{c \xrightarrow[p]{N_p, X} c'}{\frac{c \Rightarrow c'}{c \Rightarrow c'}} \text{S-ABSX} \quad \frac{c \xrightarrow[p]{c \Rightarrow c'}}{c \Rightarrow c'} \text{S-ABSP}$$

The streaming rule can be applied if there exists a derivation of the form $\Pi_p \Vdash \Sigma_p \xrightarrow{X} \Sigma'_p$ for a processor Π_p . These are called local steps, since they have access only to the local data of a processor, *i.e.*, its definition, state and locally accessible messages. These rules describe the local step of a processor, in which the processor may produce and consume messages/actions X , and update its local state to Σ'_p . The produced actions X modify the sequence numbers of the processor N_p and the messages in the system after application. This is computed by the action application function $X(N_p, M)$ and results in the new sequence numbers N'_p and messages M' for the next configuration as defined below.

Action Application. The action application rule defines how actions modify the sequence numbers and messages. A production action $+ s d$ increases the sequence number of the stream s for the producer, and adds the message to the sequence of messages. Each stream has at most one producer; thus, we do not need to specify the producer in the action or message. A consumption action $- s d$ increases the sequence number of the stream s for the consumer, but does not remove it from the sequence of messages, as there may be other consumers waiting to consume the message. To note is that the consumption action application is only defined if the message is present in the sequence of messages. Due to this, local steps may only be applied in the context of the S-STEP rule if the consumed message is present in the sequence of messages. The remaining cases of the definition are for the recursive application of actions.

► **Definition 4.1** (Action Application).

$$(+ s d)(N_p, M) = (N_p[s \mapsto N_p(s) + 1], M \cup \{N_p(s) s d\})$$

$$(- s d)(N_p, M) = (N_p[s \mapsto N_p(s) + 1], M) \text{ if } N_p(s) s d \in M, \text{ undefined otherwise}$$

$$([x] : X)(N_p, M) = X(x(N_p, M))$$

$$\varepsilon(N_p, M) = (N_p, M)$$

According to the definition, it is not always possible to apply an action. This may be the case if, for example, a message for some sequence number is not yet available on its stream. This enables indirectly “passing” messages to the local step rules. Whereas the local step rule is defined for all possible steps for all messages that it may consume, cases in which the message consumption is not applicable by the action application definition are ruled out by the streaming global step rule. This leaves only messages which are applicable to be applied to the steps, thus passing the message to the rule.

v, w	value	$e \in \mathbb{N}$	epoch number
$\pi ::= \text{TK}\langle f, [S_i]_i^{ S }, o \rangle$	task	$d ::= \langle e, d_C \rangle$	message

$\mid \langle e, v \rangle$	<i>normal state</i>		

Figure 7 Stateful dataflow syntax.

4.2 Stateful Dataflow Model

The presented stateful dataflow model consists of processing tasks, sources, and sinks. A processing task consumes messages from a set of input streams, and produces messages on its output stream. The task's behavior is defined by a function f which processes the messages. The function f takes the task's state and an input message, and produces a new state and a sequence of output messages: $f(v, w) = v', [W'_i]_i^n$. The presented formal model does not provide a syntax and semantics for functions; they can be expressed using any suitable formalism. The sources of the model are emulated by streams which are initialized in the first configuration to contain all the messages which are to be consumed from the source. That is, each source is represented by its output stream, which in turn becomes an input to one of the tasks of the computational graph. Sinks are also emulated as streams, however, in contrast to sources, they are initially empty. The computation of the system, informally, takes inputs from the sources, processes them in the processing graph, and produces outputs to the sinks.

Syntax. The syntax of the implementation model (Figure 7) extends the shared streaming syntax and semantics (Figure 5) by providing concrete instances of processors/tasks, messages, and state definitions. A task $\text{TK}\langle f, S, o \rangle$ is a three-tuple of its processing function f , sequence of input streams S , and its output stream o . Tasks process messages which are tuples of an epoch number e and the message data d_C . There are two kinds of messages: normal events $\text{EV}\langle w \rangle$ and epoch borders BD . The epoch border messages are markers used for the snapshotting algorithm, whereas the events are the actual data processed by the tasks. When processing, the tasks manipulate state which consists of a persistent *snapshot archive* a , *i.e.*, a map from epoch numbers to the corresponding local snapshots, and some *volatile state* σ_V . The snapshot archive is a map from epoch numbers e to the state v of the processor at the end of the epoch. The volatile state is either a *failed state* $f1$ or a *normal state* $\langle e, v \rangle$, consisting of the current epoch number and the state data value v of the processor. As with the messages, normal states are tagged by epoch numbers. A processor is in a failed state if it has crashed and lost its volatile state. The auxiliary data D used for this model consists of the initial input messages for the system. As we may need to restore the messages which are yet to be consumed, we keep track of all the initial input messages as the global auxiliary data of the system.

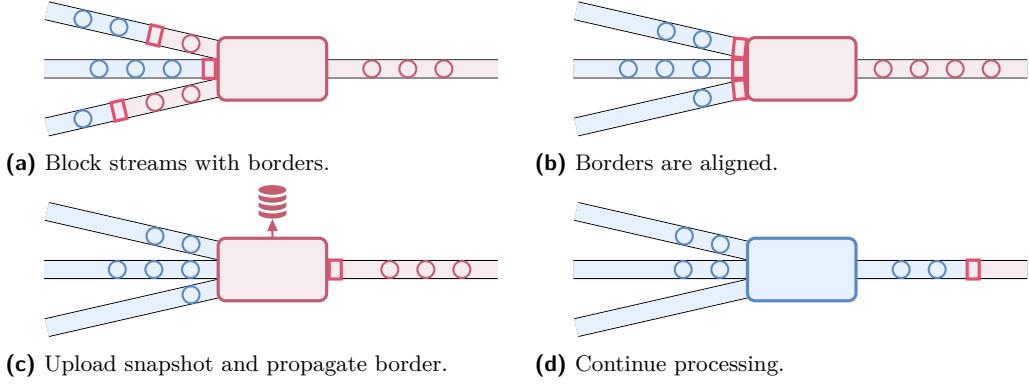

Figure 8 Epoch border alignment protocol (figure adapted from [10]).

4.2.1 Derivation Rules

The semantics of the model consists of seven rules. Three of the rules, I-EVENT, I-BORDER, and F-FAIL, are local rules which enable deriving a local step of the form $\pi \Vdash \sigma \xrightarrow{X} \sigma'$. Whereas the I-EVENT and I-BORDER rules model the processing of the system, the F-FAIL rule models nondeterministic crash-failures of a processing task within the system. These rules, together with the streaming rule S-STEP and its abstraction rules S-ABSX and S-ABSP, are used for deriving global steps. The fourth rule, F-RECOVER, is a global rule used for recovering the state of all processors after a failure.

Event Rule. The first rule, I-EVENT, models tasks processing events:

$$\frac{}{\text{TK}\langle f, S, o \rangle \Vdash \langle a, \langle e, v \rangle \rangle \xrightarrow{[-S_j \langle e, \text{EV}(w) \rangle] : [+o \langle e, \text{EV}(W'_i) \rangle]} \langle a, \langle e, v' \rangle \rangle} \text{I-EVENT}$$

The rule can perform a local step for a task $\text{TK}\langle f, [S_i]_i^{|S|}, o \rangle$, if the current state of the task is a normal state $\langle e, v \rangle$, and the task can consume an event $\text{EV}(w)$ from one of its inputs S_j . Applying a task's function f to its current state v and the consumed event w results in the task's next state v' and a sequence of output events $[W'_i]_i^n$. The rule updates the state of the task to the new state $\langle e, v' \rangle$ and produces the output events $[\text{EV}(W'_i)]_i^n$ on the output stream o . The local step produces the actions which are the concatenation of the consumed and produced events. For example, $[-S_j \langle e, \text{EV}(w) \rangle] : [+o \langle e, \text{EV}(w') \rangle]$ is the action of consuming the event $\text{EV}(w)$ with epoch number e from the input stream S_j and producing the event $\text{EV}(w')$ with epoch number e on the output stream o .

Border Rule. Whereas the event rule consumes a single event from a stream, the border rule (I-BORDER) consumes one border event BD from *every incoming stream*:

$$\frac{}{\text{TK}\langle f, [S_i]_i^n, o \rangle \Vdash \langle a, \langle e, v \rangle \rangle \xrightarrow{[-S_i \langle e, \text{BD} \rangle]_i^n : [+o \langle e, \text{BD} \rangle]} \langle a[e \mapsto v], \langle e + 1, v \rangle \rangle} \text{I-BORDER}$$

This consumption is enabled for a task if the next event to be consumed on every one of its incoming streams is a border event. In other words, the event rule consumes events up until all streams are aligned by the border events, at which point the border rule consumes

the border events from all its incoming streams. The rule is a local step which, in addition to consuming border events from all incoming streams and producing a border event on its outgoing stream, stores the current state v for epoch e to the snapshot storage a (by setting the new snapshot archive to $a[e \mapsto v]$), as well as incrementing the current epoch number.

Epochs are a key concept of Asynchronous Barrier Snapshotting. Each epoch is a sequence of data-bearing *events*, ending with an *epoch border*, and are used to define the boundaries of state snapshots. After regular processing for which some streams are blocked by border events (Figure 8a), the rule aligns the streams by the borders (Figure 8b), takes a copy of the current state of the processor storing it to the snapshot archive (Figure 8c), and propagates the epoch border message downstream and increments the epoch number, ready to process events from the next epoch (Figure 8d). The effect of this is that epochs of events are separated by the border events throughout the whole processing graph.

Failure Rule. Failures are introduced nondeterministically by the F-FAIL rule:

$$\frac{}{\text{TK} \langle f, S, o \rangle \Vdash \langle a, \sigma_V \rangle \rightarrow \langle a, \mathbf{f1} \rangle} \text{F-FAIL}$$

The failure rule sets the task's state to failed $\langle a, \mathbf{f1} \rangle$, thus losing the task's volatile state. Once a task is failed, it is no longer able to apply the steps I-EVENT and I-BORDER, and will remain idle until the F-RECOVER rule has been applied.

Failure Recovery Rule. The last rule, F-RECOVER, is a global rule which recovers the state of all failed tasks:

$$\frac{\langle a, \mathbf{f1} \rangle \in \Sigma}{\langle \Pi, \Sigma, N, M, M_0 \rangle \Rightarrow \text{lcs}(\langle \Pi, \Sigma, N, M, M_0 \rangle)} \text{F-RECOVER}$$

The rule may be triggered nondeterministically if there exists a task in a failed state, and will reset the state of the system to the latest common snapshot. The full details of how the latest common snapshot (lcs) is computed is discussed further below, as it depends on additional definitions.

The latest common snapshot is constructed by: (1) calculating the greatest common epoch for which a snapshot has been taken by all processors in the system; (2) restoring the state of all processors to their local snapshots at the greatest common epoch; and (3) restoring sequence numbers and messages to undo any messages that were produced or consumed for epochs greater than the greatest common epoch. The greatest common epoch is calculated by finding the minimum (*common*) of the maximum (*greatest*) epoch numbers of the local snapshots of all the processors.

► **Definition 4.2** (Greatest Common Epoch Number). *The greatest common epoch number of a configuration $c = \langle \Pi, \Sigma, N, M, D \rangle$ is:*

$$\text{gce}(c) = \min \{ \max(\text{dom}(a)) \mid \Sigma_p = \langle a, \sigma_V \rangle \}$$

The persistent *output messages* of the system consist of all messages produced up to and including the greatest common epoch. These messages can be identified by comparing their epoch number e to the greatest common epoch number $e \leq \text{gce}(c)$. The recovery purges any messages which are not part of this set, bar the initial input messages M_0 , thereby making these output messages (identified by out) persistent.

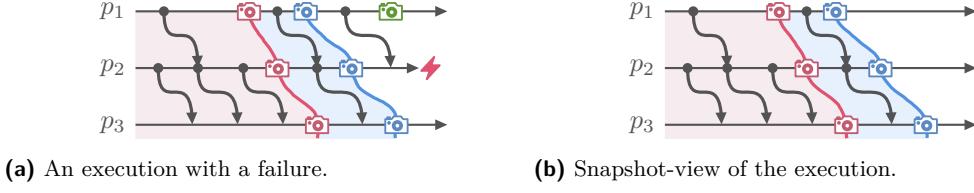

Figure 9 Executions viewed through the latest common snapshot.

► **Definition 4.3 (Output Messages).** For a configuration $c = \langle \Pi, \Sigma, N, M, D \rangle$, its output messages are:

$$\text{out}(c) = \{ns \langle e, d \rangle \mid (ns \langle e, d \rangle) \in M \wedge e \leq \text{gce}(c)\}$$

► **Definition 4.4 (Messages on a Stream).** The subset $M \downarrow s$ of messages on a particular stream is defined as:

$$M \downarrow s = \{n' s' d' \mid (n' s' d') \in M \wedge s' = s\}$$

The lcs function computes the latest common snapshot of a configuration for use as a recovery point in the F-RECOVER rule. Its computation makes use of the greatest common epoch number (gce), and the output messages (out). The states Σ' are restored by removing any stored snapshots with an epoch number larger than the gce, and the volatile states are restored to the states captured by the snapshot of the gce. The messages are updated to only keep the stable output messages $\text{out}(c)$ and the messages which are yet to be consumed M_{in} . The sequence numbers N' are updated accordingly, setting the sequence number of a processor p for a stream s to the number of messages that the processor has either produced or consumed on the stream: $|\text{out}(c) \downarrow s|$. Its complete definition is given below.

► **Definition 4.5 (Latest Common Snapshot).** The latest common snapshot of a configuration $c = \langle \Pi, \Sigma, N, M, M_0 \rangle$ is a configuration described by $\text{lcs}(c)$:

$$\text{lcs}(c) = \langle \Pi, \Sigma', N', M_0 \cup \text{out}(c), M_0 \rangle, \text{ where}$$

$$\begin{aligned} \Sigma' &= [p \mapsto \langle A(a), \langle \text{gce}(c) + 1, a(\text{gce}(c)) \rangle \rangle \mid \Sigma_p = \langle a, \sigma_V \rangle] \\ A(a) &= [e \mapsto a(e) \mid e \in \text{dom}(a) \wedge e \leq \text{gce}(c)] \\ N' &= [p \mapsto [s \mapsto |\text{out}(c) \downarrow s| \mid s \in \text{dom}(N_p)] \mid p \in \text{dom}(N)] \end{aligned}$$

Viewing computations through the lens of the latest common snapshot shows configurations which are caused by failure-free executions. Figure 9a shows an execution with a failed processor p_2 and an incompletely processed epoch (green). In contrast, the latest common snapshot view of the same execution (Figure 9b) shows only the two completed epochs (red, blue), masking the failed epoch. The snapshot is emulating an execution such that all the steps on epochs after the greatest common epoch are not taken, and all failed steps of incompletely processed epochs are ignored. This reasoning is further elaborated for the proof of failure transparency in the next section, where we show that the implementation model is failure transparent when viewed through the lens of the output messages function.

4.3 Assumptions

We make the following assumptions as a means to distill the essential mechanism of the failure recovery protocol. We assume that the message channels are FIFO ordered, a common assumption for snapshotting protocols [14]. With regard to failures, we make common

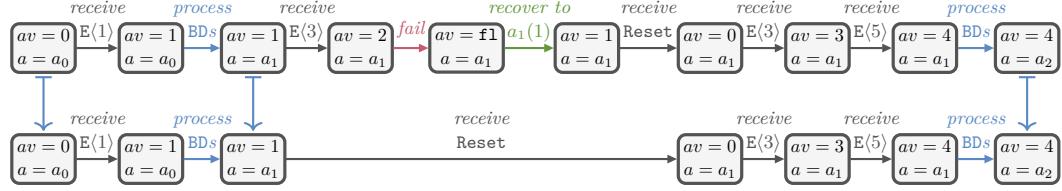

Figure 10 Execution of the incremental average task (Figure 2). Top: execution with a failure and subsequent recovery. Bottom: corresponding failure-free execution. Snapshot archives: $a_0 = [0 \mapsto 0]$, $a_1 = a_0[1 \mapsto 1]$, $a_2 = a_1[2 \mapsto 4]$.

assumptions to asynchronous distributed systems [9]. Failures are assumed to be crash-recovery failures, in which a node loses its volatile state from crashing. Further, we assume the existence of an eventually perfect failure detector, which is used for (eventually) triggering the recovery. With regard to system components, we assume the following components which can be found in production dataflow systems. The implicit coordinator instance is assumed to be failure free; in practice it is implemented using a distributed consensus protocol such as Paxos [37]. The snapshot storage is assumed to be persistent and durable; a system such as HDFS [57] would provide this. Further, the input to the dataflow graph is assumed to be logged such that it can be replayed upon failure. In practice, a durable log system such as Kafka [32] would be used for this. For our model, we make the following assumptions. The recovery is assumed to be an atomic, synchronous system-wide step. In practice, it may be implemented as an asynchronous atomic step, which allows tasks to start processing before all have been recovered. Further, the task's processing functions are assumed to be pure, *i.e.*, free from side effects. A function f may be re-executed multiple times due to failures; a common assumption in related work [8, 30].

5 Failure Transparency

In this section, we define failure transparency such that it can be applied to systems described in small-step operational semantics with distinct failure-related rules. We first provide a rationale behind failure transparency, followed by its formalization.

5.1 Rationale

The purpose of failure transparency is to provide an abstraction of a system which hides the internals of failures and failure recovery. In particular, we would like to be able to show that the implementation model presented in the previous section is failure transparent. In concrete terms, this entails showing that executions in the implementation model can be “explained” by failure-free executions, something which we explore in this section.

Consider the task of computing the incremental average from the previous example (Section 3, Figure 2). The task consumes regular events $E\langle i \rangle$, reset events, and border events BD. For this example, we consider a partial execution of the task in which it processes the events: $[E\langle 1 \rangle, BD, E\langle 3 \rangle, \text{fail}, \text{recover}, \text{Reset}, E\langle 3 \rangle, E\langle 5 \rangle, BD, \dots]$. The task's configurations consist of the task's current average value av , and its snapshot archive, a . Figure 10 shows at the top an execution of the task with a failure and subsequent failure recovery as the fourth and fifth events. After the recovery step, in its sixth configuration, the task's state is reset to its state for the snapshot $a_1(1)$, at which point it had the average value 1.

The question we ask is whether we can rely on the behavior of the task? More specifically, can we use the average value $av = 2$ in the fourth configuration (after receiving the event $E(3)$)? The problem is that the task will fail in its next step, and recover to a state in which the receiving of the event has been undone. Moreover, the task continues its execution after recovery by processing the reset event first, and does never reach a state again in which its average value is 2. For this reason, we cannot blindly rely on the observed behaviors of the task as we may observe things which are later undone. In more complex systems, failures may further result in duplications and reorderings of events, further complicating the reasoning about the system.

Dealing with these issues requires the observer of the system to reason about which events are effectful and which are to be discarded. In some sense, the observer should be able to reason about the observed execution as if it was an ideal, failure-free execution, *i.e.*, an execution in which all events are effectful. Put in another way, the solution is to find a corresponding failure-free execution, and reason about that one instead. Intuitively, the observer should find some failure-free execution which “explains” the execution. Considering the above example, a failure-free execution thereof would correspond to the bottom execution in Figure 10. Note that there are no failure or recovery steps in the failure-free execution, yet its state progresses in a similar way to the original execution.

Even though the failure-free execution on an intuitive level correspond to the original execution, we would like to have a formal notion for this. The idea is to lift the observed executions by means of “observability functions”, to a level where failure-related events and states are hidden. For example, for the executions above, we could define an observability function which takes the configuration of the task and keeps only the snapshot storage. After this transformation, applying this function to every configuration in the executions, we will not be able to distinguish the two executions by observing the system at any point in time. That is, common to both executions, we will first observe a_0 , then a_1 , and finally a_2 . On a technical level, for every configuration of the original execution, we can find a configuration in the failure-free execution which, after application of the observability functions, is equal to it (*e.g.*, the mapping from top to bottom configurations in Figure 10); this is what we mean by “observable explainability”. Thus, we can explain the original execution by the failure-free execution using the provided observability function.

The essence of our definition of failure transparency is derived from the notion of explaining the original executions by failure-free executions using observability functions. Instead of reasoning about executions, we can reason about the observable output of executions at any given moment. Using observability functions effectively hides the internals of the model and enables the user to focus on the output of the system. That is, the user can reason about failure-free executions instead of faulty executions.

This informal introduction highlights three essential parts of failure transparency: the execution system, failures within the system, and the observability of the system. The goal of the rest of this section is to define these terms and to provide a formal definition of *failure transparency*.

5.2 Executions

The execution system for the failure transparency analysis is modelled as a transition system for which the transition relation is provided as a set of inference rules. In particular, we provide a formal definition for executions as a means to discuss the execution of systems. With this notion, distributed programs can be formally modelled in small-step operational

semantics, and consequently formally verified. Although it may seem unintuitive to model distributed systems as transition systems for which the transition relation is defined over the global state, this is in fact commonly done in other formal frameworks such as TLA⁺ [38].

► **Definition 5.1** (Execution Step). *A statement $c \Rightarrow c'$ is called an execution step from c to c' . We denote the derivability of an execution step in the set of rules R by $R \vdash c \Rightarrow c'$.*

We reason about systems in terms of their executions. An execution is a sequence of configurations C , connected by execution steps derivable in a set of rules R , starting from some initial configuration C_0 .

► **Definition 5.2** (Executions). *A sequence of configurations $[C_i]_i^n$ is called an execution in a set of rules R , if $\forall i < n. R \vdash C_{i-1} \Rightarrow C_i$. The set of all possible executions starting from C_0 in R is denoted as $\mathbb{E}_{C_0}^R$.*

The set of rules R of an execution specifies its reducibility relation by providing $c \Rightarrow c'$ as a conclusion of some of its rules. This approach is commonly known as *small-step operational semantics*. In our representation, the set of rules is explicit, whereas commonly it is implicit. This is due to our need to explicitly distinguish between separate execution systems. This allows us, for example, to separate an execution system into two parts: one with failures R s.t. the failure-related rules are a subset thereof $F \subseteq R$, and one without failures $(R \setminus F)$.

5.3 Observational Explainability

The observability function represents the observer's view of the system. It notably differs from the plain configurations in the following two ways: the observer may not observe all internal details of configurations, *i.e.*, some parts of the configuration are *hidden* from the observer (*e.g.*, hiding commit messages [8]); and the observer may observe some derived views of the configuration.

► **Definition 5.3** (Observability Function). *An observability function O of an execution system is a function which maps configurations to their observable outputs. It is required to be monotonic with respect to execution steps possible in the set of rules R for some partial order \sqsubseteq_O , that is: $\forall c, c'. (R \vdash c \Rightarrow c') \implies O(c) \sqsubseteq_O O(c')$.*

We say that an implementation's execution is observably explained by a specification's execution, if the observer cannot distinguish the two executions. This is the case when, for every configuration in the implementation's execution, there is a corresponding configuration in the specification's execution, such that their observed values are equal after application of the respective observability functions.

► **Definition 5.4** (Observational Explanation). *A sequence of configurations C of length n is explained by a sequence of configurations C' of length n' with respect to observability functions O and O' , denoted as $C \stackrel{O}{\rightleftharpoons} \stackrel{O'}{=} C'$, if:*

$$\forall m < n. \exists m' < n'. O(C_m) = O'(C'_{m'})$$

An implementation's system, in turn, is observably explainable by the specification's system, if for each execution of the implementation there exists an explaining execution in the specification. We call this property *observational explainability*.

► **Definition 5.5** (Observational Explainability). *The set of rules R is observationally explainable by R' with respect to their observability functions O and O' and the translation relation T , denoted as $R \stackrel{O \xrightarrow{T} O'}{\rightleftharpoons} R'$, if:*

$$\forall c' \in \text{dom}(T). \forall c. c' T c \implies \forall C \in \mathbb{E}_c^R. \exists C' \in \mathbb{E}_{c'}^{R'}. C \stackrel{O}{\rightleftharpoons} \stackrel{O'}{=} C'$$

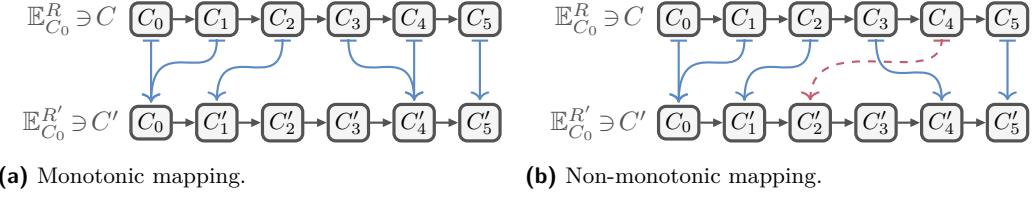

Figure 11 Monotonic and non-monotonic mapping of configurations.

Properties of Observational Explainability. Observability functions are required to be monotonic, since observations should be regarded as stable. That is, once a value has been observed, then it should remain observable in the future. The system should not be able to undo something that has been observed, otherwise the observer would not be able to rely on the output. The reason for this is twofold. First, an observer may observe the system multiple times, and newer observations should provide more up-to-date views. Second, the sequence of observations should correspond to a valid explanation with respect to the higher-level specification, this is explored next.

In the general case, it is desirable to have a monotonic mapping of configurations between the abstract-level and implementation-level executions. Figure 11a shows a monotonic mapping of configurations between an implementation (top) and a specification (bottom). What makes the mapping monotonic is that each subsequently mapped configuration of the implementation is mapped to a configuration with a monotonically growing index. Figure 11b, on the other hand, shows a non-monotonic mapping, as indicated by the red dashed line. Non-monotonic mappings, however, are not considered valid explanations. For example, if the specification consists of the sequence a followed by b , then an implementation which produces b followed by a is not considered a valid implementation thereof. Thus, we should not use non-monotonic mappings for the explainability of executions. We capture this notion in the definition of monotonic observational explanation.

► **Definition 5.6** (Monotonic Observational Explanation). *An observational explanation is monotonic if it is a monotonic mapping of configurations. That is, $[C_i]_i^n$ is monotonically explained by $[C'_j]_j^{n'}$ w.r.t. O and O' if:*

$$\exists [h_k]_k^n. (\forall k < n. \forall k' \leq k. h_{k'} \leq h_k) \wedge (\forall m < n. \exists m' = h_m < n'. O(C_m) = O'(C'_{m'}))$$

The following lemma explicitly shows that our definition of *observational explainability* is equivalent to the definition of *monotonic observational explainability*. That is, our definition does not have the problem with non-monotonic mappings of configurations since the observability functions are required to be monotonic. For this reason, we do not distinguish between the two definitions in the following sections.

► **Lemma 5.7.** *If R is observationally explainable by R' w.r.t. O , O' , T , then it is also monotonically observationally explainable:*

$$\forall c' \in \text{dom}(T). \forall c. c'Tc \implies \forall C \in \mathbb{E}_c^R. \exists C' \in \mathbb{E}_{c'}^{R'}.$$

C is monotonically explained by C' w.r.t. O and O'

Proof. The complete proof is available in the companion technical report [62]. ◀

To further aid the use of these definitions within proofs, we also show that the definition of observational explainability is transitive, as well as a compositionality lemma on the observability functions. The parametrization of the observable explainability enables reasoning

about models which differ in their initial states, and for which we want to apply different observability functions at the different levels. That is, it can be used for reasoning about sets of rules which differ in their initial states, and for which we want to apply different observability functions at the different levels.

► **Lemma 5.8** (Transitivity). $R \xrightarrow{O} R' \wedge R' \xrightarrow{O'} R'' \implies R \xrightarrow{O \circ O'} R''$

Proof. The complete proof is available in the companion technical report [62]. ◀

► **Lemma 5.9** (Composition). $\forall O''. R \xrightarrow{O} R' \implies R \xrightarrow{O'' \circ O} R'$

Proof. The complete proof is available in the companion technical report [62]. ◀

5.4 Defining Failure Transparency

The general goal of failure transparency is to provide an abstraction of a system which masks failures from the users. We express this notion using observational explainability between the implementation and its failure-free part. That is, the implementation should be observationally explainable by the implementation without failures. By explicitly separating the set of failure-related rules F , it is easy to define the two systems: namely, the implementation system with all rules, *i.e.*, R ; and another system with all rules except the failure-related rules, *i.e.*, $R \setminus F$. To fully instantiate the observational equivalence, we further use the same observability function O on both the low and high levels, and as a translation relation we use the identity relation on the set of initial configurations.

► **Definition 5.10** (Failure Transparency). *A set of rules R is failure-transparent with respect to failure rules $F \subseteq R$ for a monotonic observability function O and a set of initial configurations K , this is denoted as $R \mathbin{\Downarrow}_K^O F$, iff:*

$$R \xrightarrow{O \mathbin{\Downarrow}_{\{(c, c) \mid c \in K\}}^O} O(R \setminus F)$$

6 Failure Transparency of Stateful Dataflow

In this section, we show that the presented implementation model (Section 4) is failure transparent (Definition 5.10) for the observability function out (Definition 4.3). In order to prove this, instead of reasoning about executions directly, we reason about the traces of steps which are performed to obtain these executions. This simplifies the proof, enabling us to reorder and remove specific steps in and from a trace; in contrast, doing the same with a configuration from an execution affects all following configurations. In this section, we first define traces and a causal order relation on traces, and then prove the failure transparency of the implementation model by manipulating traces. Finally, we complete our analysis of the model by formulating and proving its liveness, showing that the implementation model eventually produces outputs for all epochs in its input.

6.1 Traces and Causality

A trace is a sequence of steps, for which each step is a compact representation of the derivation of a transition from one configuration to another.

► **Definition 6.1** (Trace). *A trace Z is a sequence of trace steps. A trace step z is one of: $\langle \text{I-EVENT}, p, N_p, X \rangle$; $\langle \text{I-BORDER}, p, N_p, X \rangle$; $\langle \text{F-FAIL}, p \rangle$; $\langle \text{F-RECOVER} \rangle$. Here I-EVENT, I-BORDER, F-FAIL, and F-RECOVER play the role of the discriminant, where the trace step is a tagged union.*

For example, if in the derivation tree of an execution step from the i th to the $i + 1$ th configuration, i.e., of $R \vdash C_i \Rightarrow C_{i+1}$, F-RECOVER was the root rule, then this execution step corresponds to the step $\langle \text{F-RECOVER} \rangle$ in the trace. To link traces with executions, we use the following definition of trace application.

► **Definition 6.2** (Trace Application). *A trace Z of length n applied to a configuration c results in a sequence of configurations C of length $n + 1$, i.e., $Z(c) = C$, if, for all steps Z_i , the represented derivation of an execution step can be applied to the i th configuration producing the $i + 1$ th configuration.*

Traces can be generated from executions; however, not every trace corresponds to an execution. This may be the case if a trace has been constructed incorrectly, or reordered in some way. For this reason, we define valid traces, which are traces that correspond to executions.

► **Definition 6.3** (Valid Trace). *A trace Z is valid from configuration c if it is applicable to it, i.e., if there exists an execution $C \in \mathbb{E}_c^I$ such that $Z(c) = C$.*

As the proof reasons about the reordering of steps in a trace, it is important to formulate which reorderings of steps preserve the validity of the trace. To handle this, we define a causal order relation on trace steps similar to the happens-before relation [35], and show how it can be used to reason about traces.

► **Definition 6.4** (Causal Order). *(See technical report [62] for the formal definition) A step Z_i happens before Z_j with $i < j$ if:*

1. *One of them is an F-RECOVER step (global recovery)*
2. *They both occur on the same processor (intraprocessor order)*
3. *If Z_i produced a message which is consumed by Z_j (interprocessor order)*
4. *If there exists some step Z_k such that Z_i happens before Z_k and Z_k happens before Z_j (transitivity)*

Finally, we state a lemma that causality-preserving permutations, i.e., permutations that preserve the causal order relation [62, Definition B.5], also preserve the validity and the end result of their application. Intuitively, it follows from the fact that causally unrelated steps should not influence each other.

► **Lemma 6.5** (Application of Causality-Preserving Permutations). *For a trace Z valid from c with size $|Z| = n$, if Z' is a causality-preserving permutation of Z , then: Z' is valid from c ; Z and Z' end in the same configuration after application to c , i.e., $Z(c)_n = Z'(c)_n$.*

Proof. The complete proof is available in the companion technical report [62]. ◀

6.2 Proving Failure Transparency

As it is required by the definition of failure transparency, we first define the sets of rules, namely I, F, and $(I \setminus F)$; and the set of valid initial configurations K .

The semantics of the model consist of seven rules, defining two separate sets of rules. The set of rules with failures I consists of all seven rules that have been defined for the stateful dataflow implementation model; it corresponds to the implementation model presented in

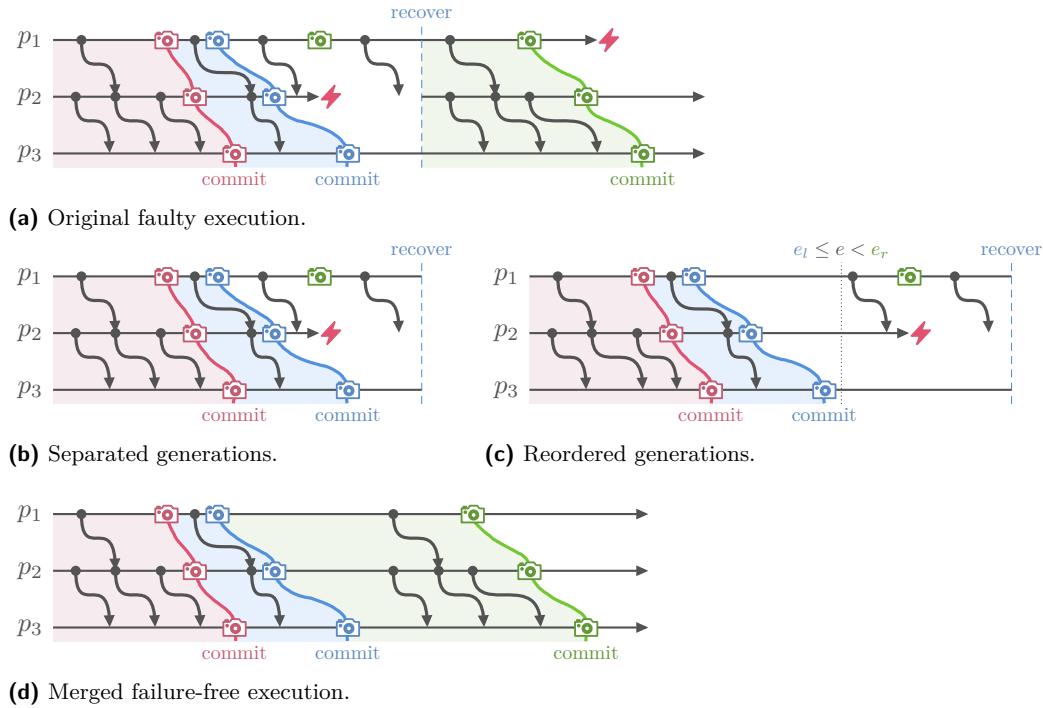

Figure 12 The step-wise construction of a failure-free execution trace from an execution with failures.

Section 4. The set of failure-related rules F within the implementation model consists of the two rules F-FAIL and F-RECOVER. This way, the rules without failures are defined as the set $(I \setminus F)$.

► **Definition 6.6** (Implementation Model Rules). $I = \{S\text{-STEP}, S\text{-ABSX}, S\text{-ABSP}, I\text{-EVENT}, I\text{-BORDER}\} \cup F$

► **Definition 6.7** (Failure-Related Rules). $F = \{F\text{-FAIL}, F\text{-RECOVER}\}$

The sets of initial configurations which are considered are any acyclic graph structures which are properly initialized.

► **Definition 6.8** (Valid Initial Configurations). $K = \langle \Pi, \Sigma, N, M, M_0 \rangle$ such that: the graph defined by Π is acyclic, and the tasks' functions f do not output infinite sequences; Σ are the initial well-formed states; N are sequence numbers initialized to 0 for the streams; M consists of the well-formed inputs to the streams; $M_0 = M$.

► **Theorem 6.9** (Failure Transparency of the Implementation Model). $I \setminus K^{\text{out}} F$, i.e., the set of rules $I = \{S\text{-STEP}, S\text{-ABSX}, S\text{-ABSP}, I\text{-EVENT}, I\text{-BORDER}\} \cup F$ is failure transparent with respect to the failure rules $F = \{F\text{-FAIL}, F\text{-RECOVER}\}$ for the observability function out and the set of initial configurations K .

Before proceeding with the proof itself, we provide a sketch of it. The proof idea is to construct a failure-free observational explanation of an arbitrary execution in the implementation model.

The construction is done using traces; we reorder and manipulate the original trace so that failures, recoveries, and discarded trace steps are removed from it. Figure 12 illustrates the construction: (1) first, we split the trace by the recovery steps into generations; (2)

next, the trace steps are reordered such that all discarded steps are moved to the end of the generation; (3) then, these steps are safely discarded; (4) finally, we concatenate the generations to get the final trace.

Next, we have to show that: (i) the constructed trace is valid, *i.e.*, it corresponds to a failure-free execution; and (ii) that the execution is an observational explanation of the original execution. We do so by reasoning about the preservation of validity and observable outputs in each step of the construction. For trace validity, the most complicated step is the reordering (step 2 of the construction). We show that the reordering is causality-preserving and thus, by Lemma 6.5, it produces a valid trace. For observational explanation, throughout the construction we maintain a mapping of observations from the steps of the original trace to the steps of the constructed trace. The challenge lies in the reordering of steps (step 2 of the construction) and the fusion of generations (step 4 of the construction). For the reordering, we show a lemma that the observable output is not changed by the discarded steps; and, for the fusion, we show that the latest common snapshot of a generation is exactly the configuration obtained by the reordering and removal of the discarded steps. This, accompanied by an analysis of the rules, lets us show that the sequence of observable outputs is the same for the original and the failure-free traces.

Proof. Expanding the definitions, we need to prove that, for all executions in \mathcal{I} with potential failures, there is an observational explanation in the failure-free model $(\mathcal{I} \setminus \mathcal{F})$. Given an arbitrary execution C of length n in \mathcal{I} from initial configuration $c \in K$, *i.e.*, $[C_i]_i^n \in \mathbb{E}_c^{\mathcal{I}}$, the goal is to construct a failure-free execution $[C'_j]_j^{n'}$ such that:

$$[C'_j]_j^{n'} \in \mathbb{E}_c^{\mathcal{I} \setminus \mathcal{F}} \wedge \forall m < n. \exists m' < n'. \text{out}(C_m) = \text{out}(C'_{m'})$$

This execution is constructed indirectly, by first constructing a trace Z' which then generates it. First, we need to prove that the constructed failure-free trace Z' is valid from c , *i.e.*, $Z(c)$; next, we need to show that the corresponding execution $C' = Z'(c)$ is an observational explanation of the original execution, that is, for each configuration in the original execution, we have to provide an observationally equal configuration in the constructed execution. From the original trace Z , for which $Z(c) = C$, we construct the failure-free trace Z' in four steps as outlined in the proof sketch and illustrated in Figure 12.

(1) First, the trace is split by the recovery steps into generations, giving us a sequence of generations G (Figure 12b). Each generation is a sequence of S-STEPs ending with an F-RECOVER step; in the case of the last generation it may not necessarily end with an F-RECOVER step. By construction, each generation is a valid trace as each of them is a contiguous part of a valid trace. We construct the observability mapping by mapping the configurations of the original trace to their closest preceding committing border steps. A *committing border step* is an I-BORDER step which changes the greatest common epoch number, gce, and thus also the observed output, out; such steps are labeled with “commit” in Figure 12. The equality of observations holds, since, by inspection of the rules, only a committing border step can change the observable output [62, Lemma B.6].

(2) Next, from each generation $g = G_i$, we construct a new reordered trace $g' = G'_i$ so that all the steps of epochs above the greatest common epoch of the generation are placed after the steps of epochs below it (Figure 12c). In effect, this moves all the discarded steps to the end of the generation, since they are discarded by the recovery, which in turn is done to the greatest common epoch of the generation. In other words, $g' = \text{filter}(x \in g. \text{epoch}(x) \leq e) : \text{filter}(x \in g. \text{epoch}(x) > e)$, where $e = \text{gce}(g|_{|g|-1})$ is the epoch number to which the recovery is done. The new traces are still valid, as the reordering is causality preserving [62,

Lemma B.7], and thus the validity follows from Lemma 6.5. The mapping of observations is kept intact, since the outputs of the committing border steps are not changed by the reordering [62, Lemma B.8]. This follows from the fact that the observable output is only changed by committing border steps [62, Lemma B.6], that causality-preserving permutations result in the same configuration (Lemma 6.5), and that the reordering is preserving causality.

(3) Then, from each G'_i we construct a new trace G''_i by removing the discarded steps and the recovery step. That is, the suffix consisting of the failure steps, recovery steps, and any steps of epochs greater than the greatest common epoch of the generation are removed. The new trace is a prefix of G'_i , and is thus still a valid trace [62, Lemma B.2]. We keep the same mapping of observations for the steps that were not removed. As, within a generation, only the suffix is removed, it does not affect the observed outputs of the remaining steps, and thus the mapping of observations is kept unchanged.

(4) Finally, we concatenate all stripped generations G''_i to get the merged trace Z' (Figure 12d). We show that the last configuration of each of the generations G''_i is exactly the latest common snapshot of the original generation G_i [62, Lemmas B.10-11], in other words, the latest common snapshot is a view of a configuration as if only the committed steps occurred. Since the recovery is done to the latest common snapshot, it is also the same configuration as the first configuration of the following generation G''_{i+1} . For this reason, the concatenation of all generations forms a trace Z' valid from c . The observed outputs are not changed by the merge, and we maintain the same mapping.

By these four steps we have constructed a failure-free observational explanation of the faulty execution, which means that the implementation model is observationally explainable (Definition 5.5) by its failure-free version, or, in other words, it is failure transparent (Definition 5.10). \blacktriangleleft

6.3 Liveness

The proposed definition of failure transparency is a safety property [3, 34], *i.e.*, it prohibits the implementation from reaching invalid states. Being as such, failure transparency does not require the implementation to take any observable execution steps; an implementation that never takes a step would trivially satisfy the property. In contrast, ensuring that the implementation eventually does something is a *liveness* property [3, 34]. To complete our analysis, we would like to show that the implementation model eventually produces outputs for all epochs in its input. This is a liveness property which, consequently, does not concern itself with the correctness of the outputs. However, in combination with the failure transparency property, the properties ensure that the presented implementation model *eventually* produces the *correct* outputs. For this reason, we prove the following theorem about the liveness of the implementation model.

► **Theorem 6.10** (Liveness of the Implementation Model). *For every input epoch present in the initial configuration, eventually a corresponding epoch appears in the output of a fair execution. That is:*

$$\begin{aligned} \forall k = \langle \Pi, \Sigma, M, N, D \rangle \in K. \forall C \in \mathbb{E}_k^I. \text{fair}(C) \implies \\ \forall (n s \langle e, d \rangle) \in M. \exists c \in C. \exists (n' s' \langle e', d' \rangle) \in \text{out}(c). e = e' \end{aligned}$$

where a fair execution is maximal (*i.e.*, it is not a prefix of another execution), has a finite amount of failures, and eventually executes any step which is eventually always enabled (see the technical report [62] for the formal definition of fair execution). \square

The liveness theorem states that for any fair execution C starting from a valid initial configuration k , and for all input epochs e , eventually there is a configuration c in the execution for which the output $\text{out}(c)$ contains the epoch e .

Proof. The complete proof is available in the companion technical report [62], it is summarized as follows. First, we show that it suffices to demonstrate that, continuing from any configuration c reachable from the valid initial configuration k , one or both of the following are true: eventually there is a failure; or eventually the epoch is visible in the output. As the considered executions have only finite amounts of failures, we further simplify the proof goal: it suffices to show that eventually the epoch appears in the output under the assumption that there are no more failures. We handle this simplified case by inductive reasoning on the acyclic dataflow graph of processors. The induction’s base case is the graph consisting of the source input streams but with no processors. The induction hypothesis states that all streams are well-formed and that the border message of all input epochs eventually appear on all streams; this is satisfied for the base case by validity of the initial configuration. Then, in the induction step, we construct the graph by adding one processor at a time, given that all of its input streams are already handled, as either source inputs or as outputs of other processors in the previous step’s graph. The assumption of fair scheduling allows us to reason about the processor locally, since, by definition of fairness, if a message has arrived to the processor, it will eventually be consumed. As a conclusion of the induction, each processor will eventually have processed a border of each epoch present in the initial configuration; thus, eventually all processors will process a border of each initial epoch. This, in turn, by analysis of I-BORDER , gce , and out , shows that the border messages of the epoch will eventually be in the output. ◀

7 Related Work

Failure Transparency, Observational Explainability. There has been a significant body of research on failure transparency [40]. To our knowledge, the earliest work on failure transparency was by von Neumann in 1956 [63] on creating reliable systems from unreliable components. Later work by Wensley in 1972 [65] discussed software techniques for failure transparent computing. Lowell and Chen discussed failure transparency in the context of consistent failure recovery protocols [44]. In their work, they introduced “equivalence functions” for comparing executions, a concept which inspired the observability functions in this paper. Our work, in contrast, restricts these functions to be monotonic, and discusses their application to both levels (low and high) of the system, which facilitates the presented transitivity lemma (Lemma 5.8). Around the same time as Lowell and Chen, Gärtner discussed general models for fault-tolerant computing [26]. Similar to our work, Gärtner separated fault-tolerant programs into two separate sets of rules (actions): the rules for normal behavior; and the rules for failure behavior. With this separation, Gärtner discussed various properties and forms of fault-tolerant programs. In the context of Gärtner’s work, our definition of failure transparency would be considered “failure masking”, in the sense that the system can recover from failures and continue its normal operation. Whereas these works defined failure transparency as a conjunct of *safety and liveness* [34, 3], we have only considered its safety property for our definition.

The presented definition for observational explainability is closely related to previous definitions of refinement (*e.g.*, TLA [38, 36], Compiler Correctness [53]), implementation (*e.g.*, I/O Automata [45]), and simulation. In simplified terms, one set of executions implements another if it is a subset thereof (modulo stuttering and multistep executions).

Our definition of observational explainability, in some sense, extends the notion of refinement to directly include a refinement mapping [1] on both sides via observability functions. It resembles notions from related work such as observational equivalence [8] and observational refinement [30]; in contrast to these works, we provide a formal definition thereof. Different from inductive proof approaches as typical for TLA [38] and simulation proof strategies, our proof approach reasons about the whole sequence. This makes it not necessary to include notions for ghost variables [49] (also known as auxiliary variables [39]) for the purpose of reasoning about past or future events.

Failure Transparency Proofs. Failure transparency and observational explainability can be proven in various ways. For example, Burckhardt et al. [8] prove “observational equivalence” for their serverless programming model. Mukherjee et al. [51] propose a failure transparency theorem for their system of reliable state machines: an execution of the implementation is a refinement of an execution without failures “with respect to its observable behavior”, reminiscent of our definition of failure transparency. Other works include models for distributed reliable actor communication [61], serverless microservices and observational refinement [30], and reliable state machines [51]. Their specific approaches may differ, some use simulation [8, 30], others model failures explicitly [30, 61, 51], and others use notions similar to observability functions [8]. Another approach is to prove the proper restoration of applications to the exact configuration as before the crash [50]. Our presented failure transparency proof shares similarities to the proof of the Asynchronous Barrier Snapshotting protocol [10], such as reasoning about causal orderings; however, our proof relies to a greater degree on abstraction in terms of refinement of models.

Distributed, Resilient Programming Models. Stateful dataflow has had a high impact [24] through systems such as: MapReduce [19], Apache Spark [67, 66], Apache Flink [12], Google Dataflow [2], IBM Streams [18], Portals [60], and others [7, 56]. However, there are other notable resilient programming models and systems, including: Pregel, a graph-based system [47], Resilient X10 [17], virtually resilient immortals [27], fault-tolerant reactives [50], thread-safe reactive programming [20], Durable Functions [8], stateful entities [54], the eXchange Calculus [6], and others [61, 30, 51, 15]. In general, these resilient programming models provide system means to recover from failures, the user does not need to implement the failure recovery mechanisms themselves. Actor models, in contrast, provide the users with manual failure-handling constructs. For example, the failure-handling constructs in Erlang, such as actor monitors and supervision [5], have been used successfully for building reliable services within the telecom industry [4]. Moreover, other programming models such as Argus [42] and transactors [22] provide constructs for transactions, which in turn can be used for building reliable services.

The formalization of distributed systems has been a long-standing research topic. Notably, formalization frameworks such as TLA [38] and I/O Automata [45], have been used to reason about distributed systems. Examples of this include a dataflow system that was formalized using I/O Automata [46]. The ABS protocol for stateful dataflow has been formalized with transition systems [10]. Recently, operational semantics have been used to model and reason about such systems [8, 61, 30, 51, 28].

Failure Recovery. A general overview of rollback-recovery protocols was given by Elnozahy et al. [21], comparing between checkpointing-based and logging-based protocols. Stateful dataflow systems use either checkpointing, or a combination of the two [7, 56, 2, 12, 64, 66,

19, 18]. The MapReduce system performs failure recovery by detecting failed nodes, and replaying the computation from sources or from persisted intermediate results [19]. Apache Spark, in contrast, improves the recovery by replaying from the sources through what is called lineage recovery [66]. A similar idea is used in a dynamic dataflow system within Ray [64]. This paper focused on the ABS protocol used in Apache Flink, which, in contrast to previous works, uses an asynchronous checkpointing technique [12]. It has been proven to provide high performance and has since been widely adopted [58]. The current version of Apache Flink’s runtime offers an opt-in feature for “unaligned checkpoints”, which allow the checkpoint markers to be treated at a higher priority, decreasing the end-to-end latency at the cost of some overhead as buffered events may become part of the snapshots [23]. Other adaptations of the Flink protocol include Clanos [59], which logs the nondeterminism to facilitate faster partial recovery after failures. Failure recovery remains an open research topic, as it has great impact on the performance characteristics of fault-tolerant systems [58].

8 Conclusions and Future Work

This paper studies failure transparency of stateful dataflow systems. We propose a novel definition of failure transparency for programming models expressed in small-step operational semantics. For the definition of failure transparency we introduce observational explainability, a notion which resembles refinement but on the level of observations of executions. We provide an implementation model of a stateful dataflow system using the Asynchronous Barrier Snapshotting protocol in a small-step operational semantics, and prove that the model is failure transparent and guarantees liveness.

In future work, we plan to implement a fully verified implementation of a stateful dataflow system based on the semantics presented in this paper, starting from our Coq mechanization. Furthermore, we would like to apply our definitions to existing related work.

Abstract

A growing trend in program analysis is to encode verification conditions within the language of the input program. This simplifies the design of analysis tools by utilizing off-the-shelf verifiers, but makes communication with the underlying solver more challenging. Essentially, the analysis tools operates at the level of input programs, whereas the solver operates at the level of problem encodings. To bridge this gap, the verifier must pass along proof-rules from the analysis tool to the solver. For example, an analysis tool for concurrent programs built on an inductive program verifier might need to declare Owicky-Gries style proof-rules for the underlying solver. Each such proof-rule further specifies how a program should be verified, meaning that the problem of passing proof-rules is a form of invariant synthesis.

Similarly, many program analysis tasks reduce to the synthesis of pure, loop-free Boolean functions (i.e., *predicates*), relative to a program. From this observation, we propose Inductive Predicate Synthesis Modulo Programs (IPS-MP) which extends high-level languages with minimal synthesis features to guide analysis. In IPS-MP, unknown predicates appear under assume and assert statements, acting as specifications modulo the program semantics. Existing synthesis solvers are inefficient at IPS-MP as they target more general problems. In this paper, we show that IPS-MP admits an *efficient* solution in the Boolean case, despite being generally undecidable. Moreover, we show that IPS-MP reduces to the satisfiability of constrained Horn clauses, which is less general than existing synthesis problems, yet expressive enough to encode verification tasks. We provide reductions from challenging verification tasks – such as parameterized model checking – to IPS-MP. We realize these reductions with an efficient IPS-MP-solver based on SEAHORN, and describe a real-world application to smart-contract verification.

1 Introduction

In recent years, many tools have emerged to verify C programs by leveraging the Clang/LLVM compiler infrastructure (e.g., [9, 60, 56, 54, 31]). These tools take as input C programs annotated with assumptions and assertions, and decide whether an assertion can be violated given that all assumptions are satisfied. One such tool is SEAHORN [31], which employs techniques from software model checking [42], abstract interpretation [32], and memory analysis [43] to enable efficient verification. Due to these features, many tool designers have started using annotated C code as an intermediate language to dispatch program analysis problems to SEAHORN (e.g., [55, 40, 4, 15, 18, 66]). In this setting, programs with specifications are transformed into C programs with assumptions and assertions, and then these C programs are analyzed using SEAHORN. The results obtained from SEAHORN are examined to draw conclusions about the input programs.

However, the flexibility afforded by C code as an intermediate language makes communication with the underlying verification algorithm more challenging. When SEAHORN is given a program to verify, it automatically applies various builtin proof-rules, such as induction for loops [3] and function summarization [42]. A tool designer has no control over how these rules are employed, nor is the developer able to introduce new proof-rules to SEAHORN. The goal of this paper is to extend SEAHORN with the language features required to communicate new declarative proof-rules to the underlying verification algorithm.

To illustrate this challenge, we consider SMARTACE [66], a tool that uses SEAHORN for modular Solidity smart-contract verification. In SMARTACE, each smart-contract is modeled by a non-terminating loop that executes a sequence of transactions¹. For SMARTACE to verify a smart-contract, it first requires an inductive invariant for the non-terminating loop, and a compositional invariant for each map² in the program. The discovery of an inductive invariant is automated by SEAHORN’s invariant inference capabilities. However, SEAHORN is unaware of the modular proof-rules used by SMARTACE, and therefore, the end-user must provide the compositional invariants manually. The authors of SMARTACE hypothesized [66] that if each proof-rule could be declared to SEAHORN, then SEAHORN could instruct the underlying verification algorithm to infer all invariants automatically. Inspired by this hypothesis, we first implemented compositional invariant synthesis in SEAHORN, and then discovered that our solution generalized to many program verification problems. Consequently, our solution forms a general-purpose framework well-suited to compositional invariant synthesis.

To illustrate this more general problem, consider a tool designer who wishes to use an off-the-shelf software verifier (e.g., SEAHORN) as the back-end to a new analysis framework (e.g., SMARTACE). Recall that many off-the-shelf verifiers rely on specialized solvers to discharge verification conditions, including solvers for Satisfiability Modulo Theories [12], Constrained Horn Clauses (CHCs) [37], or intermediate verification languages (e.g., [10, 26]). As depicted in Figure 1, an analysis framework built atop an off-the-shelf verifier takes as input a program with specifications, translates this program into the language of the verifier, and then uses the verifier to generate verification conditions for its specialized solver. Since

¹ Transactions in Solidity/Ethereum can be thought of as sequences of method invocations.

² In Solidity, maps are often used to store data for individual smart-contract users.

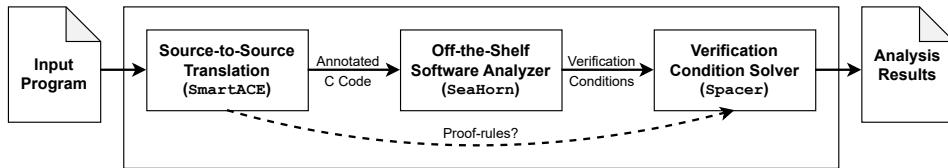

Figure 1 The architecture of an analysis framework built atop an off-the-shelf software verifier. Examples are given with respect to SMARTACE.

software verification is undecidable in general, it is often necessary for the tool designer to declare additional proof-rules for the solver. Example proof-rules include introducing predicate abstractions, suggesting modular abstractions for an array, and proposing modular decompositions for a parameterized system. However, it is challenging for the tool designer to communicate proof-rules to the solver – the former operates at the level of the input program, while the latter operates at the level of verification conditions. If a tool designer does attempt to encode proof-rules at the level of the input program, then these proof-rules are typically eliminated by optimizations from the verifier³, long before verification conditions are ever produced. That is, there is an impedance mismatch!

To bridge this gap, the verifier must pass proof-rules from the tool designer to the solver. Each proof-rule is associated with a set of invariants that the solver must find in order to prove the program correct. In other words, the invariants are declared by the proof-rules. Since these invariants span many classes (e.g., inductive, compositional, and object invariants), it is often the case that specialized invariant inference techniques cannot solve this problem. Instead, one must note that each proof-rule refines the invariants which the solver must synthesize. Consequently, one solution to the aforementioned impedance mismatch is to use synthesis techniques (e.g., [7, 25, 71, 59]). In particular, using synthesis allows the tool designer to declare proof-rules by specifying what invariants are to be synthesized at the level of the input program. This flexibility, however, comes at a price. General synthesis is significantly more expensive than verification [64]!

Our key contribution is a definition of *a new form of synthesis*, called *Inductive Predicate Synthesis Modulo Programs* (IPS-MP), that bridges the gap between flexible verification and efficient synthesis. Our *theoretical results* are two-fold, we show that: (a) IPS-MP reduces to satisfiability of CHCs, hence establishing that IPS-MP is a specialization of general synthesis [61, 63, 5, 41]; (b) for the special case of Boolean programs, IPS-MP is decidable with the same complexity as verification. We conjecture that the latter extends to other decidable models of programs (e.g., timed automata). Our *practical result* is to reduce a wide range of common proof-rules to IPS-MP. We show how IPS-MP guides inference of inductive invariants, class invariants, array invariants, and even modular parameterized model checking. In other words, IPS-MP is well-suited to many areas of program analysis. As a real-world application, we show that IPS-MP enables the full automation of SMARTACE.

Similar to existing synthesis frameworks, IPS-MP extends a programming language with unknowns. The language itself is unrestricted (i.e., it has loops, procedures, memory, etc.). However, the unknowns may only appear within `assume` and `assert` statements, denoting constraints on the strongest and weakest possible solutions, respectively. A solution to an IPS-MP problem is a mapping from each unknown to a Boolean predicate such that the resulting program is correct (i.e., satisfies all of its assertions). A high-level overview of

³ For example, a pure function with annotations may be optimized away by the Clang compiler.

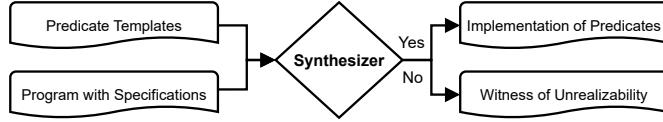

Figure 2 Overview of the IPS-MP problem.

IPS-MP is shown in Figure 2. Each problem instance consists of two components: (1) a program with its specification (described by assumptions and assertions), which contains calls to unknown predicates under assume and assert, and (2) the declarations of those predicates, which we refer to as *predicate templates*. Intuitively, a predicate template is a partial implementation with a number of unknown statements. A solution consists of a full implementation of each predicate, or a witness to unrealizability (i.e., a proof that a solution does not exist).

The reducibility of IPS-MP to CHC-solving motivates an efficient IPS-MP solver. We build on the SEAHORN framework (thus, our underlying language is the fragment of C supported by SEAHORN [31]), and integrate with two CHC solvers, namely SPACER [42], and ELDARICA [34]. Our empirical results on verification problems from various domains show that: (1) IPS-MP is effective at specifying verification strategies, (2) our implementation combined with existing CHC-solvers is highly efficient for linear arithmetic invariants, and (3) existing reductions to either general synthesis or specification inference are infeasible. Our evaluation focuses on general synthesis, rather than invariant inference, since the invariants in our benchmarks span many classes. To contextualize these results, we briefly review the state-of-the-art in synthesis.

State-of-the-art in synthesis. The general synthesis problem is the task of generating a program that satisfies a given specification. There are many general synthesis frameworks, e.g., Sketch [61], Rosette [63], SYGUS [5], and SEMGUS [41]. In Sketch and Rosette, users write programs with *holes*, representing unknowns. These holes are filled with predefined, loop-free expressions such that all program assertions are satisfied. SYGUS introduced a more language-agnostic approach to general synthesis. It generates loop-free *programs*, satisfying a given behavioral specification, from a potentially infinite language. Building on SYGUS, SEMGUS allows users to define pluggable semantics, thereby enabling synthesis of programs with loops. A distinguishing characteristic along this line of work is an emphasis on software development. In contrast, IPS-MP targets software verification and proof synthesis, which are theoretically simpler problems.

Specification synthesis (e.g., [21, 2, 53]) is another line of work that addresses a more specialized synthesis problem targeting program analysis, rather than software development. In specification synthesis, a program may call functions with unknown implementations. The goal is to synthesize specifications (e.g., the weakest specification for an unknown library procedure) that ensure the correctness of the calling program. Typically, a specification synthesizer imposes extra requirements, such as non-vacuity [53], maximality [2], or reachability [21], to ensure that solutions are reasonable. In contrast, the invariants synthesized by IPS-MP have constraints on both the strongest and weakest possible solutions, avoiding the need for additional (and often costly) requirements.

Of particular interest are the similarities and differences between IPS-MP and syntax-guided synthesis. In IPS-MP, program holes are filled by expressions from an unbounded language. To make this problem tractable, IPS-MP restricts Sketch and Rosette by requiring that holes only appear in partial predicates. Formally, this means that IPS-MP solving is

subsumed by non-linear constrained Horn clause solving. This restriction is crucial as it allows an IPS-MP solver to prove that a problem is unrealizable, unlike in Sketch or Rosette. Furthermore, IPS-MP differs from SYGUS and SEMGUS in that the behavioral specification is given with respect to a given program (in other words, modulo a given program), rather than through a separate logical specification. The program itself also places requirements on the holes, through assumptions and assertions, which is in contrast to specification synthesis.

In recent years, new extensions have been proposed to the Sketch framework. However, these extensions all generalize Sketch to more complex, and consequently less tractable, problems, whereas IPS-MP restricts Sketch to a more tractable problem which proves to be useful in the domain of program verification. To illustrate these gaps, we compare IPS-MP to PSKETCH [62], Synapse [16], Grisette [46], and MetaLift [13]. In the case of PSKETCH, both frameworks target the development of provably correct concurrent programs. However, PSKETCH focuses on inductive program verification in the presence of interleaving executions, whereas IPS-MP focuses on the verification of sequential code fragments via user-defined proof rules (e.g., the synthesis of compositional invariants in SMARTACE). In the case of Synapse, both tools aim to extend program synthesis problems with hints provided by an end-user. However, the nature of these hints is very different. In IPS-MP, the user introduces entirely new proof-rules, for which an underlying solver oversees the search for a solution. In contrast, the hints provided by an end-user to Synapse assign costs to solutions, for which the underlying solver tries to optimize. These hints do not allow the end-user to propose new proof-rules, and are suited to synthesis optimization rather than program verification. In the case of Grisette, a framework was proposed to programmatically generate and solve sketches. However, Grisette is based around bounded model-checking, whereas the IPS-MP problem targets unbounded model-checking and is, therefore, incomparable. More closely related is MetaLift, which makes use of the fact that inductive program verification can be reduced to syntax-guided synthesis. However, this verification program is not exposed to end-users. In particular, the assume and assert statements are hidden from end-users, and the end-user has no way to propose new placements for them. We conclude that IPS-MP is a novel synthesis problem.

Constrained Horn clauses. A prominent approach to verification is reduction to the satisfiability of CHCs, otherwise known as *verifier synthesis* [30]. While verifier synthesis does enable the flexible design of software verifiers, it does not address the issue of communicating proof-rules to the underlying solver. In invariant synthesis, the proof-rules are either chosen once and for all [30], or are implicit in the solving algorithm (e.g., [44, 65]). While we show that IPS-MP reduces to CHC-solving, our focus is on communicating new proof-rules to the solver via synthesis. Other solutions to IPS-MP might emerge in the future.

Contributions. This paper makes the following contributions:

1. Sec. 4 presents the novel IPS-MP problem which has many applications to both program analysis and software verification;
2. Sec. 5 shows that even though IPS-MP is undecidable in general, there exists an efficient solution modulo Boolean programs;
3. Sec. 6 provides reductions from important verification problems to IPS-MP;
4. Sec. 7 presents a solver for IPS-MP within SEAHORN. We demonstrate the effectiveness of our implementation compared to state-of-the-art synthesis frameworks CVC4 [11] (a SYGUS synthesizer) and HORN\$^{\text{SPEC}}\$ [53] (a specification synthesizer). We conclude that IPS-MP fills a gap not met by other synthesis frameworks.

All omitted proofs are found in the extended paper [68].

```

1 bool PRED_TEMPLATE Post(int x, int y) {
2   return synth(x, y); }
3 void main(int y) {
4   int x = 0;
5   assume(y > 0);
6   for (int i = 0; i < y; ++i) {
7     x+=1; }
8   assert(Post(x, y));
9   x = *; y = *; assume(Post(x, y));
10  assert(x == y); }
```

Figure 3 A simple example of the IPS-MP problem.

2 Overview

To illustrate the basics of IPS-MP, we start with an artificial example. For the moment, we focus on the language used in our presentation and the possible solutions to an IPS-MP problem. Realistic applications of IPS-MP, highlighting its importance, are presented later in this section.

Our example, shown in Figure 3, consists of a single function `main` that provides the context for a synthesis problem. The function `main` is written in a typical imperative language, with loops and function calls. We extend the language with two verification statements, `assume` and `assert`, with their usual semantics. In our example, `y` is initially positive, due to `assume(y > 0)` on line 5, and the program is correct if `assert(x == y)` on line 10 holds for all executions. That is, lines 5 and 10 provide a program specification. The goal of this example is to synthesize a pure expression `e` such that the program is correct after substituting `e` for each call to `Post`. To indicate that a predicate is a target for synthesis, the language is extended by the predicate template annotation `PRED_TEMPLATE` (line 1). Each predicate template is a pure, loop-free function whose body either returns `true`, or returns via a call to the special predicate `synth`. Each call to `synth` indicates a *hole* in the predicate implementation, and must be determined by a synthesizer. Each return of `true` places an *explicit constraint* on when the implementation must be true. In our example, `Post` always returns via a call to `synth` (line 2). In the rest of the program, a call to a partial predicate can only appear as an argument to either `assume` or `assert`. As described below, verification calls place *implicit constraints* on when the implementation must be true. Multiple calls to the same predicate are allowed. In our example, `Post` is called once under `assert` (line 8), and once under `assume` (line 9).

A *solution* to an IPS-MP problem is a mapping from each partial predicate p to a pure Boolean expression e over the arguments of p , such that if every call to `synth` in p is replaced by e , then the main program satisfies all of its assertions. If such a solution does not exist, the output is a *witness to unrealizability*, which is a mapping from each partial predicate p to a pure Boolean expression e over the arguments of p , which is both necessitated by the assertions placed on the partial predicate, and sufficient to violate an assertion that is part of the specification. In our example, there are many possible solutions. The weakest and strongest solutions are $post_{weak}(x, y) = (x = y)$ and $post_{strong}(x, y) = (y > 0 \wedge x = y)$. Each solution defines a corresponding predicate `Post` such that all assertions in the `main` program are satisfied. Intuitively, each call to `Post` under `assume` provides an implicit constraint on the weakest possible synthesized solution. Likewise, each call to `Post` under `assert` provides an implicit constraint on the strongest possible synthesized solution. Following this intuition, the example shows an application of IPS-MP to find an intermediate post-condition, over two variables `x` and `y`, that is true after the loop and is strong enough to ensure an assertion. This means that solving IPS-MP requires, in general, inferring inductive invariants for loops and summaries for functions.

To illustrate the case when synthesis is not possible, consider removing line 7 from Figure 3. Since `x` is not incremented, it will never equal `y`. However, `Post` cannot be mapped to `false`, since this violates the assertion on line 8. If `Post` is not `false`, then the assertion

on line 8 is reachable and will fail. Therefore, this IPS-MP problem is unrealizable. The witness to unrealizability is a mapping that sends `Post` to an expression over `x` and `y`, which is necessitated by the assertion on line 8 and violates the assertion on line 10. An example witness is $\text{synth}_{\text{witness}}(x, y) = (x = 0 \wedge y = 1)$.

This section continues with three important applications of IPS-MP. Sec. 2.1 presents a methodology to reduce verification problems to IPS-MP. For readers new to verification as synthesis, the standard example of inductive loop invariant inference can be found in the extended paper. Secs. 2.2, 2.3, and 2.4 extend on the techniques in the full paper to unify class invariant inference, array verification, and parameterized compositional model checking under a single synthesis framework. Sec. 2.5 discusses the benefits of predicate templates and explains why IPS-MP requires both assumptions and assertions of partial predicates. We note that the automation in SMARTACE is a special case of Sec. 2.3.

2.1 Methodology

In Figure 3, a single predicate (i.e., `Post`) represents a single unknown (i.e., the post-condition of a loop). This permits an IPS-MP solver to explore all relations between arguments (e.g. `x` and `y` of `Post`). When there are many variables, or large variable domains, the space of candidate solutions becomes very large. Restricting the syntactic structure of each unknown, referred to as its *shape*, helps to prune the search space. In general, an unknown can be split into cases (see Sec. 2.3), and the variables in each case can be partitioned (see the extended paper). Each partition is encoded by a unique predicate. Refining a predicate's shape prunes the candidate solution space, but may eliminate valid solutions.

Whenever an unknown is refined, the syntactic changes are reflected only where the unknown is assumed or asserted. The program remains unchanged otherwise. For this reason, in IPS-MP, it is convenient to separate unknowns from their shapes. In the context of program verification, this is accomplished with the following methodology. First, a proof-rule for the program of interest is reduced to assumptions and assertions on one or more unknowns. This is done once per proof-rule. Second, the shape of each unknown is refined using insight from the program. Third, the program is instrumented with assumptions and assertions. The instrumented program is an IPS-MP problem and is automatically solved by an IPS-MP solver. We illustrate this methodology using examples from object-oriented program analysis, array verification, and parameterized verification.

2.2 Class Invariant Inference as Synthesis

As a first example, we illustrate a reduction from class invariant inference to IPS-MP. In object-oriented programming, a class bundles together a data structure, its initialization procedure, and its operations. For example, the `Counter` class in Figure 4a accumulates values between 0 and some maximum value. The underlying data structure is a pair consisting of the current value, `pos`, and the maximum value, `max`. The initialization procedure on lines 3–6 first ensures that `_max` is positive, and then sets the current value to 0 and the maximum value to `_max`. The operations for `Counter` include `reset`, `capacity`, and `increment`. When `reset` is called, the current value is set back to 0. When `capacity` is called, the distance to the maximum value is returned. When `increment` is called, if `capacity` is greater than 0, then the current value is incremented and `true` is returned, else the current value is unchanged and `false` is returned.

The goal of this example is to prove that `drain` satisfies its assertions. The `drain` function takes an instance of `Counter` (in an arbitrary state), exhausts the counter's capacity, and then resets the counter to 0. The function is correct if `increment` always returns `true`

```

1 class Counter {
2     int max; int pos;
3     Counter(int _max) {
4         assume(_max > 0);
5         max = _max;
6         pos = 0;
7     }
8     void reset() { pos = 0; }
9     int capacity() {
10        return max - pos;
11    }
12    bool increment() {
13        if (pos >= max) return false;
14        pos += 1;
15        return true;
16    }
17    void drain(Counter o) {
18        while (o.capacity() > 0) {
19            assert(o.increment());
20            o.reset();
21            assert(o.capacity() > 0);
22        }
23    }
24 }
```

(a) The original program.

```

1 bool PRED_TEMPLATE CInv(int m, int p) {
2     return synth(m, p);
3 }
4 void main(void) {
5     if (*) {
6         Counter o(*);
7         assert(CInv(o.max, o.pos));
8     } else if (*) {
9         Counter o = *; assume(CInv(o.max, o.pos));
10        o.reset();
11        assert(CInv(o.max, o.pos));
12    } else if (*) {
13        Counter o = *; assume(CInv(o.max, o.pos));
14        o.increment();
15        assert(CInv(o.max, o.pos));
16    } else {
17        Counter o = *; assume(CInv(o.max, o.pos));
18        drain(o);
19    }
20 }
```

(b) The IPS-MP problem (using Figure 4a).

Figure 4 A program (see Figure 4a) which is correct relative to the choice of class invariant ($0 < \text{o}.max \wedge 0 \leq \text{o}.pos \leq \text{o}.max$), and a corresponding IPS-MP instance.

on line 17, and `capacity` always returns a positive value on line 19. Verifying these claims is non-trivial, as the correctness of `drain` depends on the possible states of `Counter`. For example, proving the assertion on line 17 requires the invariant ($0 \leq \text{max} - \text{pos}$).

A common approach to the modular analysis of object-oriented programs is class invariant inference (e.g., [24, 36, 1, 45]). A class invariant is a predicate that is true of a class instance after initialization, closed under the application of impure class methods, and sufficient to prove the correctness of the class [36]. In the case of `Counter`, the impure methods are `reset` and `increment`. Therefore, a class invariant for `Counter` must satisfy four requirements.

Figure 4b illustrates a technique to encode multiple cases in a single IPS-MP program. Intuitively, this program uses non-determinism to execute one of four possible cases. A case is selected on line 4 by a sequence of `if-else` statements, each with a non-deterministic condition. Even though the execution of each case is mutually exclusive, the IPS-MP solution must work in all cases. The cases in Figure 4b correspond to the requirements of a class invariant for `Counter`. To ensure that the class invariant holds after initialization, the first case initializes an instance of `Counter` with non-deterministic arguments, and then asserts that the instance satisfies the class invariant (lines 4–6). To ensure that the class invariant is closed with respect to `reset`, the second case selects an arbitrary instance of `Counter` (through non-determinism), assumes that this instance satisfies the class invariant, executes `reset`, and then asserts that the instance continues to satisfy the class invariant (lines 7–10). Similarly, the third case ensures that the class invariant is closed with respect to `increment` (lines 11–14). Finally, to ensure that the class invariant entails the correctness of `drain`, the fourth case selects an arbitrary instance of `Counter`, assumes that this instance satisfies the class invariant, and then calls `drain` with the instance as an argument (lines 15–17). This gives a program with unknowns, as required by the verification methodology.

Next, the shape of the class invariant is considered. In this example, we lack program-specific knowledge to help split the invariant into sub-cases. Furthermore, it would be futile to partition the invariant's arguments, as the invariant must relate `max` to `pos` (e.g., line 17 of Figure 4a requires that $0 \leq \text{max} - \text{pos}$). Therefore, `CInv(m, p)` is used as the shape of the invariant. In Figure 4b, `CInv` corresponds to the partial predicate on line 1. One solution to Figure 4b is the expression $(m > 0) \wedge (p \leq m)$ for the hole in `CInv`. To prove the correctness of `drain`, a synthesizer may also infer the invariant ($0 \leq \text{o}.pos \wedge \text{o}.pos \leq \text{o}.max$) for the loop on line 16 of Figure 4a.

```

1  bool PRED_TEMPLATE Inv3(int m, int v) {
2    if (m == 0 && v == 0) { return true; }
3    else { return synth(m, v); }
4  bool PRED_TEMPLATE Inv4(int m, int v){
5    if (m == 0 && v == 0) { return true; }
6    else { return synth(m, v); }
7  void main(int sid) {
8    int max = 0;
9    while (true) {
10      int id = *;
11      int x = *;
12      assume(id != x);
13      // int v = data[id];
14      int v = *; int u = *;
15      if (id == sid) { assume(Inv3(max,v)); }
16      else { assume(Inv4(max,v)); }
17      if (x == sid){ assume(Inv3(max,u)); }
18      else { assume(Inv4(max,u)); }
19      // Properties.
20      assert(v <= max);
21      if (id == sid) { assert(v == 0); }
22      // Update.
23      if (id != sid) { v += 1; }
24      if (v > max) { max = v; }
25      // data[id] = v;
26      if (id == sid) { assert(Inv3(max,v)); }
27      else { assert(Inv4(max,v)); }
28      if (x == sid) { assert(Inv3(max,u)); }
29      else { assert(Inv4(max,u)); }}}

```

(a) The original program.

(b) The IPS-MP problem.

Figure 5 A program (see Figure 5a) which is correct relative to the choice of array abstraction ($i = s \wedge v = 0 \vee (i \neq s \wedge 0 \leq v \leq \max)$), and a corresponding IPS-MP instance.

2.3 Verification of Array-Manipulating Programs as Synthesis

Consider the array-manipulating program in Figure 5a. This program initializes the array `data`, and then performs an unbounded sequence of updates to the cells of `data` while maintaining the maximum element of `data` in `max`. A special index, stored by `sid`, remains unchanged during execution. On lines 2–4, `data` is allocated and then zero-initialized. On line 5, `max` is set to 0, since the maximum element of a zero-initialized array is 0. On line 6, `sid` is set to an arbitrary index in `data`. The unbounded sequence of updates begins on line 7, when the program enters a non-terminating loop. During each iteration, an index is selected (lines 8–9), and if this index is not `sid`, then the corresponding cell in `data` is incremented by 1 (line 11). If the cell is incremented, then `max` is updated accordingly (line 12). Note that Figure 5a can be thought of as a simplified smart contract, where `data` is an *address mapping*, `sid` is an *address variable*, and each iteration of the loop is a *transaction*. For a more general presentation of smart contracts as array-manipulating programs, see [66].

The goal of this example is to prove two properties about the cells of `data`. The first property is that every cell of `data` is at most `max`. The second property is that `data[sid]` is always zero. It is not hard to see why these properties are true. For example, the first property is true since every cell of `data` is initially zero, and after increasing the value of a cell, `max` is updated accordingly. However, verifying these properties is challenging, since `data` has an arbitrary number of cells. One solution to this problem is to compute a summary for each cell of `data`, with respect to `max` and `sid`, and independent of `data`'s length. This summary is then used in place of each array access to obtain a new program with a finite number of cells. For simplicity, we assume that array accesses are in bounds, and that integers cannot overflow (i.e., are modeled as mathematical integers).

A common approach to obtain such a summary is to over-approximate the least fixed point of the program by an *abstract domain* that provides a tractable set of array cell partitions according to semantic properties (e.g., [29, 33, 20]). An alternative approach (followed here) is to compute a *compositional invariant* [49] for each cell of the array. A compositional (array) invariant is a predicate that is initially true of all cells in the array, and closed under every write to the array. Furthermore, a compositional invariant must be closed under *interference*, that is, if $i \neq j$ and the cell $\text{data}[i]$ is updated, then $\text{data}[j]$ continues to satisfy the compositional invariant. That is, a compositional invariant is assumed after each read and asserted after each write.

Using this approach, the program in Figure 5b is obtained. On line 10, an arbitrary index named `id` is selected, as in the original program. However, on lines 11–12, a second, *distinct* index named `x` is selected, to stand for a cell under interference. On lines 14–18, the compositional invariant is assumed, in place of reading the values at `data[id]` and `data[x]`. On lines 20–21, the two properties are asserted. If an arbitrary cell satisfies both properties, then every cell must satisfy both properties. On lines 23–24, the cell updates are performed as in the original program. On lines 26–29, the compositional invariant is asserted, in place of writing to `data[id]`. Note that lines 2–4 of Figure 5a do not appear in Figure 5b since the compositional invariant abstracts away the contents of `data`. This gives a program with unknowns, as required by the verification methodology.

Next, the shape of the compositional invariant is restricted. Observe that on line 11 of Figure 5a, the value written into `data` depends on whether the index is `sid`. This suggests that the compositional invariant has two cases that branch on whether `id` equals `sid`, namely $((\text{id} = \text{sid}) \wedge \text{Inv3}(\max, v)) \vee ((\text{id} \neq \text{sid}) \wedge \text{Inv4}(\max, v))$. In the IPS-MP encoding, both `Inv3` and `Inv4` correspond to partial predicates (see lines 1 and 4 in Figure 5b, respectively). The templates, on lines 2 and 5, correspond to the initialization rule for the invariant. Recall, however, that these templates are not strictly necessary. One alternative is to assert `Inv3(max, 0)` and `Inv4(max, 0)` before line 9, though this is not illustrated. Due to the branching shape of the invariant, each `assume` and `assert` statement must branch between the two partial predicates (see lines 14–18 and 26–29). Given Figure 5b, a synthesizer may find the expressions $(v == 0)$ for the hole in `Inv3`, and $(0 <= v) \wedge (v <= \max)$ for the hole in `Inv4`. By substitution, $((\text{id} = \text{sid}) \wedge (v = 0)) \vee ((\text{id} \neq \text{sid}) \wedge (0 \leq v) \wedge (v \leq \max))$. To verify `main`, a synthesizer may also infer the invariant $(0 \leq \max)$ for the loop at line 9.

2.4 Parameterized Verification as Synthesis

As a third example, we illustrate a reduction from parameterized verification to IPS-MP. This example considers two or more processes running in a ring network of arbitrary size. A ring network organizes processes into a single cycle, such that each process has a left and right neighbour [19]. In this ring, adjacent processes share a lock on a common resource. Processes are either *trying* to acquire a lock, or have acquired all locks and are in a *critical* section. Initially, all processes are trying and all locks are free. Each process runs the program in Figure 6a. The state of each process is given by `View` on line 3, and the transition relation of each process is given by `tr`⁴ on line 5. Since each process runs the same program with the same configuration of locks, the ring network is said to be *symmetric*.

⁴ For simplicity, `tr` is not deadlock-free as processes retain their locks until reaching their critical sections. However, the critical section can be reached any number of times without encountering a deadlock.

```

1 typedef enum { Free, Left, Right } Lock;
2 typedef enum { Try, Critical } State;
3 struct View {
4     Lock lhs; Lock rhs; State st; };
5 View tr(View v) {
6     bool held = v.lhs == Left &&
7             v.rhs == Right;
8     if (v.st == Critical) {
9         v.st = Try;
10        v.lhs = Free;
11        v.rhs = Free; }
12     else if (held) {
13         v.st = Critical; }
14     else if (v.lhs == Free) {
15         v.lhs = Left; }
16     else if (v.rhs == Free) {
17         v.rhs = Right; }
18     return v; }
```

(a) The process.

```

1 bool PRED_TEMPLATE RInv(
2     Lock l, State s, Lock r) {
3     if (l == Free && r == l && s == Try) {
4         return true;
5     } return synth(l, s, r); }
6 void main(struct View v) {
7     if (*) {
8         State otr = *;
9         assume(RInv(v.left, v.st, v.right));
10        assume(RInv(v.right, otr, v.left));
11        v = tr(v);
12        assert(RInv(v.left, v.st, v.right));
13        assert(RInv(v.right, otr, v.left));
14    } else {
15        assume(RInv(v.left, v.st, v.right));
16        bool held = v.left == Left &&
17                         v.right == Right;
18        assert(v.st != Critical || held); }}
```

(b) The IPS-MP problem (uses `tr`).

Figure 6 A process for a parameterized ring, and an IPS-MP problem that verifies the process. The process is correct relative to the compositional invariant $((v.lhs \neq \text{Left}) \vee (v.rhs \neq \text{Right})) \Rightarrow (v.st \neq \text{Critical})$, and the IPS-MP problem synthesizes the compositional invariant. Note that `Lock` and `State` are defined in Figure 6a using `typedef`, and that `otr` is a process under interference.

The goal of this example is to prove that if a process is in its critical section, then the process holds both adjacent locks. Following [49], this property is proven by computing an adequate compositional invariant for each process. An adequate compositional invariant is true of the initial state of each process, closed under the transition relation, closed under interference, and entails the property of interest. Remarkably, in a symmetric ring network, a compositional invariant can be computed by analyzing a ring with exactly two processes.

Using this approach, the program in Figure 6b is obtained. This program uses a non-deterministic `if` statement to split the analysis into two cases (line 7). The first case instantiates a two-process network using the compositional invariant (lines 8–10). Due to network symmetry, the left lock of the first process is the right lock of the second process, and vice versa. A single process in this network executes a transition (line 11), and then the closure of the compositional invariant is asserted for both processes (lines 12–13). The assertions on lines 12–13 ensure both closure under the transition relation and closure under interference, since only a single process transitioned. The second case instantiates a single process using the compositional invariant (line 15), and then asserts the property of interest (lines 16–18). Together, these cases define a compositional invariant. This gives a program with unknowns, as required by the verification methodology.

Next, the shape of the compositional invariant is considered. In this example, there is no motivation to split the invariant into cases. Furthermore, it would not make sense to partition the arguments of the invariant, since the state of a process is dependent on the combined state of its adjacent locks. Therefore, `RInv(l, s, r)` is assumed to be the shape of the invariant. In the IPS-MP encoding, `RInv` corresponds to the partial predicate on line 1. The template on line 3 ensures that the compositional invariant is true of the initial state of each process. As an alternative to a template, one can instead assert `RInv(Free, Try, Free)` before line 7. One solution to this problem is to fill the hole in `RInv` with the expression $(s == \text{Try}) \Rightarrow (l == \text{Left} \wedge r == \text{Right})$. Consequently, $((s \neq \text{Try}) \Rightarrow (l == \text{Left} \wedge r == \text{Right}))$.

```

1 bool PRED_TEMPLATE Inv(int x, int y) {
2   if (x + y == 5) { return true; }
3   else { return synth(x, y); }
4 void main(void) { ... }

```

```

1 bool PRED_TEMPLATE Inv(int x, int y) {
2   return synth(x, y); }
3 void main(void) {
4   int x = *; int y = *;
5   assume(x + y == 5);
6   assert(Inv(x, y));
7   ...

```

(a) Predicate template encoding.

(b) Assertion-based encoding.

Figure 7 The initial condition ($x + y = 5$) encoded using a predicate (see Figure 7a), and its equivalent encoding using an assertion (see Figure 7b).

2.5 Discussion

In Sec. 2.3, all explicit constraints were easily replaced by implicit constraints. However, explicit constraints can yield more succinct encodings. For example, consider the initial condition ($x + y = 5$). In Figure 7a, the condition is given as an explicit predicate template, and in Figure 7b, it is desugared as an assertion. To desugar the constraint, additional variables and assumptions are required.

In the examples presented so far, each IPS-MP problem places both assumptions and assertions on each partial predicate. All interesting IPS-MP problems follow this pattern. However, IPS-MP is well defined even if a partial predicate has only assumptions placed on it, only assertions placed on it, or neither. In these cases, the IPS-MP problem is trivial or reduces to a simpler problem.

If partial predicates only appear in assumptions, then the synthesized solution is never strengthened. In other words, the solution may be arbitrarily weak. This is an instance of specification synthesis. Usually, in specification synthesis, non-functional requirements are placed on each specification to ensure that a solution is “interesting” (e.g., [21, 2, 53]). Without these requirements, uninteresting solutions, such as `false`, are permitted. Since IPS-MP only places functional requirements on its solutions, this case is trivial and returning `false` from each predicate is always a solution (given a correct program).

If partial predicates only appear in assertions, then the synthesized solution is only ever strengthened. A solution in this case is an expression that subsumes all assertions placed on the predicate. However, an expression that evaluates to `true` subsumes all possible assertions. Therefore, this case is also trivial and returning `true` from each predicate is always a solution (given a correct program).

If partial predicates never appear in the program, then the synthesizer can select an arbitrary implementation for each predicate. However, if the synthesizer returns a solution, then the program must be correct relative to the solution. Therefore, if the program does violate an assertion, then the synthesizer must return a witness to unrealizability instead. Consequently, the output of the synthesizer indicates if the program is correct, and is equivalent to verification.

3 Background

This section recalls results from logic-based program verification. Sec. 3.1 reviews the key definitions of First Order Logic (FOL) and the Constrained Horn Clause (CHC) fragment of FOL. Sec. 3.2 introduces a programming language used throughout this paper. Sec. 3.3 recalls the connection between CHCs and program semantics through the weakest liberal precondition transformer.

3.1 First Order Logic and Constrained Horn Clauses

A *first order signature* Σ defines a set of predicates, a set of relations, and their respective arities. Given a set of variables \mathcal{V} , a *term* is either a variable from \mathcal{V} or an application of a relation in Σ to one or more terms. An *atom* is an application of a predicate in Σ to one or more terms. A *formula* joins atoms using standard logical connectives, existential quantification, and universal quantification. A formula is *quantifier-free* if it contains neither existential nor universal quantification. A formula is a *sentence* if all variable instances are quantified. Given a FO-formula φ , the formula $\varphi[x/y]$ is defined by substituting y for all free instances of x in φ . We write $\text{Term}(\Sigma, \mathcal{V})$ and $\text{QFFml}(\Sigma, \mathcal{V})$ for the sets of terms and quantifier-free formulas generated by Σ and \mathcal{V} .

A *FO-theory* \mathcal{T} is a deductively closed set of sentences over a signature Σ . A \mathcal{T} -*model* for a formula φ is an interpretation of each predicate, relation, and free variable in $\mathcal{T} \cup \{\varphi\}$ such that every formula in $\mathcal{T} \cup \{\varphi\}$ is true. If a \mathcal{T} -model exists for φ , then φ is *satisfiable*, otherwise, φ is *unsatisfiable*. In the case that all valid interpretations of \mathcal{T} are \mathcal{T} -models for φ , then φ is \mathcal{T} -valid and we write $\vdash_{\mathcal{T}} \varphi$. Furthermore, if each interpretation of a \mathcal{T} -model M can be expressed in some logical fragment \mathcal{F} , then M provides an \mathcal{F} -*solution* to φ .

Constrained Horn Clauses (CHCs) are a fragment of FOL determined by a FO-signature Σ and an set of predicates P . A CHC is a sentence of the form $\forall V \cdot \varphi \wedge p_1(\vec{x}_1) \wedge \dots \wedge p_k(\vec{x}_k) \Rightarrow h(\vec{y})$, where $\varphi \in \text{QFFml}(\Sigma, \mathcal{V})$ and $\{p_1, \dots, p_k, h\} \subseteq P$. For program semantics, it is useful to use v' to denote the value of a variable v after a program transition and $\text{keep}(W) := \bigwedge_{w \in W} w = w'$ to denote that variables $W \subseteq \mathcal{V}$ are unchanged during a transition. Given a set of variables $V = \{v_1, \dots, v_n\} \subseteq \mathcal{V}$, the set of variables $\{v'_1, \dots, v'_n\}$ is denoted V' . Likewise, given a formula φ over the variables in V , the formula $\varphi[v_1/v'_1] \dots [v_n/v'_n]$ over V' is denoted φ' .

3.2 Procedural Programming Language

Throughout this paper, we consider a simple procedural programming language, whose syntax is standard and can be found in the extended paper. We assume that all expressions are factored out by a FO-signature Σ , with variables from a set \mathcal{V} . That is, each expression is of the form $\text{QFFml}(\Sigma, \mathcal{V})$. The set of all programs in the language is denoted $\text{Progs}(\Sigma, \mathcal{V})$. For simplicity, types are omitted. In this language, a program has one or more procedures, with execution starting from `main`. Each procedure is written in an imperative language, including loops and procedure calls. The language is extended with a non-deterministic assignment (i.e., $*$), and verification statements `assume` and `assert`. The expressions in `assume` and `assert` can be either from $\text{QFFml}(\Sigma, \mathcal{V})$ or a call to a pure Boolean procedure, called a *predicate*. Predicates may only be called within `assume` or `assert` statements. Given a program $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$, $\text{Procs}(\mathcal{P})$ denotes the procedures in \mathcal{P} . A special case is when all variables are Boolean.

► **Definition 1.** Let Σ_{Bool} denote a Boolean signature. A Boolean program is a tuple $(\text{Locs}, \text{GV}, \text{LV}, E)$ with $E = (\text{NE}, \text{CE}, \text{FE}, \text{AE}, \text{PE})$ and $V = \text{GV} \cup \text{LV}$ such that:

1. Locs is a finite set of control-flow locations with entry-point `main` $\in \text{Locs}$;
2. GV and LV are disjoint sets of local and global variables (respectively);
3. $\text{NE} \subseteq \text{Locs} \times \text{QFFml}(\Sigma_{\text{Bool}}, V \cup V') \times \text{Locs}$ is a set of normal edges, $\text{CE} \subseteq \text{Locs} \times \text{Locs} \times \text{Locs}$ is a set of call edges, $\text{FE} \subseteq \text{Locs} \times \text{Locs} \times \text{Locs}$ is a set of (partial predicate) call-under-`assume` edges, $\text{AE} \subseteq \text{Locs} \times \text{Locs} \times \text{Locs}$ is a set of (partial predicate) call-under-`assert` edges, and $\text{PE} \subseteq \text{Locs} \times \text{Locs}$ is a set of procedure summary edges;
4. If $(l_1, R, l_2) \in \text{NE}$, then l_2 is reachable from l_1 by updating the variables according to R and if $(l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in \text{CE}$, then l_{ret} is reachable from l_{call} by executing the procedure with entry location l_{in} ;

$$\begin{aligned} \text{ToCHC}(\mathcal{P}) &:= wlp(\mathcal{P}(\text{Main}), \top) \wedge \left(\bigwedge_{f \in \text{Procs}(\mathcal{P})} \text{ToCHC}(f) \right) \\ \text{ToCHC}(f(\vec{x}) \{ S; \text{return } \vec{e}; \}) &:= \forall \vec{x} \cdot (\vec{x} = \vec{x} \wedge f_{pre}(\vec{x}) \Rightarrow wlp(S, f_{sum}(\vec{x}, \vec{e}))) \\ \text{ToCHC}(p(\vec{x}) \{ \text{return } e; \}) &:= \forall \vec{x} \cdot p(\vec{x}) \Leftrightarrow e \end{aligned}$$

Figure 8 The partial correctness conditions for a program $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$. This follows the presentation of [14].

5. If $(l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in FE$, then l_{ret} is reachable from l_{in} by assuming the partial predicate with entry location l_{call} and if $(l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in AE$, then l_{ret} is reachable from l_{in} by asserting the partial predicate with entry location l_{call} ;
6. If $(l_{\text{in}}, l_{\text{out}}) \in PE$, then the procedure with entry location l_{in} has exit location l_{out} .

A Boolean program consists of control-flow locations and edges between locations. Each procedure has a single entry location, l_{in} , and a single exit location, l_{out} , where $(l_{\text{in}}, l_{\text{out}}) \in PE$. The program enters at `main` $\in Locs$, and a special location $l_{\perp} \in Locs$ indicates failure. *Normal edges* connect control-flow locations within a procedure and represent non-procedural statements. For example, the statement `assert(e)` (where e is an expression) corresponds to two normal edges, $(l_1, e \wedge \text{keep}(GV \cup LV), l_2)$ and $(l_1, \neg e \wedge \text{keep}(GV \cup LV), l_{\perp})$. *Call edges* (optionally under assume or assert) connect locations in a caller's procedure and a callee's procedure by giving the call and return locations of the caller (l_{call} and l_{ret} , respectively), and the entry location for the callee (l_{in}). For simplicity, all procedures have the same local variables, and arguments are passed by global variables. The location l_{\perp} is assumed to have no outgoing edges.

The state of a Boolean program is a tuple (l, s) , where l is a location and s is an assignment to each Boolean variable. Initially, $l = \text{main}$ and s is an arbitrary assignment. For each normal edge (l_1, R, l_2) , a transition exists from (l_1, s_1) to (l_2, s_2) , if $s_1 \wedge R \wedge s'_2$ is valid. All call edges have the expected semantics.

3.3 Logical Program Verification

The Weakest Liberal Precondition (WLP) transformer gives logical semantics to imperative programs [23]. We write $wlp(S, Q)$ for the WLP of a statement S with respect to a post-condition Q . The WLP transformer for $\text{Progs}(\Sigma, \mathcal{V})$ is standard and can be found in the extended paper. Note that in this transformation, the $loop_{ln}$ predicate is an invariant for a loop at line ln .

The $wlp(-)$ transformer can be used to verify partial correctness for procedural programs. This is achieved through the $\text{ToCHC}(-)$ transformer in Figure 8. The $wlp(\mathcal{P}(\text{main}), \top)$ term asserts that `main` satisfies all assertions. For each procedure $f \in \text{Procs}(\mathcal{P})$, the term $\text{ToCHC}(f)$ asserts that f is correct for all inputs passed to f in every execution. Note that in Figure 8, f_{pre} collects inputs to f , and f_{sum} relates the inputs of f to the outputs of f . In the case that f is a predicate, f_{pre} and f_{sum} are omitted, since f is side-effect free. Together, $\text{ToCHC}(\mathcal{P})$ asserts that the program \mathcal{P} is correct for any execution starting from `main`. If $\text{ToCHC}(\mathcal{P})$ is satisfiable, then there exist loop invariants for \mathcal{P} such that \mathcal{P} satisfies all assertions [14]. Therefore, $\text{ToCHC}(\mathcal{P})$ can be used to verify \mathcal{P} . Furthermore, $\text{ToCHC}(\mathcal{P})$ is in the CHC fragment [14].

■ **Algorithm 1** Computes the least Boolean program summary (θ, σ) [8]. Follows the presentation of [17].

```

1 var  $(\theta, \sigma)$ ; // A program summary
2 var  $W$ ; // A map from  $Locs$  to a queued state
3 Func UpdateReach( $l, v$ ):
4    $s_{diff} \leftarrow v \wedge \neg \theta(l)$ ;
5   if  $s_{diff} \neq \perp$  then
6      $\theta(l) \leftarrow \theta(l) \vee s_{diff}$ ;
7      $W(l) \leftarrow W(l) \vee s_{diff}$ 
8 Func DoIntraproc( $V, NE, l_{wk}, s_{wk}$ ):
9   for  $(l_{wk}, R, l_2) \in NE$  do
10     $s_2 \leftarrow \text{elim}(s_{wk} \wedge R^*, V')$ ;
11     $s_2 \leftarrow s_2[V''/V']$ ;
12    UpdateReach( $l_2, s_2$ );
13 Func DoProcSum( $V, LV, PE, CE, l_{wk}, s_{wk}$ ):
14   for  $(l_{in}, l_{wk}) \in PE$  do
15     $s_{sum} \leftarrow \text{elim}(s_{wk}, LV \cup LV') \wedge \neg \sigma(l_{in})$ ;
16    if  $s_{sum} = \perp$  then continue;
17     $\sigma(l_{in}) \leftarrow \sigma(l_{in}) \vee s_{sum}$ ;
18    for  $(l_{call}, l_{in}, l_{ret}) \in CE$  do
19       $X \leftarrow s_{sum}^* \wedge \text{keep}(LV')$ ;
20       $s \leftarrow \text{elim}(\theta(l_{call}) \wedge X, V')[V''/V']$ ;
21      UpdateReach( $l_{ret}, s$ );
22 Func DoProcs( $V, LV, PE, CE, l_{wk}, s_{wk}$ ):
23   for  $(l_{wk}, l_{in}, l_{ret}) \in CE$  do
24     $s_{in} \leftarrow \text{elim}(s_{wk}, V \cup LV')[V'/V]$ ;
25    UpdateReach( $l_{in}, s_{in}$ );
26     $X \leftarrow \sigma(l_{in})^* \wedge \text{keep}(LV')$ ;
27     $s \leftarrow \text{elim}(s_{wk} \wedge X, V')[V''/V']$ ;
28    UpdateReach( $l_{ret}, s$ );
29 Func InitBoolReach( $Locs, PE$ ):
30   for  $l \in Locs$  do  $\theta(l) \leftarrow \perp$ ;
31   for  $(l_{in}, l_{out}) \in PE$  do  $\sigma(l_{in}) \leftarrow \perp$ ;
32    $\theta(\text{main}) \leftarrow \top; W(\text{main}) \leftarrow \top$ ;
33 Func ComputeBoolReach( $\mathcal{P}$ ):
34    $(Locs, GV, LV, (N, C, \emptyset, \emptyset, P)) \leftarrow \mathcal{P}$ ;
35    $V \leftarrow GV \cup LV$ ;
36   InitBoolReach( $Locs, P$ );
37   while  $\exists l_{wk} \in Locs \cdot W(l_{wk}) \neq \perp$  do
38     $s_{wk} \leftarrow W(l_{wk})$ ;  $W(l_{wk}) \leftarrow \perp$ ;
39    DoIntraproc( $V, N, l_{wk}, s_{wk}$ );
40    DoProcs( $V, LV, P, C, l_{wk}, s_{wk}$ );
41    DoProcSum( $V, LV, P, C, l_{wk}, s_{wk}$ );

```

Efficient procedures exist to prove that Boolean programs are correct. For example, *program summarization* simultaneously computes a summary θ from control-flow locations to input-to-reachable-state relations, and a summary σ from procedures to input-output relations. For a location $l \in Locs$, if $\theta(l) = \perp$, then l is unreachable. Therefore, a Boolean program \mathcal{P} is correct if and only if $\theta(l_\perp) = \perp$ in the least summary of \mathcal{P} [6]. Program summarization is defined in Def. 2⁵. The algorithm to compute θ is presented in full, for reuse in Sec. 5.1. For presentation, $\text{elim}(\varphi, W)$ denotes the existential elimination of W in φ .

► **Definition 2** ([6]). *A Boolean program summary for $(Locs, GV, LV, E)$, where $E = (NE, CE, \emptyset, \emptyset, PE)$ is a tuple (θ, σ) such that $Q = \text{QFFml}(\Sigma_{\text{Bool}}, V \cup V')$, $V = GV \cup LV$ and the following hold:*

1. $\sigma : Locs \rightarrow Q$ and $\theta : Locs \rightarrow Q$;
2. $\sigma(\text{main}) = \top$;
3. $\forall (l_1, R, l_2) \in NE \cdot \theta(l_1) \wedge R' \Rightarrow \theta(l_2)[V'/V'']$;
4. $\forall (l_{call}, l_{in}, l_{ret}) \in CE \cdot \theta(l_{call}) \wedge \sigma'(l_{in}) \wedge \text{keep}(LV') \Rightarrow \theta(l_{ret})[V'/V'']$;
5. $\forall (l_{call}, l_{in}, l_{ret}) \in CE \cdot \text{elim}(\theta(l_{call}), V \cup LV') \Rightarrow \theta(l_{in})$;
6. $\forall (l_{in}, l_{out}) \in PE \cdot \theta(l_{out}) \Rightarrow \sigma(l_{in})$.

`ComputeBoolReach` in Algorithm 1 is the standard algorithm to compute a least program summary. The algorithm works by iteratively applying the rules of Def. 2 until a fixed point is reached (we write $R^* := R[V'/V''][V/V']$). Termination is ensured by the finite-state of Boolean programs and the monotonicity of each rule. We extend on the algorithm `ComputeBoolReach` in Sec. 5.1.

⁵ To align with Algorithm 1, Def. 2 is non-standard but equivalent to [6].

```

1 bool Post(int x, int y) {
2   return x==y; }
3 void main(int y) {
4   assume(y>0); int x=0;
5   for (int i=0; i<y; ++i) { x+=1; }
6   assert(Post(x, y));
7   x=*>; y=*>; assume(Post(x, y)); }

```

(a) The program $\mathcal{P}[\Pi_{weak}]$.

```

1 bool Post(int x, int y) {
2   return (y>0) && (x==y); }
3 void main(int y) {
4   assume(y > 0); int x=0;
5   for (int i=0; i<y; ++i) { x+=1; }
6   assert(Post(x, y));
7   x=*>; y=*>; assume(Post(x, y)); }

```

(b) The program $\mathcal{P}[\Pi_{strong}]$.**Figure 9** Implementations of the simple program in Figure 3.

4 IPS-MP: Problem Definition

This section defines partial predicates and the IPS-MP problem. A *partial predicate* is a pure Boolean function without an implementation. A program \mathcal{P} is *open* if it contains a partial predicate p . An implementation for p is a Boolean expression e over the arguments of p . The program obtained by implementing p as `return e` is denoted $\mathcal{P}[p \leftarrow e]$. The set of all partial predicates in \mathcal{P} is written $\text{Partial}(\mathcal{P}) = \{p_1, \dots, p_k\}$. Given a function Π from $\text{Partial}(\mathcal{P})$ to pure Boolean expressions, we write $\mathcal{P}[\Pi]$ to denote $\mathcal{P}[p_1 \leftarrow \Pi(p_1)] \cdots [p_k \leftarrow \Pi(p_k)]$. The IPS-MP problem is to find a Π such that $\mathcal{P}[\Pi]$ is correct.

► **Example 3.** Recall program \mathcal{P} from Figure 3. Since `Post` is unimplemented in \mathcal{P} , then \mathcal{P} is an open program. Formally, $\text{Partial}(\mathcal{P}) = \{\text{Post}\}$. In Sec. 2, two implementations were proposed for `Post`, namely $(x = y)$ and $(y > 0 \wedge x = y)$. These implementations are represented by the mappings Π_{weak} and Π_{strong} from $\text{Partial}(\mathcal{P})$ to pure Boolean expressions such that $\Pi_{weak} : \text{Post} \mapsto (x = y)$ and $\Pi_{strong} : \text{Post} \mapsto (y > 0 \wedge x = y)$. The closed programs $\mathcal{P}[\Pi_{weak}]$ and $\mathcal{P}[\Pi_{strong}]$ are illustrated in Figure 9a and Figure 9b, respectively. ◀

► **Definition 4.** An Inductive Predicate Synthesis Modulo Programs (IPS-MP) problem is a tuple $(\mathcal{P}, \mathcal{T}, \Pi_0)$ such that $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$ with first-order signature Σ and variable set \mathcal{V} , \mathcal{T} is a first-order theory, and $\Pi_0 : \text{Partial}(\mathcal{P}) \rightarrow \text{QFFml}(\Sigma, \mathcal{V})$ are predicate templates. A solution to $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is a function $\Pi : \text{Partial}(\mathcal{P}) \rightarrow \text{QFFml}(\Sigma, \mathcal{V})$ such that $\mathcal{P}[\Pi]$ is correct relative to \mathcal{T} and $\forall p \in \text{Partial}(\mathcal{P}) \cdot \models_{\mathcal{T}} \Pi_0(p) \Rightarrow \Pi(p)$.

Assume that $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is an IPS-MP problem with a solution Π . With respect to the IPS-MP overview in Figure 2, \mathcal{P} is a *program with specifications*, Π_0 is a collection of *predicate templates*, and Π is an *implementation of partial predicates*. The *witness to unrealizability* is discussed in Sec. 5. As an example of Def. 4, Figure 5b is restated as a formal IPS-MP problem.

► **Example 5.** This example restates Figure 5b as an IPS-MP problem $(\mathcal{P}, \Pi_0, \mathcal{T})$. The program \mathcal{P} is given by lines 7–29 of Figure 5b. Then $\text{Partial}(\mathcal{P}) = \{\text{Inv3}, \text{Inv4}\}$, since `Inv3` and `Inv4` are called on lines 15–16, but lack full implementations. From lines 1–6, $\Pi_0(\text{Inv3}) = \Pi_0(\text{Inv4}) = (m = 0 \wedge v = 0)$. Now, recall from Sec. 2.3 that all variables in Figure 5b are arithmetic integers. Therefore, \mathcal{T} is the theory of integer linear arithmetic. A solution to $(\mathcal{P}, \Pi_0, \mathcal{T})$ is Π such that $\Pi(\text{Inv3}) = (v = 0)$ and $\Pi(\text{Inv4}) = (0 \leq v \wedge v \leq m)$. ◀

5 Decidability of IPS-MP

This section considers the decidability of IPS-MP. Sec. 5.1 shows that IPS-MP is efficiently decidable in the Boolean case. Sec. 5.2 shows that IPS-MP is undecidable in general, but admits sound proof-rules for realizability and unrealizability.

5.1 The Case of Boolean Programs

This section shows that for Boolean programs, IPS-MP is decidable with the same time complexity as problem verification (i.e., polynomial in the number of program states). In contrast, general synthesis is known to have exponential time complexity in the Boolean case [64]. Therefore, IPS-MP modulo Boolean programs does in fact offer the benefits of general synthesis without the associated costs. To prove this result, we first extend Boolean program summaries (Def. 2) to programs with partial predicates. These new summaries are then used to extract solutions to IPS-MP (or witnesses to unrealizability). `Analyze` of Algorithm 2 extends on Algorithm 1 to compute these new summaries. The total correctness and time complexity of `Analyze` are proven in Cor. 9 and Thm. 7, respectively.

To simplify our presentation, we assume that all predicates are partial. In a Boolean program, each partial predicate has an entry location, but no edges nor exit location. This means that a standard summary can be obtained for a Boolean program with partial predicates by discarding all calls to partial predicates. Such a summary characterizes reachability, under the assumption that partial predicates are never called. From this summary, the arguments passed to each partial predicate under assert can be collected. For the program summary to be correct, the partial predicates must return true on these asserted arguments. If the partial predicate returns true on these asserted arguments, then for any call under assume using the same arguments, the program execution must continue to the next state. This procedure can then be repeated until a fixed point is obtained. This new *partial program summary* is defined formally in Def. 6.

► **Definition 6.** Let $\mathcal{P} = (\text{Locs}, \text{GV}, \text{LV}, (\text{NE}, \text{CE}, \text{FE}, \text{AE}, \text{PE}))$ be a Boolean program. A partial program summary for \mathcal{P} is a tuple (θ, σ, Π) such that:

1. $\Pi : \text{Partial}(\mathcal{P}) \rightarrow \text{QFFml}(\Sigma_{\text{Bool}}, \text{GV})$;
2. (θ, σ) is a program summary for $(\text{Locs}, \text{GV}, \text{LV}, (\text{NE}, \text{CE}, \emptyset, \emptyset, \text{PE}))$;
3. $\forall (l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in \text{AE} \cdot \theta(l_{\text{call}}) \Rightarrow \Pi'(l_{\text{in}})$;
4. $\forall (l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in \text{AE} \cdot \theta(l_{\text{call}}) \Rightarrow \theta(l_{\text{ret}})$;
5. $\forall (l_{\text{call}}, l_{\text{in}}, l_{\text{ret}}) \in \text{FE} \cdot \theta(l_{\text{call}}) \wedge \Pi'(l_{\text{in}}) \Rightarrow \theta(l_{\text{ret}})$.

The rules of Def. 6 follow directly from the preceding discussion. Rule 2 ensures that (θ, σ) is a program summary for \mathcal{P} after discarding all calls to partial predicates. Rules 3 and 4 collect the arguments passed to partial predicates under assert. Rule 5 advances the program state from calls to partial predicates under assume, according to the collected arguments. These steps are made operational by `Analyze` of Algorithm 2. Note that `Analyze` does not call `ComputeBoolReach` directly, and instead applies all rules in a single loop.

The termination of `Analyze` follows analogously to `ComputeBoolReach`. First, note that `Analyze` terminates if all work items have been processed. Each iteration of the loop at line 22 processes at least one work item. A state is added to the work list only if it has not yet been visited. The number of states is finite, since Boolean programs are finite-state. Therefore, `Analyze` must terminate with time polynomial in the number of program states. This is in contrast to general synthesis, which requires time exponential in the number of program states [64].

► **Theorem 7.** Let $\mathcal{P} = (\text{Locs}, \text{GV}, \text{LV}, E)$ with $E = (\text{NE}, \text{CE}, \text{FE}, \text{AE}, \text{PE})$ be a Boolean program. Then for each input (\mathcal{P}, Π_0) , `Analyze` of Algorithm 2 terminates in $O(n^2 m \cdot |\text{Locs}|)$ symbolic Boolean operations where $n = 2^{|\text{GV} \cup \text{LV}|}$ is the number of variable assignments and $m = |\text{NE} \cup \text{CE} \cup \text{FE} \cup \text{AE}|$ is the number of edges.

Algorithm 2 An extension of Algorithm 1 to solve IPS-MP for Boolean programs.

```

1 var  $(\theta, \sigma, \Pi)$ ; // A partial program summary    16 Func Init( $Locs, PE, \Pi_0$ ):
2 var  $W$ ; // A map from  $Locs$  to queued states    17   InitBoolReach( $Locs, PE$ );
3 Func DoAssumes( $V, LV, PE, FE, l_{wk}, s_{wk}$ ):      18   for  $l \in \text{Partial}(\mathcal{P})$  do  $\Pi(l) \leftarrow \Pi_0(l)$ ;
4   for  $(l_{wk}, l_{in}, l_{ret}) \in FE$  do                19 Func Analyze( $\mathcal{P}, \Pi_0$ ):
5      $s_{in} \leftarrow \text{elim}(s_{wk}, V \cup LV')[V'/V]$ ;  20   ( $Locs, GV, LV, (N, C, F, A, P)$ )  $\leftarrow \mathcal{P}$ ;

13      $\Pi(l_{wk}) \leftarrow \Pi(l_{wk}) \vee s_{wk}$ ;        28     DoProcSum( $V, LV, P, C, l_{wk}, s_{wk}$ );
14     for  $(l_{call}, l_{wk}, l_{ret}) \in FE \cup AE$  do  29     DoFuncSum( $V, LV, F, A, l_{wk}, s_{wk}$ );
15       UpdateReach( $l_{ret}, \theta(l_{call}) \wedge s_{wk}$ );      30 Func BoolSynth( $\mathcal{P}, \Pi_0$ ):
16   |                                         31   Analyze( $\mathcal{P}, \Pi_0$ );
17   |                                         32   if  $\theta(l_{\perp}) = \perp$  then return  $(\checkmark, \Pi)$ ;
18   |                                         33   else return  $(\times, \Pi)$ ;

```

The correctness of `BoolSynth` follows from the correctness of `ComputeBoolReach` in [17]. Thm. 8 proves that `Analyze` extends `ComputeBoolReach` to obtain a least partial program summary. Cor. 9 proves that an IPS-MP solution (or a witness to unrealizability) can be extracted from a least partial program summary. Since `Analyze` terminates, this is a decision procedure for the Boolean case of IPS-MP.

► **Theorem 8.** *Let $\mathcal{P} = (Locs, GV, LV, E)$ be a Boolean program and Π_0 be a collection of predicate templates for \mathcal{P} . `Analyze` of Algorithm 2 computes a least partial program summary, (θ, σ, Π) , for \mathcal{P} such that $\forall p \in \text{Partial}(\mathcal{P}) \cdot \Pi_0(p) \Rightarrow \Pi(p)$.*

► **Corollary 9.** `BoolSynth` of Algorithm 2 decides IPS-MP for Boolean programs.

5.2 The General Case

This section presents sound proof-rules for the realizability and unrealizability of IPS-MP problems. These rules are shown to be instances of CHC-solving. To justify the reduction from IPS-MP to this undecidable problem, the general case of IPS-MP is also shown to be undecidable. First, assume that $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is an IPS-MP problem. Recall that $\mathcal{P} \in \text{Progs}(\mathcal{F}, \mathcal{V})$ where \mathcal{F} is the FO-fragment of pure program expressions. A logical encoding of $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is given by:

$$\text{CHCSynth}(\mathcal{P}, \Pi_0) := \text{ToCHC}(\mathcal{P}) \wedge \left(\bigwedge_{p \in \text{Partial}(\mathcal{P})} \forall \vec{x} \cdot (\Pi_0(p) \Rightarrow p(\vec{x})) \right)$$

The term `ToCHC`(\mathcal{P}) encodes verification conditions for \mathcal{P} , in which each partial predicate is unspecified. Calls to a partial predicate p , under assume and assert, provide constraints on the strongest and weakest possible solutions to `CHCSynth`(\mathcal{P}, Π_0). The clause $\forall \vec{x} \cdot (\Pi_0(p) \Rightarrow p(\vec{x}))$ then ensures the strongest solution to p subsumes $\Pi_0(p)$. Then a solution σ to `CHCSynth`(\mathcal{P}, Π) contains an implementation $\sigma(p)$ for each partial predicate p , that subsumes $\Pi_0(p)$ and ensures the correctness of \mathcal{P} (Thm. 10). Furthermore, if σ is an \mathcal{F} -solution, then each $\sigma(p)$ can be implemented in the programming language. On the other hand, if `CHCSynth`(\mathcal{P}, Π_0) is unsatisfiable, then for every choice of implementation Π satisfying Π_0 , the closed program $\mathcal{P}[\Pi]$ is incorrect (Thm. 11). Together, these theorems give sound proof rules for the realizability and unrealizability of $(\mathcal{P}, \mathcal{T}, \Pi_0)$. In practice, \mathcal{F} is chosen to be the same fragment used by the CHC-solver.

► **Theorem 10.** Let Σ be a first-order signature, \mathcal{V} be a set of variable symbols, $\mathcal{F} = \text{QFFml}(\Sigma, \mathcal{V})$, $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$, and $(\mathcal{P}, \mathcal{T}, \Pi_0)$ be an IPS-MP problem. If σ is an \mathcal{F} -solution to $\text{CHCSynth}(\mathcal{P}, \Pi_0)$ relative to \mathcal{T} , then $\Pi : \text{Partial}(\mathcal{P}) \rightarrow \mathcal{F}$ such that $\Pi : p \mapsto \sigma(p)$ is a solution to $(\mathcal{P}, \mathcal{T}, \Pi_0)$.

► **Theorem 11.** If $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is an IPS-MP problem and $\text{CHCSynth}(\mathcal{P}, \Pi_0)$ is \mathcal{T} -unsatisfiable, then $(\mathcal{P}, \mathcal{T}, \Pi_0)$ is unrealizable.

$\text{CHCSynth}(\mathcal{P}, \Pi_0)$ strengthens $\text{ToCHC}(\mathcal{P})$ by adding additional CHCs. Since $\text{ToCHC}(\mathcal{P})$ is a conjunction of CHCs, then $\text{CHCSynth}(\mathcal{P}, \Pi_0)$ is also a conjunction of CHCs. Therefore, a CHC solver can check the satisfiability and unsatisfiability of $\text{CHCSynth}(\mathcal{P}, \Pi_0)$. As a result, a CHC solver can find a solution to $(\mathcal{P}, \mathcal{T}, \Pi_0)$ (Thm. 10), or prove that the problem is unrealizable (Thm. 11).

► **Theorem 12.** $\text{CHCSynth}(\mathcal{P}, \Pi_0)$ is a CHC conjunction.

► **Example 13.** This example uses Thm. 10 to solve the IPS-MP problem in Figure 4b. The program in Figure 4b corresponds to the IPS-MP problem $(\mathcal{P}, \mathcal{T}, \Pi_0)$ where \mathcal{P} is the source code, \mathcal{T} is the theory of integer linear arithmetic, and $\Pi_0 : \text{CInv} \rightarrow \perp$. In this example we let \mathcal{F} be the fragment of linear inequalities of the variables $\{\mathbf{m}, \mathbf{p}\}$, where \mathbf{m} and \mathbf{p} are the arguments to CInv . Then our goal is to find an expression $e \in \mathcal{F}$ such that $\mathcal{P}[\text{CInv} \leftarrow e]$ is correct. According to Thm. 10, we can extract e from the output of a CHC-solver. The first step in this process is to construct the input $\text{CHCSynth}(\mathcal{P}, \Pi_0)$. To construct $\text{CHCSynth}(\mathcal{P}, \Pi_0)$ we must first construct the term $\text{ToCHC}(\mathcal{P})$. Recall that $\text{ToCHC}(\mathcal{P})$ encodes verification conditions for the program \mathcal{P} . Since \mathcal{P} is open (CInv is unimplemented), then CInv will be an unknown in $\text{ToCHC}(\mathcal{P})$. According to Sec. 3.3, $\text{ToCHC}(\mathcal{P})$ will consist of the verification conditions for $\mathcal{P}[\text{main}]$, along with a summary for each function in \mathcal{P} . We begin by constructing a summary for each method from the `Counter` object in \mathcal{P} . As described in Sec. 3.3, each predicate $f_{pre}(\mathbf{x})$ collects the inputs \mathbf{x} to a function f , and each predicate $f_{sum}(\mathbf{x}, \mathbf{e})$ each argument \mathbf{x} to a return value \mathbf{e} . For simplicity, we encode object state by passing member fields as arguments and return values. Redundant declarations are omitted.

$$\begin{aligned}\varphi_{Ctor} &:= \forall m \cdot \text{Counter}_{pre}(m) \Rightarrow ((m > 0) \Rightarrow \text{Counter}_{sum}(m, m, 0)) \\ \varphi_{Reset} &:= \forall m \cdot \forall p \cdot \text{reset}_{pre}(m, p) \Rightarrow \text{reset}_{post}(m, p, m, 0) \\ \varphi_{Cap} &:= \forall m \cdot \forall p \cdot \text{capacity}_{pre}(m, p) \Rightarrow \text{capacity}_{sum}(m, p, m - p \neq 0) \\ \varphi_{Incr} &:= \forall m \cdot \forall p \cdot \text{increment}_{pre}(m, p) \Rightarrow (((p \geq m) \Rightarrow \text{increment}_{sum}(m, p, \perp)) \wedge \\ &\quad ((p < m) \Rightarrow \text{increment}_{sum}(m, p + 1, \top)))\end{aligned}$$

Next, we construct a summary for the function `drain`. Note that, unlike the methods of `Counter`, the function `drain` contains a loop. As described in Sec. 3.3, loops are encoded using loop invariants with the loop at line n associated with an invariant $loop_n$. In our example, the loop at Line 16 of Figure 4a is associated with a loop invariant $loop_{13}$. Then the summary of `drain` is as follows.

$$\begin{aligned}\varphi_{Exit} &:= \text{capacity}_{pre}(p', m') \cdot \forall x \cdot (\text{capacity}_{sum}(p', m', x) \Rightarrow (x \wedge \text{drain}_{sum}(p, m, p', m'))) \\ \varphi_{Loop} &:= loop_{13}(p, m, x) \wedge \\ &\quad (((loop_{13}(p, m, x) \wedge x > 0) \Rightarrow (\text{capacity}_{pre}(p, m) \wedge \forall x \cdot (\text{capacity}_{sum}(p, mx) \Rightarrow loop_{13}))) \wedge \\ &\quad (((loop_{13}(p, m, x) \wedge x \leq 0) \Rightarrow \text{reset}_{pre}(p, m) \wedge \forall p' \cdot \forall m' \cdot (\text{reset}_{sum}(p, m, p', m') \Rightarrow \varphi_{Exit})) \\ \varphi_{Dr} &:= \forall p \cdot \forall m \cdot \text{drain}_{pre}(p, m) \Rightarrow (\text{capacity}_{pre}(p, m) \wedge \forall x \cdot (\text{capacity}_{sum}(p, m, x) \Rightarrow \varphi_{Loop}))\end{aligned}$$

Finally, we construct the verification conditions for `main`. Since `main` is the entry-point to \mathcal{P} , then `main` must be safe for all possible inputs. This means that `main` does not require a summary. The conditions are as follows.

$$\begin{aligned}
\varphi_{Main} := & \forall b_1 \cdot \forall b_2 \cdot \forall b_3 \cdot \\
& (b_1 = 1) \Rightarrow (\forall m \cdot Counter_{pre}(m) \wedge \forall m' \cdot \forall p \cdot (Counter_{sum}(m, m', p) \Rightarrow CInv(m', p)) \wedge \\
& (b_1 \neq 1 \wedge b_2 = 1) \Rightarrow (\forall m \cdot \forall p \cdot CInv(m, p) \Rightarrow \\
& (reset_{pre}(m, p) \wedge \forall m' \cdot \forall p' (reset_{sum}(p, m, p', m') \Rightarrow CInv(p', m')))) \wedge \\
& (b_1 \neq 1 \wedge b_2 \neq 1 \wedge b_3 = 1) \Rightarrow (\forall m \cdot \forall p \cdot CInv(m, p) \Rightarrow \\
& (increment_{pre}(m, p) \wedge \forall m' \cdot \forall p' (increment_{sum}(p, m, p', m') \Rightarrow CInv(p', m')))) \wedge \\
& (b_1 \neq 1 \wedge b_2 \neq 1 \neq b_3 = 1) \Rightarrow (\forall m \cdot \forall p \cdot CInv(m, p) \Rightarrow \\
& (drain_{pre}(m, p) \wedge \forall m' \cdot \forall p' (drain_{sum}(p, m, p', m') \Rightarrow \top)))
\end{aligned}$$

As outlined in Sec. 3.3, $\text{ToCHC}(\mathcal{P}) = \varphi_{Main} \wedge \varphi_{Ctor} \wedge \varphi_{Reset} \wedge \varphi_{Cap} \wedge \varphi_{Incr} \wedge \varphi_{Dr}$. Next, $\text{ToCHC}(\mathcal{P})$ is strengthened by the predicate template $\Pi_0(\text{CInv})$ to obtain $\text{CHCSynth}(\mathcal{P}, \Pi_0) = \text{ToCHC}(\mathcal{P}) \wedge (\forall m \cdot \forall p \cdot \perp \Rightarrow \text{CInv}(m, p))$. Clearly the term $\perp \Rightarrow \text{CInv}(m, p)$ is trivially satisfied. This is because the predicate template $\Pi_0(\text{CInv})$ is also trivial. In general, this need not be the case. Nonetheless, the term $\text{ToCHC}(\mathcal{P})$ is non-trivial. If $\text{ToCHC}(\mathcal{P})$ is provided to a CHC-solver, then the CHC-solver will return a solution σ containing the following components: expressions $\sigma(Counter_{pre})$, $\sigma(Reset_{pre})$, $\sigma(Capacity_{pre})$, $\sigma(Increment_{pre})$, and $\sigma(Drain_{pre})$, which over-approximate the inputs passed to each function; expressions $\sigma(Counter_{sum})$, $\sigma(Reset_{sum})$, $\sigma(Capacity_{sum})$, $\sigma(Increment_{sum})$, and $\sigma(Drain_{sum})$, which over-approximate the return values of each function; an expression $\sigma(loop_{13})$ which over-approximates the reachable states of the loop in `drain`; an expression $\sigma(\text{CInv})$ which describes a safe implementation for `CInv`. In one solution, $\sigma(loop_{13}) = (p \leq m \wedge (x \neq 0 \Rightarrow 0 < p) \wedge (x = 0 \Rightarrow 0 = p))$. This states that the counter is always in a valid position, and in position zero if and only if the capacity returns to zero. In such a solution, it is also possible that $\sigma(\text{CInv}) = (m > 0 \wedge p \leq m)$. Clearly $\sigma(\text{CInv})$ is an \mathcal{F} -solution since $\sigma(\text{CInv})$ is a conjunction of linear inequalities. Then by Thm. 10, $\Pi : \text{CInv} \rightarrow (m > 0 \wedge p \leq m)$ is a solution to $(\mathcal{P}, \mathcal{T}, \Pi_0)$ with $\mathcal{P}[\Pi]$ both closed and safe. \blacktriangleleft

Like CHC-solving, the general IPS-MP problem is also undecidable. This is because program verification reduces to IPS-MP. Intuitively, if a closed program \mathcal{P} is given to an IPS-MP solver, then a solution to the IPS-MP problem implies that \mathcal{P} is correct, and a witness to unrealizability implies that \mathcal{P} is incorrect. In this way, the halting problem also reduces to IPS-MP.

We show that IPS-MP is undecidable for linear integer arithmetic by reducing the halting problem for 2-counter machines to IPS-MP. Recall that a 2-counter machine is a program with a program counter and two integer variables [48]. The program has a finite number of locations, each with one of four instructions: (1) `inc(x)` increases the variable x by 1 and increment the program counter; (2) `dec(x)` decreases the variable x by 1 and increment the program counter; (3) `jump(x, i)` goes to location i if x is 0, else increments the program counter; (4) `halt()` halts execution of the program. The halting problem for 2-counter machines is known to be undecidable [48].

► **Theorem 14.** *The IPS-MP problem is undecidable for linear integer arithmetic.*

6 From Verification to Synthesis

This section establishes reductions of Sec. 2. Class invariant inference is proven directly. Array abstraction and symmetric ring verification are subsumed by a reduction from parameterized compositional model checking to IPS-MP. Loop invariant synthesis is proven in the extended paper. We write Σ for a first-order signature, \mathcal{V} for a set of variables, and Π_\perp for a collection of predicate templates which maps each predicate to \perp .

```

1  bool PRED_TEMPLATE Inv(int x, int y) {
2    return synth(x, y); }
3  void main(int br, int a, int b) {
4    if (br == 0) {
5      Cls ob = Cls(a);
6      assert(Inv(ob));
7    } else if (br == 1) {
8      Cls ob = *; assume(Inv(ob));
9      ob.f(a);
10     assert(Inv(ob));
11   } else if (br==2) {
12     Cls ob = *; assume(Inv(ob));
13     ob.g(a, b);
14     assert(Inv(ob));
15   } else if (br==3) {
16     Cls ob = *; assume(Inv(ob));
17     func(ob, a); }

```

(a) The input program.

(b) The IPS-MP reduction.

Figure 10 A reduction from class invariant inference to IPS-MP.

6.1 Class Invariant Inference

A *safe class invariant* is a predicate that is true of a class instance after initialization, closed under the execution of each impure class method, and sufficient to prove the correctness of a function taking class instances as arguments [36]. *Class invariant inference* asks to find a safe class invariant given a program. The inference problem is *intensional* if solutions are in the same logical fragment as assertions in the programming language [50]. A definition of (intensional) class invariant inference is found in Def. 15. In this definition, $\text{ToCHC}(f)$ relates the class invariant φ to a summary of each method f in \mathcal{P} , and f_{pre} is used to enforce that f is summarized. For simplicity, a class has two fields and two impure methods, each taking at most two arguments (Figure 10a). A generalization to m methods is not difficult. A generalization to n arguments follows immediately.

► **Definition 15.** A class invariant inference problem is a tuple $(\mathcal{P}, \mathcal{T})$ such that $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$ is an open program as in Figure 10a and \mathcal{T} is a theory. A solution to $(\mathcal{P}, \mathcal{T})$ is a $\varphi \in \text{QFFml}(\Sigma, \{x, y\})$ such that the following are \mathcal{T} -satisfiable:

$$\begin{aligned}\psi_{Init} &:= \forall V (\text{Cls}_{pre}(a) \wedge \text{Cls}_{sum}(a, x, y) \Rightarrow \varphi) & \psi_{Close1} &:= \forall V (\varphi \wedge f_{sum}(x, y, a, x', y') \Rightarrow \varphi') \\ \psi_{Close2} &:= \forall V (\varphi \wedge g_{sum}(x, y, a, b, x', y') \Rightarrow \varphi') & \psi_{Suffic} &:= \forall V (\varphi \Rightarrow \text{func}_{sum}(x, y, a)) \\ \psi_{Sum} &:= \text{ToCHC}(\mathcal{P}) \wedge \forall V (\varphi \Rightarrow f_{pre}(x, y, a) \wedge g_{pre}(x, y, a, b) \wedge \text{func}_{pre}(x, y, a))\end{aligned}$$

► **Theorem 16.** Let $(\mathcal{P}, \mathcal{T})$ be a class invariant inference problem and \mathcal{P}' be the program obtained by adding `main` in Figure 10b to \mathcal{P} . Then Π is a solution to $(\mathcal{P}', \Pi_\perp, \mathcal{T})$ if and only if $\Pi(\text{Inv})$ is a solution to $(\mathcal{P}, \mathcal{T})$.

6.2 Reducing PCMC to IPS-MP

Parameterized compositional model checking (PCMC) is a framework to verify structures with arbitrarily many components (e.g., an array with arbitrarily many cells, or a ring with arbitrarily many processes) by decomposing the structure into smaller structures of fixed sizes [49]. Intuitively, each of these smaller structures is a view of the larger structure from the perspective of a single component. A proof of the larger structure is obtained by verifying each of the smaller structures, and showing that their proofs compose with one another [49]. If the number of smaller structures is finite (i.e., most perspectives are similar), then PCMC is applicable [49]. For example, in Sec. 2.3 and Sec. 2.4, the array and ring were highly symmetric, and therefore, all perspectives were similar.

```

1 bool PRED_TEMPLATE Inv(
2   int l, int s, int, r) {
3   if (init(l, s, r)) { return true; }
4   else { return synth(l, s, r); }
5 void main(int br, struct View v) {
6   if (br == 0) {
7     int inf = *;
8     assume(Inv(v.left, v.st, v.right));
9     assume(Inv(v.right, inf, v.left));
10    v = tr(v);
11    assert(Inv(v.left, v.st, v.right));
12    assert(Inv(v.right, inf, v.left));
13  } else if (br == 1) {
14    assume(Inv(v.left, v.st, v.right));
15    assert(property(v)); }

```

(a) The input program.

(b) The IPS-MP reduction.

Figure 11 A reduction from compositional ring invariant synthesis to IPS-MP. The state of each process and resource are both assumed to be integer values.

Once the larger structure has been decomposed, the proof of compositionality follows by inferring *adequate compositional invariants* for groups of similar components [49]. The number of compositional invariants, and the properties they must satisfy, depend on the decomposition. However, each property is one of initialization, closure, or non-interference. An initialization property states that a compositional invariant is true for the initial state of a component. A closure property states that a compositional invariant is closed under all transitions of its components. A non-interference property states that for any component c , if c satisfies its compositional invariant and an adjacent component (*also satisfying its compositional invariant*) performs a transition, then c continues to satisfy its compositional invariant after the transition. In addition, all composition invariants must be adequate in that they imply the correctness of the larger structure. To make the rest of this section concrete, we restrict ourselves to compositional ring invariants⁶. As in Sec. 6.1, the inference problem is assumed to be intensional. A formal definition of (intensional) compositional invariant inference is given in Def. 17⁷. Note that in Def. 17 ToCHC relates the compositional invariant φ to the summary of tr , tr_{pre} enforces that tr is summarized, and $\varphi_{\text{Inf}} := \varphi[l/r][s/i][r/l]$ is the compositional invariant applied to a process (r, i, l) .

► **Definition 17.** A compositional ring invariant (CRI) inference problem is a tuple $(\mathcal{P}, \mathcal{T})$ such that $\mathcal{P} \in \text{Progs}(\Sigma, \mathcal{V})$ is an open program as in Figure 11a and \mathcal{T} is a theory. A solution to $(\mathcal{P}, \mathcal{T})$ is a $\varphi \in \text{QFFml}(\Sigma, \{l, s, r\})$ such that the following are \mathcal{T} -satisfiable given $\varphi_{\text{Inf}} := \varphi[l/r][s/i][r/l]$:

$$\begin{aligned}
\psi_{\text{Init}} &:= \forall V (\text{init}(l, s, r) \Rightarrow \varphi) & \psi_{\text{Close}} &:= \forall V (\varphi \wedge \varphi_{\text{Inf}} \wedge \text{tr}_{\text{sum}}(l, s, r, l', s', r') \Rightarrow \varphi') \\
\psi_{\text{Adeq}} &:= \forall V (\varphi \Rightarrow \text{property}(l, s, r)) & \psi_{\text{Inf}} &:= \forall V (\varphi \wedge \varphi_{\text{Inf}} \wedge \text{tr}_{\text{sum}}(l, s, r, l', s', r') \Rightarrow \varphi_{\text{Inf}}) \\
\psi_{\text{Sum}} &:= \text{ToCHC}(\mathcal{P}) \wedge \forall V \cdot (\varphi \wedge \varphi_{\text{Inf}} \Rightarrow \text{tr}_{\text{pre}}(l, s, r))
\end{aligned}$$

► **Theorem 18.** Let $(\mathcal{P}, \mathcal{T})$ be a CRI inference problem, \mathcal{P}' be the program obtained by adding `main` of Figure 11b to \mathcal{P} , and Π_0 be the predicate template from Figure 11b. Then Π is a solution to $(\mathcal{P}', \Pi_0, \mathcal{T})$ if and only if $\Pi(\text{Inv})$ is a solution to $(\mathcal{P}, \mathcal{T})$.

⁶ Sec. 2.3 is a degenerate case. In this ring, processes communicate through locks. In an array, cells do not “communicate”.

⁷ In PCMC, a witness to unrealizability does not entail the incorrectness of a structure. Instead, no proof of correctness exists relative to the chosen decomposition.

7 Implementation and Evaluation

We have implemented an IPS-MP solver within the SEAHORN verification framework. SEAHORN takes as input a C program, and returns a CHC-based verification problem in the SMT-LIB format according to Sec. 3.3 [31]. We extend SEAHORN to recognize predicate templates. For each predicate, SEAHORN adds clauses to the verification conditions according to Sec. 5.2. Proofs of unrealizability are generated with the implementation of [28] found in SEAHORN. That is, proofs of unrealizability are already supported by SEAHORN.

The goal of our evaluation is to confirm that:

1. IPS-MP is practical for the reduction described in Sec. 6;
2. CHC-based solvers are more efficient than general synthesis solvers for IPS-MP instances;
3. The overhead incurred when using IPS-MP is tolerable.

Towards (1) and (2), we have collected 92 IPS-MP problems with linear integer arithmetic as the background theory (see **Safe** in Tab. 1). Of these benchmarks, 7 reflect loop invariant inference (and interpolation [47]), 6 reflect class invariant synthesis, 4 reflect array (and memory) abstraction, 2 reflect ring PCMC, 3 reflect procedure summarization, and 70 reflect parameterized analysis of smart-contract (SC) programs (see [66, 67]). The first 20 benchmarks were collected from research papers in the area of software verification. The remaining benchmarks, involving the parameterized analysis of SCs, were obtained by extending SMARTACE with support for IPS-MP. Of these 70 SC benchmarks, 62 are taken from real-world examples used to manage monetary assets [52]. To address question (3), we compare the performance of SMARTACE with and without IPS-MP, relative to these real-world examples. Note that the extension to SMARTACE was a routine exercise, due to the original design of SMARTACE. In particular, SMARTACE encodes all compositional invariants as predicates returning `true`, to then be refined manually by an end-user [67]. These predicates appear in assume and assert statements, as described in Sec. 2.4. Our extended version of SMARTACE can replace these predicates with predicate templates, yielding valid IPS-MP problems.

A summary of all benchmarks can be found in Tab. 1. As reflected by their size (see **Size** in Tab. 1) and total number of unknown predicates across all realizable instances (see **Preds** in Tab. 1), SCs are included to evaluate IPS-MP on large programs. When possible, benchmarks are drawn from prior works in program analysis (i.e., [39, 45, 58, 52]). To reflect unrealizability in IPS-MP, 29 faults have been injected in these benchmarks (see **Buggy** in Tab. 1). Further information can be found about the realizable real-world SC's in Tab. 2. Each SC in this table is associated with one or more safety properties (see **Props** in Tab. 2), which in turn, corresponds to a realizable IPS-MP instance. As before, **Preds** and **Size** indicate the total predicate count and size for these instances. All benchmarks are available at <https://doi.org/10.5281/zenodo.5083785>.

 **Table 2** Overhead of integrating IPS-MP-solving with SMARTACE.

Name	Contracts				Performance (Time)		
	Props	Preds	Size	✓	VERX [52]	SMARTACE (Manual) [66]	SMARTACE (IPS-MP)
Alchemist	3	12	36 MB	3	29	7	208
Brickblock	6	12	122 MB	6	191	13	1214
Crowdsale	9	27	76 MB	9	261	223	238
ERC20	9	27	45 MB	9	158	12	103
Melon	16	32	149 MB	16	408	30	979
PolicyPal	4	16	123 MB	4	20 773	26	3118
VUToken	5	22	319 MB	1	715	19	17
Zebi	5	14	45 MB	5	77	8	487
Zilliqa	5	10	54 MB	5	94	8	501
Total	62	172	969 MB	58	22 706	346	5685

To evaluate IPS-MP, we find the number of benchmarks that are solved by either of two state-of-the-art CHC solvers: ELDARICA [34] and SPACER [42]. To compare CHC solvers to general synthesis tools, we provide our benchmarks to a state-of-the-art specification synthesizer, HORNSPEC [53], and a state-of-the-art SyGUS solver, CVC4⁸ [11]. Since CVC4 solves SyGUS instances, which do not support proofs on unrealizability, then we only evaluate CVC4 on realizable benchmarks (see N/A in Tab. 1). Due to the size of each SC benchmark, we only ran the tools that could solve `Loop` through to `Proc` on these benchmarks. The results for each tool are reported in Tab. 1, where `TO` is the number of timeouts (after 30 minutes), `MEM` is the number of failures due to memory limits, `UN` is the number of benchmarks for which a tool returned `unknown`, `✓` is the number of benchmarks solved, and `Time` is the total time (in seconds) to find all solutions in a given set. In Tab. 2, the total time for SPACER is further broken down by SC (see SMARTACE (IPS-MP) in Tab. 2). For comparison, the verification times for VERX (an automated SC verifier with user-guided predicate abstraction [52]) and the original version of SMARTACE (see SMARTACE (Manual) in Tab. 2) are also provided. All evaluations were run on an Intel® Core i7® CPU @ 1.8GHz 8-core machine with 16GB of RAM running Ubuntu 20.04.

From this evaluation, we answer questions (1) through to (3) in the positive.

- As illustrated by Tab. 1, many examples of class invariant inference and compositional invariant inference (i.e., CLASS, ARRAY, RING, and SC) taken from the literature could be encoded using IPS-MP. In the case of SC, the generation of IPS-MP instances could be fully-automated using a modified version of SMARTACE. We conclude that IPS-MP is practical for the reductions described in Sec. 6.
- As shown in Tab. 1, all small benchmarks were solved by ELDARICA and SPACER, with average times under a minute. Furthermore, all but four SC benchmarks were solved by SPACER within a 30-minute timeout, with an average time of 96 seconds. Upon closer inspection, we found that SPACER would fail to solve these four examples, and would return `unknown` after approximately one hour. However, CVC4 failed to solve any SC benchmarks within 30-minutes. Therefore, we conclude that CHC-based IPS-MP-solving is effective for the reductions of Sec. 6, and can outperform general synthesis solutions. We note that HORNSPEC returned `unknown` on all but two benchmarks⁹.

⁸ To support CVC4, we convert each *realizable* problem from SMT-LIB format to the SyGUS input language.

⁹ The authors of HORNSPEC confirm this result though the cause is unknown.

3. As shown in Tab. 2, the IPS-MP version of SMARTACE incurred an average time overhead of 18x as compared to the manual version of SMARTACE. This should come as no surprise, since the manual version of SMARTACE achieved a verification time of under 3 seconds for 44 of the 62 properties with the help of user-provided compositional invariants. In these cases, a solving time as low as 60 seconds would correspond to an overhead of at least 20x. To better contextualize this overhead, we compare the verification time of IPS-MP version of SMARTACE to the verification time of VERX. We first note the outlying case of POLICYPAL, in which the IPS-MP version of SMARTACE achieves a speedup of over 6x. For the remaining SC’s, the IPS-MP version of SMARTACE fell within 1.3x of VERX on average. Since VERX is a specialized tool with less automation than the IPS-MP version of SMARTACE, we conclude that the overhead incurred by IPS-MP is tolerable in this particular real-world application. We note that in [52], only the “average” times were reported for VERX. It is unclear whether this is the average time to verify all properties, or an average across all properties. The authors of VERX were contacted, but were unable to provide the original data. For this reason, we assume conservatively that all times reported by VERX are total.

One limitation of the evaluation is its emphasis on SC verification. However, compositional SC verification is representative of compositional verification, as illustrated in [66]. We do acknowledge that design patterns specific to SC development might bias the benchmark set. We hope for this benchmark set to be expanded in future work.

Note, however, that we do not plan to benchmark our IPS-MP solver against invariant synthesis tools. Recall that our implementation simply extends SEAHORN with support for the IPS-MP synthesis language. In cases where the IPS-MP instance reduces to invariant synthesis, our extension is bypassed, and verification reduces to executing SEAHORN. Therefore, a direct comparison is not possible, and the evaluation results would not be meaningful. Furthermore, SEAHORN is a state-of-the-art program verifier with prior success in SV-COMP. Thus, SEAHORN is already known to perform well on invariant synthesis tasks.

An important direction for future work is to understand why CVC4 times out on all benchmarks. We hypothesize that the lack of a grammar in IPS-MP proves challenging for CVC4’s enumerative search. We also note that many of our benchmarks produce non-linear CHC’s, whereas the invariant synthesis track for SYGUS reduces to solving linear CHC’s.

8 Related Work

General program synthesis. As explained in Sec. 1, general synthesis engines (e.g., Sketch [61], Rosette [63], SYGUS [5], and SEMGUS [41]) are fundamentally different from IPS-MP. Among these frameworks, only SEMGUS can both solve synthesis problems and prove unrealizability. Similar to IPS-MP, SEMGUS reduces the synthesis problem to satisfiability of CHCs. However, this is where the similarities end. SEMGUS reduces synthesis to unsatisfiability and extracts solutions from the refutation proofs. In contrast, IPS-MP reduces to satisfiability and solutions are extracted from model of the CHCs. SEMGUS solves a more general problem, which comes at a high price both from a theoretical and practical perspective. We show that IPS-MP modulo Boolean programs can be solved in polynomial time (in the number of states), while SEMGUS lacks this guarantee. Existing SEMGUS solvers (e.g., MESSY [41]) synthesize programs from sets of candidates described using regular tree grammars. As a result, their CHCs use constraints over Algebraic Data Types to represent the grammar terms, which are harder to solve than either Boolean or linear arithmetic constraints. Only Sketch and Rosette are “modulo programs”, but do not allow loops nor recursion.

Specification synthesis. Specification synthesis solves the problem of finding specifications for unknown procedures which enable the verification of a given program (e.g., [21, 2, 53]). Unlike IPS-MP, specification synthesis is under-specified. Trivial specifications such as *false* are often sufficient but undesirable. As a consequence, many tools aim to synthesize either *weakest* (i.e., maximal) or non-vacuous solutions. In IPS-MP, any solution is valid as long as it satisfies all program assertions. In Sec. 7, we also compare our IPS-MP solver with HORNSPEC [53] and demonstrate that HORNSPEC is unsuitable for IPS-MP.

Data-driven invariant generation. Multiple approaches have been proposed (e.g., [27, 71, 59, 69, 57, 35]) that rephrase loop invariant synthesis as a learning problem. Recent work has extended these techniques to parameterized verification [70]. Often, these techniques require problem-specific biases to learn useful invariants (e.g., [59, 69, 57, 70]). Furthermore, these techniques lack the complexity bounds of decidable verification. In contrast, IPS-MP is problem-agnostic, and achieves the same complexity as verification in the Boolean case. Adapting data-driven techniques to IPS-MP-solving is an interesting future direction.

Constrained Horn clauses. In recent years, CHC-solvers have become a common tool for verification and synthesis problems. Examples include SEAHORN [31], SEMGUUS [41], and HORNSPEC [53]. The connection between CHCs and verification has long been explored in the CLP community (e.g., [38, 51, 22]). This direction was popularized again by the work of Rybalchenko et al. [30]. According to the annual CHC-COMP competition¹⁰, SPACER [42] and ELDARICA [34] are the most effective general-purpose CHC-solvers.

9 Conclusion

We proposed IPS-MP, a novel synthesis problem suitable for solving a wide range of verification problems, such as invariant inference and verification of parameterized systems. To demonstrate the relevance of IPS-MP, we provided three reductions from classic verification problems to IPS-MP. To highlight IPS-MP’s practicality, we proposed a solution that effectively leverages off-the-shelf CHC solvers and implemented it in the SEAHORN verification framework. Our evaluation demonstrates the effectiveness of CHC solvers in solving IPS-MP when compared with general synthesis tools such as HORNSPEC and CVC4.

Finally, we demonstrated that the interesting instance of IPS-MP for Boolean programs is efficiently decidable, whereas the general instance is undecidable. Despite this, the general instance of IPS-MP is theoretically simpler than general synthesis, and thus, warrants specialized solvers. In future work, we plan to study other instances of IPS-MP, such as IPS modulo timed automata. We further suspect that IPS-MP will enable new practical applications of PCMC.

Abstract

Type systems evolve too slowly to keep up with the quick evolution of libraries – especially libraries that introduce abstractions. Type tailoring offers a lightweight solution by equipping the core language with an API for modifying the elaboration of surface code into the internal language of the typechecker. Through user-programmable elaboration, tailoring rules appear to improve the precision and expressiveness of the underlying type system. Furthermore, type tailoring cooperates with the host type system by expanding to code that the host then typechecks. In the context of a hygienic metaprogramming system, tailoring rules can even harmoniously compose with one another.

Type tailoring has emerged as a theme across several languages and metaprogramming systems, but never with direct support and rarely in the same shape twice. For example, both OCaml and Typed Racket enable forms of tailoring, but in quite different ways. This paper identifies key dimensions of type tailoring systems and tradeoffs along each dimension. It demonstrates the usefulness of tailoring with examples that cover sized vectors, database queries, and optional types. Finally, it outlines a vision for future research at the intersection of types and metaprogramming.

1 Type Tailoring Helps Programmers

Every typed language should come with a *type tailoring* toolkit to let programmers systematically rewrite code before it reaches the typechecker. Tailoring is essential for keeping up with libraries, domain specific languages, and even built-in embedded languages. Consider

44.2 Type Tailoring

regular expressions, which are often embedded in strings. The following example builds a regular expression that matches and extracts a two-digit number from a username. Without tailoring, the Typed Racket typechecker rejects this program:

```
(define dig-pat "[0-9]")
(define two-digs (string-append dig-pat dig-pat))

(define (user-idnum (username : String)) : Number
  (define full-pat (string-append "(" two-digs ")"))
  (define m (regexp-match full-pat username))
  (if m
      (string->number (second m))
      (error "bad username")))

(user-idnum "dent42")
```

Language: Typed Racket

Without Tailoring

Type error: second
argument: (Listof (Option String))
expected result: String

With Tailoring

Success: 42

Programmers fluent in regular expressions know that a call to `user-idnum` returns a number when `regexp-match` succeeds; otherwise, `user-idnum` raises an error. A standard type system knows much less because it ignores the values of strings: it does not know that the first capture group (`second m`) must exist when the match succeeds, and it does not know that the call to `string->number` must also succeed. To resolve these issues, the typechecker requires explicit checks and casts. Type tailoring can insert sufficient casts automatically by analyzing the regular expression string and transforming the program, thereby convincing the typechecker that the code is safe. For programmers, the net result is that the code above just works – without the clutter of casts, and without the need to migrate to an alternative regular expression syntax [58, 95, 107].

Type tailoring improves type analysis by observing and propagating static information. First, a tailoring for regular expressions observes the structure of the pattern string and finds that it has balanced parentheses that enclose a two-digit pattern:

```
(define full-pat
  (string-append "(" two-digs ")"))
```

Tailoring sees: full-pat is a literal:
"([0-9] [0-9])".

If the string were not available for static analysis there would be nothing to observe:

```
(define hidden-pat (read-line))
```

Tailoring sees: hidden-pat is a string.

Second, tailoring propagates information about the pattern string from where it is defined to where it is used. Since this example is implemented in Typed Racket, it uses Racket syntax properties to store and retrieve metadata; other languages use similar mechanisms (Section 3). At the `regexp-match` call, this static information implies that the result of a successful match must be a specific list value:

```
(regexp-match full-pat username)
```

Tailoring sees: since full-pat has one capture group, the match returns either #false or a list of two strings, the second of which consists of two digits.

Third, tailoring elaborates (rewrites) the `regexp-match` call to cast a successful match result, thereby communicating the structure of the result value to the typechecker. Similarly, tailoring can elaborate the access (`second m`) to a faster, unsafe memory access because it is sure to be in bounds when the match succeeds:

```
(if m (second m) ...)
  ~~ (if m (unsafe-ref m 1) ...)
```

Tailoring sees: since `m` is a list in this branch, it has two strings.

Information about the extracted string flows into a tailoring for `string->number` and justifies a final cast to convince the typechecker that the result must be number.

```
(string->number •)
  ~~ (cast (string->number •) Number)
```

Tailoring sees: the cast cannot fail because `•` evaluates to a two-digit string.

Stepping back from this example, the overall message is that incorporating a bit of partial evaluation, flow analysis, and metaprogramming into the front end of a conventional typechecker is an effective way to support domain-specific typing for embedded languages. Type tailorings can compose with one another and can enhance an entire module with a few changes to its preamble (e.g. by importing a tailored regular expression library) rather than whole-program edits. There is of course a risk that arbitrary tailorings can perform unexpected or unsafe elaborations, but we show in Section 5 how the authors of tailorings can mitigate these concerns by appealing to baseline program behavior and static information.

Contributions

Type tailoring has appeared in many contexts, but never as an officially-supported language feature. This paper analyzes the spectrum of type tailoring across languages and libraries, identifies the linguistic features that make tailoring work, and establishes a framework for future research to push the boundaries of *end-user* programmable type elaboration. Concretely, the paper makes the following contributions:

- it proposes *type tailoring* as an overarching concept in user-level metaprogramming that should be recognized and more-widely adopted;
- it demonstrates the usefulness of tailoring with a variety of examples using Typed Racket, Rhombus, Julia, and Elixir (Section 2);
- it analyzes tailoring systems along six technical dimensions (Section 3), thereby revealing three notable points in the language design space (Section 4); and
- it provides a recipe for reasoning about the behavior of tailorings and establishing the validity of their transformations (Section 5).

The paper concludes with related work (Section 6), future work (Section 7), and takeaways (Section 8).

2 Tailoring in Action

To illustrate the variety of type tailoring, this section presents five examples in four languages: a tailoring framework and type programming in Typed Racket [102], dynamic typing in Static Rhombus [33], sized arrays in Julia [7], and statically-checked web routes in Elixir [28]. Each example contributes a unique perspective to showcase the range of type tailoring applications. Typed Racket supports a family of related tailorings, Rhombus weakens types instead of strengthening them, Julia achieves order-of-magnitude performance improvements, and Elixir shows how tailoring can benefit an untyped language.

2.1 Refining Data in Typed Racket

Typed Racket enables type tailoring by exposing key pieces of Racket’s macro API and by typechecking code after macro expansion [21, 104]. Macros can thus inspect and transform code to manipulate what the typechecker sees. The `trivial` library [40, 41] uses this API to tailor a variety of domains from `printf` strings to SQL queries and beyond.

44:4 Type Tailoring

Format Strings

For `printf`, tailoring uncovers static information from escape characters in format strings. This tailoring stores information in a dictionary, mapping the key `fmt-args` to the expected types of the remaining arguments of `printf`. (Through the use of a key-value store, multiple tailorings can work together, as we will see later in this section.)

```
(require trivial)          Typed Racket
(define fmt1 "hello ~a\n") :: { fmt-args : [any] }
(define fmt2 "int to bin: ~b\n") :: { fmt-args : [Integer] }
```

Calls to `printf` statically check whether their first argument has format information. When this information is present, the tailoring checks the number and type of other arguments and raises an error at compile time if there is a mismatch. Without tailoring, such checks do not happen until runtime:

```
(printf fmt1 "world")
(printf fmt1 "john" "hancock")
(printf fmt2 "NaN")
```

Typed Racket

Without Tailoring

- Runtime errors: `printf`
 - `[fmt1]` expected 1 argument, given 2
 - `[fmt2]` expected an integer, given something else

With Tailoring

- Tailoring errors:
 - `[fmt1]` expected 1 argument, given 2
 - `[fmt2]` expected Integer, given String

Query Strings

For SQL queries, two sources of information come together to provide static checks via tailoring: database schemas and query strings. Programmers must write the schemas as type annotations in a notation specified by the SQL tailoring. Query strings use conventional SQL syntax to access the database. The tailoring parses query strings to reveal type constraints.

In the following example, the schema argument states that the database has one table named `Cats` with three columns for an identifier, pet name, and breed. Tailoring elaborates the `query-row` call to validate argument types. Without tailoring, the database executes the nonsensical query and returns an empty result:

```
(define db
  (sqlite3-connect #:user "user"
                  #:database "Pets"
                  #:schema [Cats
                            [(id : Integer)
                             (name : String)
                             (breed : String)]]))

(query-row db
           "SELECT breed FROM Cats
            WHERE name = ?"
           69105)
```

Typed Racket

Without Tailoring

- Runtime error: `query-row`
query returned zero rows

With Tailoring

- Tailoring error:
expected String, given Integer

This tailoring additionally propagates information about the result of a query. When a query selects only the `breed` column, the result is a vector with only one string value:

```
(query-row db          Typed Racket
           "SELECT breed FROM Cats
            WHERE name = ?"
           "mittens") :: { type : (Vector String) }
```

While the `regexp-match` example from Section 1 and the `printf` example from this section improve code with no effort from users, the SQL tailoring cannot act without a schema as input. But, since the tailoring works through surface syntax, it can get this input in an idiomatic way without being constrained by the typechecker or host language. In particular, tailoring adds support for the `#:schema` argument by parsing the schema and elaborating to a plain `sqlite3-connect` call with only two keyword arguments.

Cooperating Tailorings

Static information embedded in strings can be useful in domains beyond `printf`, database queries, and regular expressions. By storing domain-specific information in a dictionary and using uniquely generated keys (Section 3.4), different tailorings can annotate the same value. For example, the following string has at least three interesting properties:

```
(define str          Typed Racket
  "(SELECT breed FROM Cats)") :: { rx-groups : 1
                                     db       : [SELECT (breed) Cats]
                                     string-len : 24 }
```

Of course, strings are not the only data structure that get repurposed in domain-specific ways. Vectors, lists, functions, and numbers also benefit from tailoring:

```
(define buffer        Typed Racket
  (make-vector (expt 2 5))) :: { vector-len : 32 }

(define (swap ab)
  (list (second ab) (first ab))) :: { fn-arity : 1 }

(define pairs '((1 2) (3 4)))
  :: { list-len : 2 }
(map swap pairs) :: { list-len : 2 }
```

In all cases, there is a general recipe at hand:

- Static information originates in surface syntax, such as the characters in a string literal or the shape of a function declaration. Information can also come from an external source, such as a database schema or online API specification.
- When static information is present, type tailoring attaches it to variables and propagates it through operations such as `map` and `regexp-match`.
- Tailoring elaborates surface syntax to code that the host typechecker can understand.

Defining a new tailoring requires three steps. First, define a unique key (e.g. via `gensym`). Second, create tailored variants of constructors that identify and attach static information. Third, create wrapper macros (i.e., compile-time functions) around various operations to leverage static information when it is present and otherwise preserve the default behavior.

Evaluation: Typing Regular Expressions

Regular expression tailoring comes with immediate benefits for typed code because, by default, programmers must use casts to guard against match failures even when such failures obviously cannot occur. In Typed Racket, the need for casts arises from the conservative

44:6 Type Tailoring

type of `regexp-match` results, which says that all match results are either `#false` or lists with one string element and an unknown number of additional elements that are either strings or `#false`. This type is always correct but usually too imprecise to be useful:

```
(regexp-match full-pat username)
: (Option (Pairof String (Listof (Option String))))
```

Typed Racket

Searching the Racket 6.5 distribution and code on its package server revealed 160 files using `regexp-match` with capture groups. Migrating the files to use type tailoring obviated the need for casts in 116 originally-untyped files and 6 typed files. These improvements resolved a total of 329 false type errors (that Typed Racket would have reported) across 93 % of all `regexp-match` occurrences in the dataset [108].

Only 38 files were not improved by tailoring. Most of these files (20 of 38) extracted a capture group, but did not depend on the result being a string. The others either used non-constant pattern strings (5 files), used helper functions to assemble patterns (9 files), or used patterns with groups that may indeed fail to capture – such as "(a)|(b)" (4 files).

Evaluation: Predicting Vector Bounds

Racket library code occasionally employs fixed-size vectors. For example, the built-in `gzip` implementation declares vector constants to implement a Huffman tree. When these vectors get accessed with a statically-known index, tailoring can refine code to skip the bounds check.

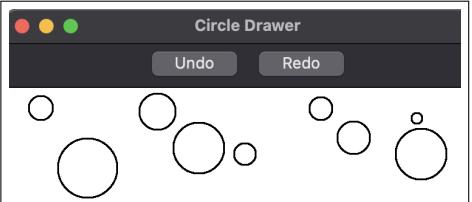

Across the Racket core distribution and packages, we found 88 files using vector constants. Tailoring eliminated bounds checks in 11 files. This number is low, but within these few files, tailoring improved 104 bounds checks in total. Most of these (80 of 104) appear in a Parcheesi implementation that uses a macro to generate code that accesses valid locations; this example shows that tailorings are robust even when other metaprogramming is present.

2.2 Elaborating Types in Typed Racket

Types themselves can benefit from tailoring. Since types are mere syntax before the type-checker gives them meaning, tailoring can elaborate declarative syntax into fine-tuned types.

Concise GUI Subtypes

Felleisen's implementation [29] of the 7GUI benchmark [53, 54] uses tailoring to simplify class type declarations. In Typed Racket, subclasses must declare types for all inherited methods and fields. While this requirement means that a subclass may refine the types of methods defined in its superclass, it also imposes a significant burden on programmers. In 7GUI, subclasses of the `Canvas%` type would normally have to spell out the types of thirteen methods. Type tailoring lets programmers specify just the differences from the parent class:

```
(define-type-canvas Circle-Canvas%
 #:minus-init (paint-callback)
 (unlock (-> Void))
 (draw-circles
 (-> (Optional Circle)
 (Optional (Listof Circle))
 Void)))
```

TR

Without Tailoring	With Tailoring
13 method declarations (not shown)	2 method declarations, 1 subtraction

The tailored 7GUI specification for a circle-drawing canvas simply gives the name of one constructor input to remove (`paint-callback`) and the types for two methods to add: an `unlock` method to freeze the canvas (`lock` is private) and a method to draw circles on the canvas. Without tailoring, this specification would require twelve redundant names and types from the parent class.

Functional-Style Object Types

The `zombie` program from the GTP benchmark suite [42] presents an example of types tailored for readability. The original, untyped program uses functions to mimic message-passing objects [106]. Equipping such a program with types is challenging. For example, the function `new-zombie` takes a coordinate pair (`Posn`) and returns another function (`Zombie`) from a symbol to a method representation. These method representations are pairs that combine a label and function. In the code below, there are two methods that have different types:

```
(define (new-zombie p) ;; Posn -> Zombie
  (λ (msg)
    (case msg
      [(can-grab?)
       (cons 'can-grab? ;; Method 1: Posn -> Bool
             (λ (q) (<= ((posn-dist p) q) *grab-radius*)))
      [(move-to)
       (cons 'move-to ;; Method 2: Posn -> Zombie
             (λ (q) (new-zombie ((posn-move-to p) q *speed*))))]
      [else
       (error "unknown message")])))
```

Typed Racket

Although Typed Racket can express the overloaded return type for a `Zombie` object (via singleton types for labels [44]), writing such types requires intimate knowledge of the encoding. With tailoring, the types can essentially match Typed Racket's object type syntax:

```
(define-type Zombie
  (-> Symbol
    (U (Pair 'can-grab? (-> Posn Bool))
        (Pair 'move-to (-> Posn Zombie)))))
```

Typed Racket

```
(define-obj-ty Zombie
  [can-grab? (-> Posn Bool)]
  [move-to (-> Posn Zombie)])
```

TR

Without Tailoring

Encoding with pair and union types

With Tailoring

Domain-specific representation

Type Expanders

The type expanders library [94] can build types such as `Zombie` and `Circle-Canvas%` *within* another type, without the need to declare a top level definition via `define-type`. The following example, from the library documentation, presents a type expander `HomogeneousList` that uses an integer literal to expand to a `List` type:

```
(: five-strings (-> String (HomogeneousList String 5)))
(define (five-strings x)
  (list x "a" "b" "c" "d"))
```

Typed Racket

Without Tailoring

`(List String String String String String)`

With Tailoring

`(HomogeneousList String 5)`

Type expanders supports a wide range of additional tailorings. These include type abstraction (Λ) and local definitions in types (`Let`).

2.3 Relaxing Types in Rhombus

Rhombus enables tailoring in the same manner as Typed Racket by inheriting Racket's metaprogramming tools [33]. To illustrate, we equip the static variant of Rhombus (akin to strict JavaScript [25]) with a dynamic type (`Dyn`) in the spirit of optional and gradual typing [92, 100, 101]. Gradually typed languages are often defined by elaboration into a typed language with casts, making them a natural application for tailoring.

Rhombus comes with an annotation language that can, among other things, statically resolve method calls. For example, a function whose argument has the `List` annotation knows where to find the appropriate `length` method for this argument:

```
fun len_plus_one(l :: List):
    l.length() + 1
```

Static Rhombus

Static Rhombus requires annotations for the receivers of all methods calls, all list and map lookups, and similar operations [80]. It uses these annotations to guard against errors and to compile optimized code. Getting the annotations right can become a burden, as the long history of gradual typing attests [39, 68, 93, 103]. It would be useful to selectively disable the requirement, but by default Rhombus provides only a coarse-grained solution via a keyword `use_dynamic` that disables annotation requirements within an entire block of code.

The `Dyn` tailoring is an annotation that selectively disables static checks for an individual variable without losing guarantees in other parts of the same code block. This can be useful, for example, to implement a dynamic equality function for lists:

```
fun list_equals(l1 :: List.of(Dyn), l2 :: List.of(Dyn)):
    def len = l1.length()
    len == l2.length()
    && for all (i: 0..len):
        l1[i].equals(l2[i])
```

Static Rhombus

Without Tailoring

Compile error: `l1[i].equals`
`no such method based on static information`

With Tailoring

Success

Static Rhombus accepts this code and resolves the call to `.equals()` at runtime. Other calls, such as `l1.length()` and the `for`-comprehension iterator, resolve statically.

Evaluation: Using Dyn in Shplait

Shplait is a typed, ML-like language developed for teaching and implemented in Rhombus [33]. It is one of the largest Rhombus programs to date. Within the Shplait codebase, there are 84 type annotations that appear in function, variable, and class definitions. These annotations appear in 21 of the 46 core Shplait files. Replacing these annotations with `Dyn` does not raise any compilation errors. The only difficulties that arose were due to import clashes with operations that `Dyn` overrides (such as `++`), which were straightforward to resolve by importing `Dyn` with a prefix.

2.4 Static Arrays in Julia

Array accesses in Julia incur a runtime bounds check by default. This check can become a significant and unnecessary cost in scientific code. For example, the coordinates for bodies in an N -body simulation might be stored in fixed-length arrays that get accessed in a highly repetitive pattern. A bounds check on each access would quickly incur a significant and unnecessary performance cost.

The StaticArrays package implements a form of type tailoring that elaborates normal-looking array code into fixed-size tuples [97]. To declare a static array, programmers wrap a normal array declaration in the `@SVector` macro. The package supports several kinds of declarations, including array comprehensions:

<code>vec1 = @SVector [1]</code>	<code>Julia</code>	:: { <i>vector-len</i> : 1 }
<code>vec3 = @SVector zeros(3)</code>	<code>Julia</code>	:: { <i>vector-len</i> : 3 }
<code>vec9 = @SVector [i^2 for i = 1:9]</code>	<code>Julia</code>	:: { <i>vector-len</i> : 9 }

In addition to array constructors and references, StaticArrays tailors a variety of linear algebra operations to use size information. Matrix multiplication, transposition, and reshaping can all propagate sizes. Eigenvalue decomposition uses a fast algorithm for small matrices:

<code>m3 = @SMatrix randn(3,3)</code>	<code>Julia</code>	:: { <i>matrix-shape</i> : (3, 3) }
<code>eigen(m3).values</code>	<code>Julia</code>	:: { <i>vector-len</i> : 3 }

Elaborating arrays to tuples is impractical for large arrays in Julia; the StaticArrays documentation recommends 100 elements as a rule-of-thumb upper bound. Nevertheless, StaticArrays is an important part of the Julia ecosystem. As of January 2024, it has over 800 direct dependents and 3,000 indirect dependents (30 % of the 10,292 packages on JuliaHub). One of its clients is the popular OrdinaryDiffEq package [89], which helps explain the large number of indirect dependents.

Evaluation: Fast Matrix Rotations

The documentation for StaticArrays reports order-of-magnitude speedups on a variety of linear algebra microbenchmarks using 3×3 matrices [97]. Examples include a 5.9x speedup for matrix multiplication, a 113x speedup for determinant computation, and a 8.8x speedup for Cholesky decomposition. We built our own microbenchmark that rotates a vector by a 10×10 matrix one hundred million times. The results in Table 1 show a 10x speedup and a dramatic decrease in memory use thanks to inlining and predictable array layout. These numbers are the average after two hours of sampling with `BenchmarkTools.jl` in Julia 1.8 on a single-user Linux machine with 4 physical i7-4790 3.60GHz cores and 16GB RAM.

Table 1 StaticArrays yields a 10x speedup on a synthetic matrix rotation benchmark.

	mean (stddev)	Memory Use	GC % (stddev)	samples
Without Tailoring: Arrays	10.7 s (8.3 ms)	13 GB	1.7% (0.07%)	671
With Tailoring: StaticArrays	1.5 s (8.9 µs)	0 B	0% (0%)	4856

2.5 Verified Web Routes in Elixir

The Phoenix web framework [76] uses Elixir’s macro system to validate web routes. Programmers declare routes and corresponding handlers in a dedicated module. Phoenix leverages information from the route module in a three-step validation process: first, it collects route references that marked by a certain macro (`~p`); second, it elaborates these marked references into plain strings; and third, it checks that each reference has a matching handler.

Route references commonly appear in page templates. For example, the following template code block contains the references `/users/register` and `/users/login`. Suppose that the second route has a typo, and the correct path is `/users/log_in` with an underscore. Without tailoring, routes are mere strings; a typo in a route name is not a problem until a user requests the page and gets a 404 error. With tailoring, a static check catches the error immediately.

```
<p>
  <%= link "Register", to: ~p"/users/register" %>
  <%= link "Log in", to: ~p"/users/login" %>
</p>
```

Elixir

Without Tailoring

Possible 404 at runtime

With TailoringTailoring error:
no route path matches /users/login

Thus, even a dynamically typed language such as Elixir can benefit from domain-specific static checks during the elaboration of source code to baseline Elixir. Prior work in Scheme illustrates the same point in several other domains [45], though at a much smaller scale than Phoenix. Ruby on Rails [6] and Haskell [66] have their own methods of static route validation; this is a common issue that tailoring helps to solve.

Evaluation: Adoption Data

Phoenix introduced verified routes in February 2023 [65]. They are an optional feature for existing projects, while for new projects Phoenix generates code with verified routes by default. As of January 2024, over 1,800 Elixir files on GitHub are using verified routes [36].

3 Dimensions of Tailoring Systems

Many languages and libraries support a form of type tailoring. Examples include the macro systems in Clojure [18], Scala 2 [9], Scala 3 [87], and Rust [86]; elaborators in Idris 1 [13]; Template Haskell [90]; OCaml PPX [70], MetaOCaml [52], and MacoCaml [110]; CompRDL [50]; and type providers in the style of F# [14, 75]. Despite differences in their specific aims and affordances, they all enable metaprogramming of the elaboration from surface code into typechecked code.

As a step toward an analysis of language support for tailoring and of relative strengths and weaknesses, this section introduces a framework of *technical dimensions* (inspired by prior work [38, 46]) for type tailoring. The dimensions fall into two groups: the first four describe metaprogramming features, and the last two describe contextual information that may be available to tailoring:

Metaprogramming Features

Metadata. For tailoring to work together, they must have a way of sharing static information. Metaprogramming systems that can attach metadata directly to AST nodes enable this sharing in a direct way. (Compile-time state is an alternative.)

Binding. How to handle bindings is a crucial aspect of information sharing. Information must be able to flow from a variable declaration to its use. Metaprogramming systems can discover these connections and expose them to tailoring.

Order. Cooperating tailoring need a reliable and customizable order of expansion. One tailoring might depend on input from another, and it may wish to have a third tailoring analyze its output.

Hygiene. To a first approximation, a hygienic metaprogramming system respects the lexical structure of code. Hygiene is important for tailoring to compose with one another and with user code. Users, for example, should not need to worry about whether the `f` in `f(x)` is a tailoring (e.g., a macro) or a normal function.

■ **Table 2** Technical dimensions of tailoring systems.

System	Metaprogramming				Context	
	Metadata	Binding	Order	Hygiene	Definitions	Types
Racket	●	●	●	●	●	×
Clojure	●	●	●	○	●	×
Elixir	●	✗	●	●	●	✗
Julia	○	✗	●	○	●	✗
Idris 1	✗	○	○	✗	●	●
Scala 3	✗	✗	●	●	●	●
Template Haskell	✗	✗	○	●	○	✗
Type Providers	✗	✗	✗	✗	●	○
OCaml PPX	○	✗	✗	✗	○	✗
Rust	✗	✗	○	○	●	✗

● Full support ○ Partial support ✗ No support

Context Information

Definitions. Tailorings benefit from local definitions and external data, such as a database, as sources of static information. Without definitions, tailorings are limited to local transformations such as refining calls to `printf` that apply a literal format string.

Types. Type context is a dimension that has benefits and drawbacks. On one hand, if tailorings receive typechecked input then they can leverage the types and need not handle malformed syntax. On the other hand, types restrict the shape of domain-specific syntax to terms of the host language.

Table 2 presents an evaluation of representative tailoring systems along these technical dimensions. The rows are *not* an exhaustive list of tailoring systems but rather give an overview of distinct feature-sets. For example, there is no row for Rhombus because it has the same feature set as Racket. The table suggests two high-level takeaways:

1. A number of systems lack support along several dimensions. These represent trade-offs that realize some benefits at a modest effort. Section 4 examines three points in depth.
2. No system has full support along every dimension. Section 7 presents ideas for designing a full-featured system as future work.

The rest of this section explores the cells of Table 2 in detail. For each dimension, a subsection provides a detailed description of what it means and justifies the partial cells (○). The last subsection gives a concrete implementation of a tailoring for static vector references; this example shows how one tailoring benefits from several dimensions.

3.1 Metadata

Static information is metadata. Examples include the length of a string literal, the capture groups in a regular expression, and the schema of a database. Tailorings discover this metadata, and they need a way to disseminate it to reap the benefits. For example, discovering the length of a literal vector may be useful by itself, but it is more useful if length information can propagate through operations such as vector concatenation.

Attaching metadata to AST nodes is a direct way to propagate information. Any piece of syntax – whether it describes a value, an expression, or a definition – should support metadata. Furthermore, as the examples from Section 2.1 demonstrate, the metadata should

be a key-value store that can hold data structures as values. Keys clarify the interpretation of data such as numbers, which, in the examples, represent lengths and regexp groupings. Structured values declaratively express format-string constraints and database schemas.

Racket [78], Clojure [19], Rhombus [81], and Elixir [27] support general key-value metadata on arbitrary nodes. Julia [48] and OCaml [70] support a limited form of metadata; only a specific type of AST node can hold metadata. These metadata nodes can, however, be inserted as siblings to other nodes in the syntax tree. To the best of our knowledge, the other systems in Table 2 have no direct support for metadata, though Idris has highly-expressive dependent types that can achieve similar goals.

3.2 Binding

Variable declarations call for a special kind of metadata that flows from a binding to its references. Consider a basic `let` expression that binds a format string to a variable `str`; a tailoring system should ensure that calls to `printf` within the body have access to format metadata:

```
(let ([str "age: ~a"])
  ...
  (printf str n) ;; need data here
  ...
  (lambda (str) (printf str n))) ;; but not here
```

Racket

In Racket and Rhombus, *rename transformers* flow data to references [79]. Clojure has libraries for similar functionality [17, 64]. None of the other systems support renaming in a programmatic manner, which means that the authors of tailorings need to manage propagation on their own – perhaps by handcrafting AST structures.

3.3 Order

Control over the order of elaboration makes it possible for tailorings to share their results with one another. For example, static-length vectors and constant folding are somewhat useful in their own right, but are more effective together:

```
(define buf-size (* 4 4))      Typed Racket :: { int-value : 16 }
(define buffer (make-vector buf-size)) :: { vector-len : 16 }
(sub1 (vector-length buffer))    :: { int-value : 15 }
```

Unlike in a normal metaprogramming system, it is crucial that the order of elaboration matches the order of runtime evaluation. The tailoring for `make-vector` must happen after the tailoring for multiplication, and the tailoring for `sub1` must happen last of all because it depends on the first two results.

Clojure macros give control over ordering in a simple way through a `macroexpand` directive [69] inherited from Lisp [98] and Scheme [23]. Julia [49] and Elixir [27] provide a similar directive. This method is unhygienic, and may cause problems when macros depend on one another [31]. There are several alternative forms of sequencing that fall short of arbitrary ordering. Elixir provides compile-time hooks to register code that runs before and after a module compiles; these hooks let Phoenix (Section 2.5) verify routes after registration. Template Haskell allows stacks of tailorings, but programmers must manage them explicitly by wrapping each piece of syntax in a suitable number of template quotes [90]; the Haskell type system does help to manage the layers. Idris elaborators require similar management [13]. Rust macros can expand to other macros that have been defined in a separate crate [86]. Type providers in F# cannot expand to one another [75]. OCaml PPX recommends that users do not rely on the order of expansion [70].

3.4 Hygiene

A hygienic metaprogramming system enables composable tailorings. Macro hygiene ensures that compile-time transformations respect the binding structure of the code they manipulate. A classic illustration is an `or` macro that introduces a temporary variable:

```
(defmacro or (a b)
  '(let ((tmp ,a))
    (if tmp tmp ,b)))
```

Common Lisp

If a call to this macro simply replaces code, the `tmp` variable can shadow a binding and produce the wrong result:

```
; ; before expansion
(let ((tmp 42))
  (or nil tmp))
;; expected result: 42
```

```
; ; after unhygienic expansion
(let ((tmp 42))
  (let ((tmp nil))
    (if tmp tmp tmp)))
;; actual result: nil
```

A second hygiene issue concerns references from macro definitions to functions. For example, the SQL tailoring from Section 2.1 relies on helper functions to analyze strings. If the helpers’ names were to get shadowed at the macro use-site – as is the case with unhygienic systems – the tailoring would crash or produce flawed results.

A third related issue is that tailorings ought to work as a drop-in replacement in user code. Code that calls a standard function such as `make-vector` should work with a tailored variant instead, without the programmer needing to annotate the call site as a macro call rather than a function call. Since functions are typically first-class values, this means that macros must work hygienically in first-class use-sites.

Lastly, the keys used to label static information need a form of hygiene. If two tailorings inadvertently choose the same key, they may attach conflicting information to a value. Tailoring systems must provide a facility to generate unique keys – such as `gensym` in Julia and other languages – to prevent clashes.

Racket [32], Rhombus [33], Elixir [27], Scala 3 [88], Template Haskell [90] all support macro hygiene. Julia is hygienic for simple macros, but in complex macros programmers must manually rename variables to avoid issues [49]. Rust’s support for hygienic macros is currently experimental [51, 86]. F# type providers, OCaml PPX [70], Idris [13], and Scala 2 [9] provide no support for hygienic macros.

3.5 Definitions in Context

There are two aspects of definitions that relate to tailoring. The first and most important is access to external data, whether it be a relational database (Section 2.1), a manifest of web routes (Section 2.5), or a JSON endpoint [75]. To add two more examples to the mix, CompRDL uses domain-specific knowledge of Ruby on Rails and database schemas to achieve dependent types for table functions [50], and the Rust SQLx library checks the well-formedness of query strings [59]. Both leverage external data to analyze code without asking programmers to change their idiomatic code (conventional Rails in Ruby, raw SQL in Rust). Every tailoring system in Table 2 provides access to external data.

The second aspect of definitions is access to local variables and helper functions. As mentioned in Section 3.4, a tailoring that parses query strings benefits from access to helper functions. (Without access, the tailoring must duplicate code in its definition, which then increases the size of the object code.) Most systems provide access to local definitions, though

in the context of unhygienic systems this must be done with care. Template Haskell code can access local definitions but is subject to Haskell’s disciplined use of side effects [90]. OCaml PPX runs macros in isolation, so they cannot use compile-time definitions [70].

3.6 Types in Context

In Scala, the typechecker validates input to macros as well as the expanded code. Types provide extra context to tailorings and detect certain malformed input. However, types also put restrictions on inputs. In the Squid metaprogramming framework for Scala 2 [74], programmers typically wrap code in quasiquotes to bypass the surface typechecker. The following example is from the Squid documentation [73]:

```
val powCode = code"${(x: Variable[Double]) => mkPow(code"$x", Const(n))}"
```

After some syntactic adaptations, the expanded code is thoroughly typechecked. (Squid also accepts Scala code fragments directly; these inputs must be well-typed.)

Idris distinguishes between typed and raw terms during elaboration [13]. All terms must eventually pass the typechecker, but elaboration can manipulate both sorts of terms. The other systems in Table 2 do not typecheck their input, though type providers can effectively rely on types because their inputs are restricted to literal constants. There are, however, several metaprogramming systems in the literature that do typecheck their inputs. Examples include SoundX (which furthermore guarantees well-typed transformations) [62], Wyvern [71], Dependent ML [109], and Scala 2 [9].

3.7 Essential Non-Dimensions

Table 2 focuses on elements that are significant for tailoring but lack full adoption. As such, it omits basic features that enable type tailoring. The following are requirements rather than dimensions, but they are nevertheless important for language designers to know about:

Typechecking After Elaboration Regardless of whether or not typechecking happens before elaboration, it must happen afterward to check the results of user-defined tailorings.

Elaboration-Time Computation Tailorings need infrastructure, such as procedural macros, to perform non-trivial computations. By contrast, pattern-based macros (which unpack the syntax of their call-site and rearrange it [56]) cannot even read from an external file.

AST Datatype Without an AST datatype, tailorings are limited to using a token stream as input and output (e.g., in Rust [86]). Token streams cannot carry metadata (though it might be stored off to the side) and must be parsed to find their binding structure.

3.8 Example Tailoring Implementation

Let us show how the dimensions work together with an example that tailors vector references in Racket. This demo replaces `vector-ref` with either a fast `unsafe-vector-ref` or an error when it finds both a literal vector and a literal index; otherwise, it leaves the reference as is:

```
(vector-ref (vector 5 2 8) 1)  ~>  (unsafe-vector-ref (vector 5 2 8) 1)
(vector-ref (vector 4 9 1) 4)  ~>  error: out-of-bounds
(vector-ref (read-vec) 9)     ~>  (vector-ref (read-vec) 9)
```

See the documentation of the `trivial` library [41] for a full-featured implementation that works for identifiers as well as data literals.

The six code blocks below define the `vector-ref` tailoring. When defining the tailoring, we use the name `tailored-vector-ref` to avoid shadowing the base `vector-ref` function. On export, we rename this tailoring to `vector-ref` so clients of this library can use the tailored version as a drop-in replacement in their code:

```
(provide
  (rename-out [tailored-vector-ref vector-ref]))
```

Racket, 1/6

The tailoring module imports `unsafe-vector-ref` for use in expanded code, and three other libraries to define the tailoring:

```
(require
  (only-in racket/unsafe/ops unsafe-vector-ref)
  (for-syntax ;; import these things for macros
    racket/base syntax/parse (only-in "tailoring-api.rkt" ~φ V I)))
```

Racket, 2/6

The helper module `tailoring-api.rkt` is a small wrapper over Racket's metaprogramming facilities. Specifically, it provides a bridge for the following dimensions:

Order of expansion (\rightsquigarrow) The syntax class \rightsquigarrow triggers macro expansion on a subexpression, allowing the tailoring to discover static information.

Metadata (ϕ) The function ϕ uses Racket syntax properties to store and retrieve static information using domain-specific keys.

Hygiene (V, I) The keys V and I are unique gensyms for vector length and integer value information. (Under the hood, `tailoring-api.rkt` registers such information when it encounters relevant data literals during expansion.) Uniqueness means that other tailorings cannot accidentally use the same names and cause a collision; however, it does not stop a malicious tailoring from writing bad information using the keys.

For details on `tailoring-api.rkt`, refer to the artifact for this paper.

The tailoring itself is a macro so that it can statically rewrite source code. First, it parses its input syntax object (`stx`) to extract and expand two subexpressions:

```
(define-syntax (tailored-vector-ref stx)
  (syntax-parse stx
    [(_ e1:~φ e2:~φ)])
```

Racket, 3/6

The expanded form of subexpression `e1` is available as `e1.~φ`, and similarly for `e2`. The tailoring checks whether these expanded expressions have the static information that it needs; specifically, it needs a vector length (key: V) and an integer value (key: I):

```
#:do [(define n (φ (syntax e1.~φ V)))
       (define i (φ (syntax e2.~φ I)))]
#:when (and (integer? n) (integer? i))
```

Racket, 4/6

If the information is present, the tailoring checks whether the index is in bounds and expands to code that either performs a fast vector reference or raises an exception:

```
(if (and (≤ 0 i) (< i n))
    (syntax (unsafe-vector-ref e1.~φ e2.~φ))
    (syntax (error 'Index-Exn))))
```

Racket, 5/6

Otherwise, the default behavior is whatever Racket's un-tailored `vector-ref` does:

```
[(_ e1:~φ e2:~φ)
  (syntax (vector-ref e1.~φ e2.~φ)))]
```

Racket, 6/6

With that, the tailoring is complete. A Racket program can import this tailoring to replace the default `vector-ref`:

44:16 Type Tailoring

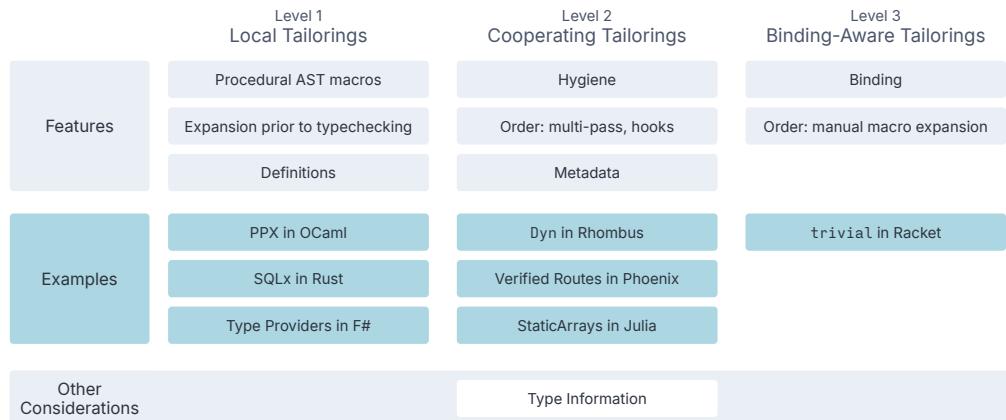

Figure 1 Three levels of support for type tailoring.

(vector-ref (vector 5 2 8) 1)

Racket

Without Tailoring

No change; use checked lookup
(vector-ref ...)

With Tailoring

Use unsafe, fast lookup
(unsafe-vector-ref ...)

In summary, tailoring `vector-ref` relies on a specific *order of expansion* to receive *metadata* about subexpressions, it extracts that metadata in a reliable way that composes with other tailorings using macro *hygiene*, and it relies on several *definitions* from the Racket standard library such as `<=` to compare numbers and Racket's `vector-ref` to provide a default behavior. Thus, four technical dimensions come together in this one example. Both the tailoring and its helper module are defined in user code; they require no changes to the Racket language to seamlessly improve client code.

4 Design Space Reflections

Tailoring systems come in wide variety in the literature, and yet they all enable at least some similarly-useful applications. For example, OCaml PPX achieves a pinch of dependent typing, F# type providers give an early warning when a web service changes its API, and Julia StaticArrays can propagate array dimensions. None of these systems can propagate metadata through binding forms, but their implementations are simpler than those that do. This tension suggests that there are points in the design space of tailorings that offer compelling tradeoffs between implementation complexity and useful capabilities.

In all, there are three important levels of tailoring support: (1) *local tailorings* that can use external data to generate types, (2) *cooperating tailorings* that share metadata and run in a customizable order, and (3) *binding-aware tailorings* that can manage an environment of static information. Figure 1 summarizes these levels both in terms of their required metaprogramming features and in terms of the tailorings these features enable. The bottom of the figure lists type information as a notable but orthogonal direction. Scala and Idris are the only systems that provide type information to macros, though it is unclear whether type information advances the frontier of tailoring systems.

4.1 Level 1: Local Tailorings

The first level of support for type tailoring enables local transformations that can query external sources of information. The PPX preprocessor in OCaml, SQLx in Rust, and type providers in F# all fall into this category. These systems can retrieve input from databases, websites, and/or constant literals to generate tailored code.

At this level, the main ingredient is support for compile-time computation: the preprocessor cannot be limited to simple pattern-and-template transformations. The preprocessor should also receive AST objects as input and it must be able to inspect these objects, query external sources, and have its output validated by the typechecker (compare to Section 3.7). Weakening any of these ingredients makes writing tailorings a challenge for language end-users, who do not have access to compiler internals. Without access to the AST, for instance, users must parse the input token stream before they can manipulate it in a meaningful way.

4.2 Level 2: Cooperating Tailorings

The second level of support allows tailorings to work together in basic ways. For example, `Dyn` in Rhombus uses metadata to tell operations how to handle an expression, `StaticArrays` in Julia lifts array structure into types, and Phoenix in Elixir collects web routes in a first pass before validating the routes in a second pass. All three require tools for sharing static information and controlling the order of elaboration.

Hygiene is crucial to enable sharing without bugs. In systems like Julia with partial support for hygiene, the authors of tailorings must fill the gap manually, for instance, by calling `gensym` to create fresh names.

Order in elaboration can come about in two ways. The direct way is to allow tailorings to expand to other tailorings. In this setting, the elaborator (macro expander) must continually process AST nodes until no tailoring uses remain. The indirect way, exemplified by Phoenix and CompRDL, is to use hooks to register tailorings that should happen at a certain point. In Phoenix, these points are just before and just after the compilation of a module.

Lastly, cooperating tailorings need a way to share information. An API for attaching metadata to AST nodes is the straightforward solution. Keeping information off to the side in metadata nodes (as in Julia) or in mutable structures is an alternative.

4.3 Level 3: Binding-Aware Tailorings

The third level of support is to equip the metaprogramming system with binding information. This level also allows fine-grained control over when the tailorings in a piece of syntax elaborate. Typed Racket requires these ingredients for its lightweight flow analysis, which lets tailorings flow through variable declarations and standard operations:

```
(let ([greeting "hello ~s"])
  (printf greeting "world"))
  ~~> (printf "hello ~s" "world")
  (make-vector (+ 40 2))
  ~~> (make-vector 42)
```

To deal with variables, tailorings need access to the binding structure of code. To ensure that subterms elaborate before the outer term, tailorings need control over the order of expansion. Among the languages in Section 3, only Racket and Clojure give full control over binding structure. Manual macro expansion is more common, with support from Elixir [27], Julia [49], and Idris [13]. Only Racket and Rhombus provide both in a hygienic way.

5 How to Reason About Tailorings

Programmers need an easy-to-use guide for the design of correct tailorings because tailorings can rewrite source code arbitrarily. Tailorings come with a degree of safety because the host language typechecks their output, but types alone do not prevent an incorrect rewrite from $\sqrt{2}$ to 42 or an unsafe rewrite that accesses out-of-bounds memory.

In general, tailorings accomplish two goals: they discover and propagate static information, and they elaborate source expressions to the host language. These goals motivate two correctness requirements. The first requirement is *prediction soundness*. If tailoring attaches static information to an expression and the expression reduces to a value, then the static information must be a correct description of the value. For example, the key-value pair `{string-len : 4}` is correct for string values with exactly 4 characters. If tailoring propagates static information for a variable, then the prediction must hold for all values the variable might take on.

The second requirement, *compatibility*, pertains to the behavior of elaborated code. Based on the examples from Section 2, there are three ways that a source expression and its tailored variant may relate to one another. Tailorings can:

- *express new behaviors* by translating invalid source syntax into valid host code;
Examples: SQL in Typed Racket (Section 2.1), Dyn in Rhombus (Section 2.3).
- *refine existing behaviors* by changing how, but not what, an expression computes; or
Example: StaticArrays in Julia (Section 2.4).
- *predict errors* by identifying a mismatch in static information.
Example: Verified Routes in Elixir (Section 2.5).

Tailorings that refine behavior or predict errors can use the untailored program as a source of truth. They should be compatible in the sense of computing equivalent values or rejecting the same programs. Tailorings that express new behavior generally require a fine-tuned correctness argument, but they may benefit from the idea of compatibility as well. For example, the Typed Racket regular expression example in Section 1 should be compatible with the baseline behavior of untyped Racket.

A Recipe

Showing that a tailoring system is correct calls for a two-part effort. First, the designers of a *cooperating* tailoring system (Section 4) must show that any propagation rules or environment-management rules respect prediction soundness. The designers of a *binding-aware* system must show that metadata propagates correctly. The designers of a *local* system have no obligations at this stage.

Second, the authors of domain-specific tailorings have three tasks:

1. Confirm the prediction soundness of rules that infer static information from values. These may be straightforward, such as inferring a length from a literal vector, and they may be sophisticated, such as the F# algorithm for JSON shapes [75].
2. Categorize tailorings that elaborate expressions as either: expressing new behavior, refining existing behavior, or predicting errors.
3. Argue that the elaborations are acceptable. Elaborations should either be compatible with some baseline behavior or desirable in some other sense.

By way of example, the next three subsections present two domain-specific tailorings and one set of general propagation rules.

5.1 Express New Behavior: Variable-Arity Map

With arity information about functions, a language with simple function types (such as Haskell, but not Typed Racket [99]) can support a variable-arity `map` function by generating code for a fixed-arity `map`. In the examples below, `map1` expects exactly one list, while `map2` expects exactly two lists and applies the function to their elements in parallel:

```
(map add1 '(1 2 3))
~~ (map1 add1 '(1 2 3))
```

```
(map max '(1 2 3) '(4 5 6))
~~ (map2 max '(1 2 3) '(4 5 6))
```

When variable-arity `map` receives a function with unknown arity, or when the arity does not match the number of lists given, it raises an exception:

```
(map max '(1 2 3))
~~ Exn: `max' expects 2 arguments, but `map' got only 1 list
```

For the first piece of static information, we need a tailoring that discovers the arity of functions – for example, that `max` takes 2 arguments:

```
(: max (-> Real Real Real))
(define (max a b)
  (if (>= a b) a b))
```

:: { fn-arity : 2 }

Prediction soundness comes from a function's arity being statically apparent. Likewise, predicting the number of list arguments is a simple matter of counting the arguments to `map`.

This tailoring is *expressing new behavior* when there is no variable-arity `map` in the source language. A reasonable baseline is to generalize the behavior of `map1`, `map2`, and so on in a compatible way. Assuming prediction soundness, `map` should elaborate to the correct `mapi` or predict the error that `mapi` would raise.

5.2 Refine Behavior and Predict Errors: Vector Bounds

When a tailoring expands to potentially-unsafe code, demonstrating soundness is crucial. Consider a tailoring that optimizes array references: when accesses (`vector-ref`) are known to be in bounds, it is safe to bypass the bounds check (`unsafe-ref`). However, if the index or the array length are not known statically, the tailoring falls back to a safe variant (`checked-ref`). This tailoring should always return the same result that a normal in-bounds access would, and should also optimize only when it is safe to do so:

```
(define my-vect (vector 1 2 3))

(vector-ref my-vect 1)           ~~ (unsafe-ref my-vect 1)
(vector-ref (read-vector) 3)     ~~ (checked-ref (read-vector) 3)
(vector-ref my-vect (read-int)) ~~ (checked-ref my-vect (read-int))
```

If this tailoring detects an out-of-bounds access statically, it can predict an error at tailoring time instead of leaving it until runtime.

```
(vector-ref my-vect 42)          ~~ Exn: Index '42' out of range
```

Information about vector sizes can come from two sources: static `vector` declarations and constructors such as `make-vector` that use statically-known sizes:

```
(vector 1 2 3)                  :: { vector-len : 3 }
(make-vector 42 0)               :: { vector-len : 42 }
```

Prediction soundness follows from the semantics of these built-ins.

This tailoring is *refining existing behavior* by optimizing accesses that are known to be safe. It also *predicts errors* when it can statically discover an out-of-bounds access. With prediction soundness in hand, behavioral soundness follows from comparing known lengths to known offsets.

5.3 Propagation and Substitution

Tailoring systems that propagate static information from variable definitions to references (i.e., *cooperating* systems in Section 4) must demonstrate *prediction soundness* for the forwarded information. Metadata must remain an accurate description for any runtime value the variable may take on. For instance, consider a vector bound to a variable `x`:

<code>(let ([x (vector 1 2 3)]) ... x ...)</code>	<code>x :: { vector-len : 3 }</code>
---	--------------------------------------

In the body of the `let`, the identifier `x` should have the information `{vector-len : 3}` attached to it. Subsequent tailorings inside the body of the `let` form should be able to take advantage of this information:

<code>(let ([x ...]) (vector-ref x 1))</code>	<code>~></code>	<code>(let ([x ...]) (unsafe-ref x 1))</code>
---	--------------------	---

At the same time, if `x` is shadowed by a different binding inside the body of the `let`, that same static information must not be attached to the new binding – transgressing lexical scoping would violate prediction soundness.

Aside from propagation through bindings, a *binding-aware* system can propagate information through a bottom-up tree traversal. For instance, `if` expressions can join the predictions from both branches:

<code>(if (daylight-savings) (vector 1 2 3) (vector 4 5 6))</code>	<code>:: { vector-len : 3 }</code>
--	------------------------------------

In this example, both branches carry the same static information; but when the branches disagree, precise information cannot propagate upward:

<code>(if (daylight-savings) (vector 1 2 3) (read-vector))</code>	<code>:: { empty map }</code>
---	-------------------------------

Exactly how to join pieces static information is context-dependent. For example, if both branches of an `if` are static vectors, but one is longer than the other, it might be sensible to propagate a length that is known to be safe. In other domains, defaulting to an empty set of properties might be the sensible thing to do.

6 Related Work

Type tailoring combines aspects of types, metaprogramming, and static analysis. In closely related work that inspired our Typed Racket tailorings, Herman and Meunier [45] show how a macro system can implement domain-specific static analyses for format strings, regular expressions, and database queries. They do not consider the interplay of domain-specific information and types. Ziggurat is a tailoring system for a C-like language [30]. It enables towers of language levels, each with a custom type system or flow analysis, and lets neighboring levels share information. Pluggable typecheckers add layers in a similar sense, though without direct support for sharing information across layers [8, 22, 67, 72]. Squid provides a framework for type-checked partial evaluation using the Scala macro system [74]. Scala LMS is another tailoring system specialized to partial evaluation that has enabled extensible optimizing compilers for domains ranging from databases to linear algebra [82, 83, 84, 85]. The finally-tagless encoding of staged interpreters is a third technique for partial evaluation that can be implemented within a typed language such as ML [10]. While its applications are more limited than the tailorings in this paper, it avoids the need for a metaprogramming layer.

The ingredients of a full-featured tailoring systems are made possible by research from the Lisp family of languages [20, 21, 33, 34, 55, 56, 98]. In particular, we note the long line of research on hygiene [1, 15, 16, 32, 55, 77].

Tailoring achieves a modicum of dependent typing in the context of a simply-typed language and without the burden of formal proof. The `printf` and vector size tailorings are similar to work on dependent types [26]. Cayenne is related as a practical compromise with dependent types; its typechecker takes care of the proof burden, but may run indefinitely [3]. Dependent type systems are common targets for metaprogramming. Prior work includes the Lean 4 macro system [24], type-directed editing and elaborator reflection in Idris [13, 58], certified metaprogramming in Coq [2], and elaboration-time solvers in Agda [57, 60]. Extensible tactic languages such as Cur [11] and VeriML [96] are tailoring systems that turn concise proofs into elementary ones.

By contrast to metaprogramming systems in general, tailoring is limited to the elaboration of surface syntax to a typed host language. Closely-related systems include Turnstile [12] and Klister [5], which create whole typed languages; Haskell typechecker plugins [4, 43], which customize the type constraint solver; and Nx [105], which compiles Elixir-like source code to GPU kernels. On a similar note, the Haskell library Servant checks web APIs statically using typechecker extensions rather than metaprogramming [66].

7 Future Work

Developing improved support for tailoring is an ongoing challenge. In addition to the quest for a system that productively combines all technical dimensions from Table 2, the following are key areas of focus going forward:

Deeper Control Flow Analysis. While the tailorings in this paper leverage some control flow analysis, this analysis is limited to local, forward propagation. No information flows through function calls, and join points (conditionals and loops) lose information to produce a conservative approximation. One way to recover precision is with annotations supported by runtime checks, though annotations put extra responsibility on programmers and checks introduce costs. Another way is to embed full [91] or demand-driven [35] control flow analysis in the tailoring system. Work on Turnstile is closely related, as it shows how macros can implement type analyses [11, 12].

Elaboration-Time Performance, How Much Metadata? The compile-time performance of tailorings has not been an issue for tailorings thus far, but it will become an issue if tailorings strive for whole-program or even whole-module analyses. Turnstile and k -CFA both suffer in this respect. A related issue is how much metadata to attach to AST nodes. Typed Racket tailoring (Section 2.1) inspects every data literal for every form of domain-specific information, which means that a string value can carry several kinds of information if it matches regular expression, `printf`, and SQL query syntax. Tracking information may, at some point, incur a noticeable compile-time cost.

How to Interleave Elaboration and Typechecking. Most tailorings in this paper happen before typechecking, which leaves them free to accept DSL syntax but also forces them to accommodate ill-typed or even ill-formed programs. In Scala, typechecking happens before and after tailoring. Further research is needed to weigh the strengths of each approach on concrete examples. On a related note, several features in Typed Racket including `match` and list comprehensions are implemented as macros and therefore get typechecked only after expansion. The typechecker struggles to reason about this post-expansion code. A source-level type analysis may be more straightforward.

Toward a Proof API. Typechecking before expansion raises the question of how to share results with the host type system. The tailorings in this paper either produce simple code or use casts to share results. Other tailoring-adjacent systems, such as the units-of-measure Haskell plugin [43], merely assert results to the host language. One avenue for enhancement is to equip a standard typechecker with a tactic language (e.g., [37, 63]) to support proof objects. The System DE calculus implements a similar design for termination proofs [61]; it contains a sublanguage for constructing proof terms that the typechecker can accept and erase during compilation.

8 Discussion

Type tailoring is a lightweight way to grow [47] a type system by equipping it with additional expressiveness. Critically, tailorings are mere library code produced by and for ordinary users, rather than by compiler engineers. Additionally, tailorings cooperate with the existing type system and are composable with one another. Since tailorings run before the typechecker, host-language typechecking provides a basic correctness guarantee; for further assurance, this paper also presents a framework for reasoning about behavioral changes that tailorings may introduce. Finally, since a type tailoring leverages the host’s metaprogramming system, no extra effort is needed to integrate it into a language’s build system – unlike what a bespoke static analysis might require.

Although this paper has shown that support from a metaprogramming system empowers end users to build a type tailoring system, it would be interesting to see how first-class support for tailoring might improve its expressiveness and efficiency. No programming language includes type tailoring as an official, documented aspect of the language, but programmers clearly benefit from what support exists anyway. The many forms of tailoring in the programming language landscape give ample evidence that tailoring is a useful idea. The API blueprints presented here may allow these related efforts to build on one another.

In summary, this paper provides a research foundation that has takeaways for end users, language designers, and the authors of tailorings:

- For users, the examples in Section 2 show that type tailoring balances ease of use with some expressiveness of dependent types.
- For designers, the analysis in Section 3 explains why a powerful metaprogramming system is desirable. Tailoring in Julia, for example, falls short of what it could achieve with *cooperating API* features (Figure 1).
- For authors of tailorings, the guidelines in Section 5 separate well-reasoned tailorings from arbitrary reprogramming of the compiler front end.

Type tailoring leads to a broader perspective on what metaprogramming for types can achieve. It can facilitate maintainability and reliability for end users, help researchers prototype type system ideas, and reduce demands on the core type system.

Abstract

Synthetic Separation Logic (SSL) is a formalism that powers SuSLik, the state-of-the-art approach for the deductive synthesis of provably-correct programs in C-like languages that manipulate heap-based linked data structures. Despite its expressivity, SSL suffers from two shortcomings that hinder its utility. First, its main specification component, inductive predicates, only admits *first-order* definitions of data structure shapes, which leads to the proliferation of “boiler-plate” predicates for specifying common patterns. Second, SSL requires *concrete* definitions of data structures to synthesise programs that manipulate them, which results in the need to change a specification for a synthesis task every time changes are introduced into the layout of the involved structures.

We propose to significantly lift the level of abstraction used in writing Separation Logic specifications for synthesis – both simplifying the approach and making the specifications more usable and easy to read and follow. We avoid the need to repetitively re-state low-level representation details throughout the specifications – allowing the reuse of different implementations of the same data structure by abstracting away the details of a specific layout used in memory. Our novel *high-level front-end language* called Pika significantly improves the expressiveness of SuSLik.

We implemented a layout-agnostic synthesiser from Pika to SuSLik enabling push-button synthesis of C programs with in-place memory updates, along with the accompanying full proofs that they meet Separation Logic-style specifications, from high-level specifications that resemble ordinary functional programs. Our experiments show that our tool can produce C code that is comparable in its performance characteristics and is sometimes faster than Haskell.

2012 ACM Subject Classification Software and its engineering → General programming languages; Software and its engineering → Automatic programming; Software and its engineering → Compilers

1 Introduction

Recent advances in program synthesis have allowed programmers to concentrate on stating precise specifications – leaving the job of generating provably correct and efficient imperative code to the synthesiser, such as SuSLik [6, 9, 13]. Such specifications are usually expressed using (Synthetic) Separation Logic [7, 10] that while hugely successful in verifying properties of pointer-manipulating programs remains out of reach to many mainstream developers. As the programs grow in complexity, such SSL specifications can become exceedingly verbose and complex – making the job of specification writer especially error-prone and defeating the purpose of a *usable proof automation toolchain*.

The power of Separation Logic (SL) specifications for the tasks of both verification and synthesis, is its mechanism of *inductive predicates* that concisely capture the shape of possibly recursive pointer-based tree-like data structures, determining both induction schemes for verification and the shape of recursion for the synthesis tasks of the programs that manipulate such data structures [10]. The surprising ability of SL specifications to capture precisely the logic of a desired program to be synthesised in the logical assertions comes at the price of the involved inductive predicates being (a) *first-order* and (b) somewhat *low-level*, with both these aspects posing limitations to the usability of SL-based program synthesis.

The first-order nature of the predicates means, for instance, that synthesis tasks that involve several data structures with very similar heap layouts would require to use *different* predicate definitions. As a specific example, consider a task synthesising two functions, *f* and *g*. Both *f* and *g* take as an argument a pointer to a linked list of integers; *f* increments all elements of the list by one, while *g* multiplies all its elements by two. To specify these two tasks, the state-of-the-art tools for program synthesis based on SL specifications require the user to provide, in addition to the pre-/postconditions, *three* different inductive predicates: one for an arbitrary list, another for a list that carries a known payload, with each element incremented by one, and the final capturing the multiplication of each element by two.

The second aspect, *i.e.*, the low-level nature of the SL inductive predicates used for synthesis, shows up when we try to *rewrite* an already specified synthesis task for a data structure with a slightly different layout. As an example, imagine defining the task of concatenating two lists. It is natural to expect that the specification will look very similar for both singly and doubly linked lists. Yet, since those are two different structures, with two different layouts, the user would require to supply two different task specifications.

A seasoned programmer would immediately notice that both issues (a) and (b) very much resemble the struggle that one faces when programming in a language that does not provide certain abstractions, which are nowadays mostly taken for granted: *higher-order functions* and *abstract data types*. Our first example could be streamlined should the SL-based specification language offer a way to define a function similar to *List.map*, available in all popular functional programming languages, so it could be used to concisely express the two scenarios of manipulating with the payload of a list’s elements. The second example would benefit from the ability to specify concatenation of *abstract* lists, while separately handling manipulations with single- or doubly-linked lists in terms of their memory *layouts*.

■ **Figure 1** Pika translation pipeline.

Key Ideas

The two challenges faced by the SSL specification language for the synthesis of heap-manipulating programs – the need for higher-order functions and abstract data types – have provided the primary motivation for this work.

As a solution, we developed **Pika**: a high-level front-end language and specification translation framework built on top of the state-of-the-art SL-based program synthesiser **SuSLik**.¹ **SuSLik** is based on a variant of separation logic called *synthetic separation logic* or **SSL** [9]. **Pika** has a syntax similar to popular functional programming languages and features specification-level higher-order functions on Algebraic Data Types (ADTs). In addition to being more succinct in comparison to Synthetic Separation Logic (SSL), the specification formalism of **SuSLik**, **Pika** also addresses its reusability issues outlined above. First, the use of specification-level higher-order functions allows the user to abstract over the specific properties of the payloads of the heap-based data structures, thus, generalising existing inductive predicates so they could be employed in a wider range of synthesis tasks. Second, by manipulating ADTs, the synthesis specifications do not need to deal with the specific memory layouts of the data structures. This separates the specification of the tasks that operate on those data structures from the low-level details of their memory representations.

The **Pika** pipeline is depicted in Figure 1. As our goal was to extend the expressivity of **SuSLik** by giving it a high-level specification language while retaining its meta-theoretical guarantees (*i.e.*, the certifiable correctness of the programs it synthesises), we had to overcome several technical obstacles when designing **Pika** and implementing it on top of **SuSLik**. First, we had to formally define the operational semantics of **Pika** and its translation to SSL-based specifications of **SuSLik**, defining the corresponding soundness result, relating the behaviour of programs eventually synthesised to that of their high-level counterparts (Section 3). Second, to support the higher-order specifications of **Pika**, we introduced conservative extensions to **SuSLik**'s specification language as well as to its deductive synthesis rules, to make it capable of handling pre-/postconditions with first-class functions operating on the payload of heap-stored data types (Section 4).

Pika as a Programming Language

Given the close similarity of **Pika**, our new specification language, to general-purpose functional programming languages, such as Haskell, it is natural to wonder whether it's possible to leverage its underlying synthesis pipeline as a way to produce efficient imperative programs in a language such as C from equivalent high-level functional programs. In other words, if we decide to use a combination **Pika** + **SuSLik** as a *compiler*, would it be a viable replacement to many-decades old tools such as Glasgow Haskell Compiler (GHC) [3], for producing efficient runnable code? To answer this question, we have conducted evaluation on several list- and tree-manipulating benchmarks, comparing the performance of verified C code, emitted by **SuSLik** from **Pika** specifications, to that of executables produced for equivalent tasks by GHC.

¹ Both susliks and pikas are Central Asian mammals. Pikas might look similar to susliks, but are more nimble and have longer life expectancy.

Our preliminary results are encouraging: thanks to avoiding unnecessary allocation and using destructive heap updates whenever possible, the C code synthesised by Pika + SuSLik outperforms the GHC output (with compiler optimisations flags turned) in the majority of list-manipulating benchmarks we've tried; our synthesis tool also produces strictly more performant C code for tree-manipulating benchmarks when compared to the corresponding Haskell programs, compiled by GHC without or with optimisations (Section 5). In particular, we specifically observe this when we compare C code synthesised by Pika + SuSLik with no C compiler optimisation flags to GHC compiled code with no GHC compiler flags.

Contributions

In this work, we make the following contributions:

- We address the expressivity limitations of SSL, the specification formalism of the state-of-the-art deductive synthesis tool SuSLik by developing Pika— a high-level specification language with higher-order functions and abstract data types.
- We formally define the operational semantics of Pika and prove the soundness of translation from Pika to pre-/postconditions in SSL.
- We develop an extension to SuSLik's specification and synthesis mechanism that enables translation from Pika specifications featuring first-class functions.
- We observe that the synthesis tool resulting from the combination Pika + SuSLik enables certified memory-layout-agnostic compilation from a functional specification to C code.
- We report on the evaluation of the Pika regarding its expressiveness and performance. In particular, we show that the C code it produces frequently outperforms equivalent Haskell programs compiled by GHC.

2 Overview

2.1 Background

The Pika language is translated into SuSLik [9], which is a program synthesis tool that uses Synthetic Separation Logic (SSL)-a variant of Hoare-style [4] Separation Logic (SL) [7].

A synthesis task specification in SuSLik is given as a function signature together with a pair of pre- and post-conditions, which are both SL assertions [9]. The synthesiser generates code that satisfies the given specification, along with the SL *proof* of its correctness by searching in a space of proofs that can be derived by using the rules of the underlying logic [13]. A distinguishing feature of *Synthetic Separation Logic* is the format of its assertions. An SSL assertion consists of two parts: a *pure part* and a *spatial part*. The pure part is a Boolean expression constraining the variables of the specification using a few basic relations, like equality and the less-than relation for integers. The spatial part is a *symbolic heap*, which consists of a list of *heaplets* separated by the * symbol.

Each heaplet takes on one of the following forms [9]:

- **emp**: This represents the empty heap. It is also the left and right identity for *.
- $\ell \mapsto a$: This asserts that memory location ℓ points to the value a . It also asserts that the location ℓ is accessible.
- $[\ell, \iota]$: At memory location ℓ , there is a block of size ι .
- $p(\bar{\phi})$: This is an application of the **inductive predicate** p to the arguments $\bar{\phi}$. An inductive predicate has a collection of branches, guarded by Boolean expressions (conditions) on the parameters. The body of each branch is an SSL assertion. The assertion associated with the first branch condition that is satisfied is used in place of the application. Note that inductive predicates can be (and often are) recursively defined.

Variable	x, y Alpha-numeric identifiers $\in \text{Var}$
Size, offset	n, ι Non-negative integers
Expression	$e ::= 0 \mid \text{true} \mid x \mid e = e \mid e \wedge e \mid \neg e \mid d$
\mathcal{T} -expr.	$d ::= n \mid x \mid d + d \mid n \cdot d \mid \{\} \mid d \mid \dots$
Command	$c ::= \text{let } x = *(\mathbf{x} + \iota) \mid *(\mathbf{x} + \iota) = e \mid$ $\quad \quad \quad \text{let } x = \text{malloc}(n) \mid \text{free}(x) \mid \text{error} \mid f(\overline{e_i})$
Program	$\Pi ::= \overline{f(\overline{x_i}) \{ c \}} ; c$
Logical variable	ν, ω
Cardinality variable	α
\mathcal{T} -term	$\kappa ::= \nu \mid e \mid \dots$
Pure logic term	$\phi, \psi, \chi ::= \kappa \mid \phi = \phi \mid \phi \wedge \phi \mid \neg \phi$
Symbolic heap	$P, Q, R ::= \text{emp} \mid \langle e, \iota \rangle \mapsto e \mid [e, \iota] \mid p^\alpha(\overline{\phi_i}) \mid P * Q$
Heap predicate	$\mathcal{D} ::= p^\alpha(\overline{x_i}) : e_j \Rightarrow \exists \overline{y}. \{ \chi_j; R_j \}$
Assertion	$\mathcal{P}, \mathcal{Q} ::= \{ \phi; P \}$
Environment	$\Gamma ::= \forall \overline{x_i}. \exists \overline{y_j}.$
Context	$\Sigma ::= \overline{\mathcal{D}}$
Synthesis goal	$\mathcal{G} ::= P \rightsquigarrow Q$

Figure 2 Syntax of Synthetic Separation Logic.

The general form of an SSL assertion is $(p; h_1 * h_2 * \dots * h_n)$, where p is the pure part and h_1, h_2, \dots, h_n are the heaplets which are the conjuncts that make up a separated conjunction of the spatial part. $*$ is *separating conjunction*: $h_1 * h_2$ means that the heaplets h_1 and h_2 apply to disjoint parts of the heap. A syntax definition for SSL is given in Figure 2, which is adapted from *Cyclic Program Synthesis* by Itzhaky *et al.* [6]. We will also use the symbol $**$ for separating conjunction and the symbol \rightarrowtail for \mapsto .

As the specification language of SuSLik, SSL serves as the compilation target for the Pika language. From there, executable programs are generated through SuSLik’s program synthesis. Consider a program that takes an integer x and a result in location r and stores $x + 1$ at location r . This can be written as the SuSLik specification:

```
void add1Proc(int x, loc r)
{ r :> 0 }
{ y == x + 1 ; r :> y }
{ ?? }
```

This example can be written as follows in our tool:

```
add1Proc : Int -> Int;
add1Proc x := x + 1;
```

In contrast with SuSLik spec, the Pika one requires no direct manipulation with pointers.

2.2 The Pika Language

While SSL provides a specification language that allows tools like SuSLik to synthesise code, it is only able to express specifications as pointers. This is useful for some applications, such as embedded systems, but it does not provide any high-level abstractions. As a result, every part of a specification is tailored to a specific memory representation of each data structure involved. To address this shortcoming, we introduce a language with algebraic data types that gets translated into SSL specifications. Additionally, we introduce a language construct that allows the programmer to specify a *memory representation* of an algebraic

```

data List := Nil | Cons Int List;

S11 : List >-> layout[x];
S11 (Nil) := emp;
S11 (Cons head tail) := x :-> head, (x+1) :-> tail, S11 tail;

```

Figure 3 List algebraic data type together with its singly-linked list layout S11.

data type called a *layout*. The distinction between algebraic data types and layouts provides the separation of concerns between the low-level representation of a data structure and code that manipulates it at a high level.

Syntactically, Pika resembles a functional programming language of the Miranda [12] and Haskell [5] lineage. It supports algebraic data types, pattern matching at top-level function definitions (though not inside expressions) and Boolean guards. The primary difference arises due to the existence of layouts and the fact that the language is compiled to an SSL specification rather than executable code. Beyond algebraic data types and layouts, Pika has a built-in type for integers as well as Booleans.

Functions in Pika are only defined by their operations on algebraic data types. Thus, all function definitions are “layout-polymorphic” over the particular choices of layouts for their arguments and result. Giving a layout polymorphic function, a particular choice of layouts is called “instantiation”. Specifying the layout of a non-function value is called “lowering.”

The code generator is instructed to generate a SuSLik specification for a certain function at a certain instantiation by using a `%generate` directive. For example, if there is a function definition with the type signature `mapAdd1 : List -> List`, a line reading `%generate mapAdd1 [S11] S11` would instruct the Pika compiler to generate the SuSLik inductive predicate corresponding to `mapAdd1` instantiated to the `S11` layout for both its argument and its result. An example of an ADT definition and a corresponding layout definition is given in Figure 3. There is one unusual part of the syntax in particular that requires further explanation: layout type signatures. A layout definition consists of a *layout type signature* and a pattern match (much like a function definition), with lists of SSL heaplets on the right-hand sides. A layout type signature has a special form `A : α → layout[x]`. This says that the layout `A` is for the algebraic data type `α` and the SSL output variable `x` denoting the “head” pointer of the respective structure.

2.3 Pika by Example

We demonstrate the characteristic usages of Pika by a series of examples. In these examples, we will often make use of the `List` algebraic data type and its `S11` layout from Figure 3. A simple example of Pika code that illustrates algebraic data types and layouts is a function which creates a singleton list out of the given integer argument:

```

%generate singleton [Int] S11

singleton : Int -> List;
singleton x := Cons x (Nil);

```

This gets compiled to the following SuSLik specification (modulo auto-generated names):

```

predicate singleton(int p, loc r) {
| true => { r :-> p ** (r+1) :-> 0 ** [r,2] }
}

```

```

predicate sll(loc x) {
| x == 0 => { emp }
| not (x == 0) => { [x, 2] ** x :-> v ** (x+1) :-> nxt ** sll(nxt) }
}

predicate mapAdd1(loc x, loc r) {
| x == 0 => { emp }
| not (x == 0) => { [x, 2] ** x :-> v ** (x+1) :-> xNxt ** [r, 2]
                      ** r :-> (v+1) ** (r+1) :-> rNxt ** mapAdd1(xNxt, rNxt) }
}

void mapAdd1_fn(loc x, loc y)
{ sll(x) ** y :-> 0 }
{ y :-> r ** mapAdd1(x, r) }
{ ?? }

```

Figure 4 Specifying a function that adds one to each element of a singly-linked list in SuSLik.

A slightly more complicated example comes from trying to write a functional-style `map` function directly in SuSLik. Consider a function which adds 1 to each integer in a list of integers. Considering the list implementation to be a singly-linked list with a fixed layout, one way to express this in SuSLik is shown in Figure 4. In the `mapAdd1` predicate, the input list is given as the `x` parameter and the `r` parameter points to the output list. In the non-null case, the head of `r` is required to be the successor of the head of `x`. The predicate is then applied recursively to the tails.

Note that inductive predicates are used for *two* different purposes: the `sll` inductive predicate describes a singly-linked list data structure, while the `mapAdd1` inductive predicate describes how the input list relates to the output list. Both are used in the specification of `mapAdd1_fn`: `sll` in the precondition and `mapAdd1` in the postcondition.

Using the `mapAdd1` inductive predicate gives us two advantages over attempting to put the SSL propositions directly into the postcondition of `mapAdd1_fn`:

1. We are able to express a conditional on the shape of the list. This is much like pattern matching in a language with algebraic data types, but we are examining the pointer involved directly.
2. We are able to express *recursion* part of the postcondition: the `mapAdd1` inductive predicate refers to itself in the `not (x == 0)` branch.

These two features are both reminiscent of features common in functional programming languages: pattern matching and recursion. However, there are still some significant differences:

- In traditional pattern matching, the underlying memory representation of the data structure is not exposed.
- Compared to a functional programming language, the meaning of the specification is more obscured. It is necessary to think about the structure of the linked data structure to determine what the specification is saying. This is related to the first point: The memory representation is front-and-center.
- In many functional languages, mutation is either restricted or generally discouraged. In SuSLik, mutation is commonplace.

Suppose we want to write the functional program that corresponds to this specification. One way to do this in a Haskell-like language is by using the `List` type from Figure 3.

```

mapAdd1_fn : List -> List;
mapAdd1_fn (Nil) := 0;
mapAdd1_fn (Cons head tail) := Cons (head + 1) (mapAdd1_fn tail);

```

The only missing information is the memory representation of the `List` data structure. We do not want the `mapAdd1_fn` implementation to deal with this directly, however. We want to separate the more abstract notions of pattern matching and constructors from the concrete memory layout that the data structure has.

To accomplish this, we now extend the code with the definition of `S11` from Figure 3. `S11` is a *layout* for the algebraic data type `List`. Now we have all of the information of the original specification but rearranged so that the low-level memory layout is separated from the rest of the code. This separation brings us to an important observation about the language, manifested throughout these examples: none of the function definitions need to *directly* perform any pointer manipulations. This is relegated entirely to the reusable layout definitions for the ADTs. The examples are written entirely as recursive functions that pattern match on, and construct, ADTs.

All that is left is to connect these two parts: the layouts and the function definitions. We instruct a `SuSLik` specification generator to generate a `SuSLik` specification from the `mapAdd1_fn` function using the `S11` layout:

```
%generate mapAdd1_fn [S11] S11
```

The `[S11]` part of the directive tells the generator which layouts are used for the arguments. In this case, the function only has one argument and the `S11` layout is used. The `S11` at the end specifies the layout for the result.

2.3.1 Synthesising the in-place map function

We can generalise our `mapAdd1` to map arbitrary `Int` functions over a list and then redefine `mapAdd1` using the new `map`.

```
%generate mapAdd1 [S11] S11

data List := Nil | Cons Int List;

S11 : List >-> layout[x];
S11 (Nil) := emp;
S11 (Cons head tail) := x :-> head, (x+1) :-> tail, S11 tail;

map : (Int -> Int) -> List -> List;
map f (Nil) := Nil;
map f (Cons x xs) := Cons (instantiate [Int] Int f x) (map f xs);

add1 : Int -> Int;
add1 x := x + 1;

mapAdd1 : List -> List;
mapAdd1 xs := instantiate [Int -> Int, S11] S11 map add1 xs;
```

The keyword `instantiate` gives specific layouts to use for the types in function applications, *e.g.*, if a function `g` has type `A -> B -> C -> D`, then `instantiate [L1, L2, L3] L4 g x y z` will use layout `L1` for type `A`, `L2` for type `B`, `L3` for type `C` and, finally, `L4` for the result type `D`, while applying the function `g` to the three arguments `x`, `y` and `z`.

This example makes use of `instantiate` in two places. The first one in the call of `instantiate [Int] Int f x`: the builtin `Int` layout is used for both the input and output. In this special case, the `Int` layout shares a name with the `Int` type that it represents. This is necessary since `instantiate` is used for all non-recursive (non constructor) calls.

```

predicate filterLt9(loc x, loc r) {
| (x == 0) => { r == 0 ; emp }
| not (x == 0) && head < 9 =>
  { x :-> head ** (x+1) :-> tail ** [x,2] ** filterLt9(tail, r) }
| not (x == 0) && not (head < 9) =>
  { x :-> head ** (x+1) :-> tail ** [x,2] ** filterLt9(tail, y)
    ** r :-> head ** (r+1) :-> y ** [r,2] } }

void filterLt9(loc x1, loc r)
{ S11(x1) ** r :-> 0 }
{ filterLt9(x1, r0) ** r :-> r0 }
{ ?? }

```

Figure 5 SuSLik specification of `filterLt9`, excluding `S11`, which is given in Figure 3.

In the second use, `instantiate [Int -> Int, S11] S11 map add1 xs`, we specify that the second argument uses the `S11` layout for the `List` type from Figure 3. We also give `S11` as the layout for the result of the call. Note that it is not necessary to use `instantiate` for the recursive call to `map`. This is because the appropriate layout is inferred for recursive calls.

The type signature of `mapAdd1` implies that it is layout polymorphic, as the type does not refer to any specific layout. It might be surprising that `instantiate` is required in the body of `mapAdd1` since the type signature of `mapAdd1` suggests that it is layout polymorphic and yet we must pick a specific `List` layout when we use `instantiate` to call `map`. This is because, in general, a call inside the body of some function `fn` might use any layout, even layouts that have no relation to the layouts that `fn` is instantiated to. Finally, please note that our benchmarks shown in Figure 1 include a more general version of `mapAdd`.

2.3.2 Guards

While we have a pattern-matching construct at the top level of a function definition, we have not seen a way to branch on a Boolean value so far. This is a feature that is readily available at the level of `SuSLik`, since the same conditional construct we use to implement pattern matching can also use other Boolean expressions.

We can expose this in the functional language using a *guard*, much like Haskell's guards. Suppose we want to write a specialised filter-like function. Specifically, we want a function that filters out all elements of a list that are less than 9. This is a specific example where the `SuSLik` specification is noticeably more difficult to read. For a `SuSLik` specification of this example, see Figure 5. On the other hand, an implementation of this in `Pika` is:

```

%generate filterLt9 [S11] S11

filterLt9 : List -> List;
filterLt9 (Nil) := Nil;
filterLt9 (Cons head tail)
| head < 9      := filterLt9 tail;
| not (head < 9) := Cons head (filterLt9 tail);

```

When translating a guarded function body, the translator takes the conjunction of the Boolean guard condition with the condition for the pattern match. Finally, please note that our benchmarks shown in Figure 1 include a more general version of `filterLt`.

While the SuSLik version of `filterLt9` requires working with pointers directly, the Pika version uses pattern matching and constructor application. This allows the Pika code to work independent of the layout used.

2.3.3 if-then-else

Another feature that is common in functional languages is `if-then-else` expressions. This has a straightforward translation into SuSLik. The `if-then-else` construct corresponds to SuSLik's C-like ternary operator. We can use this feature to implement the `even` function which produces 1 if the argument is even and 0 otherwise.

```
%generate even [Int] Int

even : Int -> Int;
even (n) := if (n % 2) == 0 then 1 else 0;
```

2.3.4 Using multiple layouts

To show the interaction between multiple algebraic data types, we write a function that follows the left branches of a binary tree and collects the values stored in those nodes into a list. This example demonstrates a binary tree algebraic data type and a layout that corresponds to it.

```
%generate leftList [TreeLayout] S11

data Tree := Leaf | Node Int Tree Tree;

TreeLayout : Tree -> layout[x];
TreeLayout (Leaf) := emp;
TreeLayout (Node payload left right) := x :-> payload, (x+1) :-> left,
(x+2) :-> right, TreeLayout left, TreeLayout right;

leftList : Tree -> List;
leftList (Leaf) := Nil;
leftList (Node a b c) := Cons a (leftList b);
```

2.3.5 Synthesising fold

A fold is a common kind of operation on a data structure in functional programming, where a binary function is applied to the elements of a data structure to create a summary value. For example, if the binary function is the addition function, it will give the sum of all the elements of the data structure. The classic example of such a fold is a fold on a list. In this example, we will write a right fold over a `List`.

```
%generate fold_List [Int, S11] Int
fold_List : Int -> List -> Int;
fold_List z (Nil) := z;
fold_List z (Cons x xs) :=
  instantiate [Int, Int] Int f x (fold_List z xs);
```

We will specifically look at the specialization where we use the addition function for `f` so that we can focus on way that layouts are used in the translation. This sort of specialization corresponds to defunctionalization. The compiler produces the following SuSLik specification for `fold_List`:

```
predicate fold_List(int i1, loc x, int i2) {
| x == 0 => { i2 == i1 ; emp }
| not (x == 0) => { (zz4 == i1) && ((zz5 == nxt13) &&
| (i2 == (h + b3))) ; [x,2] ** x :-> h ** (x + 1) :-> nxt13 **
| fold_List(zz4, zz5, b3) }
```

The first two parameters of the SuSLik predicate correspond to the two arguments of the Pika function. The final parameter of the predicate, `i2`, corresponds to the output of the Pika function. There are two cases:

1. The `x == 0` case corresponds to the `Nil` case in Pika. In this case, the pure part of the assertion (to the left of the semicolon) requires that the output is equal to the first parameter. This is because the Pika function returns the first parameter in its `Nil` case.
2. The `not (x == 0)` case corresponds to the `Cons` case. First, let's look at the spatial part (this is everything to the *right* of the semicolon). The pattern match destructures the `Cons` into its head and tail. Likewise, in the spatial part of the SuSLik predicate, we require that `x` points to `h` (the head) and `x + 1` points to `nxt13` (the tail). We also recursively call the predicate on the tail. The pure part does two things: it introduces new names for things (these are used internally) and it requires that the output `i2` is the sum of the head (`h`) and the value obtained from the recursive call (`b3`).

3 Formal Semantics of Pika

In this section, we have the following plan:

- We define abstract machine semantics for executing a subset of Pika programs. This semantics is given by the big-step relation \rightarrow which we define later.
- We define the translation from that subset of Pika into SSL. This translation is given by the function $\mathcal{T}[e]_{V,r}$ from Pika expressions into SSL propositions. The r is a variable name to be used in the resulting proposition and V is a collection of fresh names.
- We prove a soundness theorem. Given any well-typed expression e and an abstract machine reduction producing the store-heap pair (σ', h') , the SSL translation of e should be satisfied by SSL model (σ', h') . This is stated formally, and proven, in Theorem 3.

This subset of Pika does not have guards or conditional expressions, but it does have pattern matching. It also has the requirement that functions can only have one argument. Unlike the implementation, there is no elaboration. As a result, every algebraic data type value must be lowered to a specific layout at every usage and every function application must be explicitly instantiated with a layout for the argument and a layout for the result. We also limit the available integer and Boolean operations for brevity.

The grammar for this subset is given in Figure 6. The grammar for types, layout definitions and algebraic data type definitions remain the same as before and are therefore omitted. `instA,B(f)` corresponds to `instantiate [A] B f`. We also include another construct, `lowerA(C e1 ... en)`. This says to use the specific layout A for the given constructor application $C e_1 \dots e_n$.

The semantics for SSL are largely derived [9] from standard separation logic semantics. [11]

```

⟨i⟩ ::= ... | -2 | -1 | 0 | 1 | 2 | ...
⟨b⟩ ::= true | false
⟨e⟩ ::= ⟨var⟩ | ⟨i⟩ | ⟨b⟩ | ⟨e⟩ + ⟨e⟩ | C  $\overline{\langle e \rangle}$  | instA,B(f)(⟨e⟩) | lowerA(⟨e⟩)
⟨fn-def⟩ ::=  $\overline{\langle fn-case \rangle}$ 
⟨fn-case⟩ ::= f ⟨pattern⟩ := ⟨e⟩

```

■ **Figure 6** Grammar for restricted Pika subset.

3.1 Overview of the Two Interpretations

The soundness theorem will link the abstract machine semantics to the translation. In fact, the abstract machine semantics and the translation are similar to each other. For the abstract machine we manipulate *concrete* heaps, while for the translation we generate *symbolic* heaps.

Comparing the two further, there are two main points (beyond what we've already mentioned) where these two interpretations of Pika differ:

1. When we need to unfold a layout, how do we know which layout branch to choose?
2. How do we translate function applications (including, but not limited to, recursive applications)?

First, consider the abstract machine semantics. In this case, we are able to choose which branch of a layout to use by evaluating the expression we are applying it to until the expression is reduced to a constructor value (where a “constructor value” is either a value or a constructor applied to constructor values). If the expression is well-typed, this will always be a constructor of the algebraic data type corresponding to the layout. The two rules that this applies to are AM-LOWER and AM-INSTANTIATE. To interpret a function application, we interpret its arguments and substitute the results into the body of the function. We then proceed to interpret the substituted function body. This process is performed by the AM-INSTANTIATE rule.

Next, consider the SSL translation. Here we can determine which layout branch to use by generating a Boolean condition that will be true if and only if the SSL proposition on the right-hand side of the branch holds for the heap. Note that we assume that the programmer-supplied layout definitions are *injective* functions from algebraic data types to SSL assertions (up to bi-implication). We can directly translate function applications into SSL inductive predicate applications. Since inductive predicates already allow for recursive applications, there is no special handling necessary for recursion.

After defining these interpretations, we show how the abstract machine relation \rightarrowtail and the SSL interpretation function $\mathcal{T}[e]_{V,r}$ relate to each other by the Soundness Theorem 3.

3.2 Abstract Machine Semantics

In this section, we will define an abstract machine semantics for Pika and relate this to the standard semantics for SSL.

3.2.1 Notation and Setup

The set of values is $\text{Val} = \mathbb{Z} \cup \mathbb{B} \cup \text{Loc}$. Each of these three sets is disjoint from the other two. In particular, note that Loc and \mathbb{Z} are disjoint.

There is also a set of **Pika** values FsVal . This includes all the elements of Val , but also includes “constructor values” given by the rules in Figure 7. In addition to the store and heap of standard SSL semantics, the abstract machine semantics uses an FsStore . This is a partial function from locations to **Pika** values: $\text{FsStore} = \text{Loc} \rightarrow \text{FsVal}$. The primary purpose of this is to recover constructor values when given a location.

The general format of the transition relation is $(e, \sigma, h, \mathcal{F}) \mapsto (v, \sigma', h', \mathcal{F}', r)$, where the expression e results in the store being updated from σ to σ' , the heap being updated from h to h' , v is the Val obtained by evaluating e , the initial and final FsStore are \mathcal{F} and \mathcal{F}' and the result is stored in variable r . We assume that there is a global environment Σ which contains all layout definition equations and function definition equations.

Given a heap h and a heap layout H , we will make use of the notation $h \cdot [H]$. This extends the heap with the location assignments given in H . We say that the layout body H is *acting* on the heap h . This is defined in Figure 9. The intuition for this is that h gets updated using the symbolic heap description in H . For example, $\emptyset \cdot [a : \rightarrow 7]$ will contain only the value 7 at the location a . It is assumed that H does not have any variables on the right-hand side of $: \rightarrow$.

3.2.2 Abstract Machine Rules

The abstract machine semantics provides big-step operational semantics for evaluating **Pika** expressions on a heap machine. Its rules, given by Figure 8, make use of standard SSL models:

Model	$\mathcal{M} ::= (\sigma, h)$
Store	$\sigma : \text{Var} \rightarrow \text{Val}$
Heap	$h : \text{Loc} \rightarrow \text{Val}$

Note that a compound expression, consisting of multiple subexpressions, uses *disjoint* parts of the heap for each subexpression. This can be seen in the AM-ADD, AM-LOWER and AM-INSTANTIATE rules, which is essential for the proof of Soundness Theorem 3.

3.3 Translating Pika Specifications into SSL

We will define two translations: One from **Pika** *expressions* into SSL propositions and the other from **Pika** *definitions* into SSL inductive predicate definitions. We start with the former.

3.3.1 Translating Expressions

In the rules given in Figure 10, the notation $\mathcal{I}_{A,B}(f)$ gives the name of the inductive predicate that the **Pika** function f translates to when it is instantiated to the layouts A and B .

We start by defining the translation rules for expressions. We use these translation rules in Lemma 1 to define a translation function $\mathcal{T}[\cdot]_{V,r}$. Then, we will define translation rules for function definitions. The translation relation for expressions has the form $(e, V) \Downarrow (p, s, V', v)$, where p and s are the pure part and spatial part (respectively) of an SSL assertion and $V, V' \in \mathcal{P}(\text{Var})$.

The rules can be thought of as being in two groups:

1. Rules for base type expressions, such as S-LIT and S-ADD.
2. Rules for using layouts to translate expressions whose types involve algebraic data types.

Examples include S-LOWER-CONSTR and S-INST-INST.

$$\frac{x \in \text{Val}}{x \in \text{FsVal}} \text{ FsVal-BASE} \quad \frac{x_1 \in \text{FsVal} \cdots x_n \in \text{FsVal}}{(C x_1 \cdots x_n) \in \text{FsVal}} \text{ FsVal-CONSTR}$$

Figure 7 FsVal judgment rules.

$$\begin{array}{c} r \text{ fresh } i \in \mathbb{Z} \sigma' = \sigma \cup \{(r, i)\} \text{ AM-INT} \quad \frac{r \text{ fresh } b \in \mathbb{B} \sigma' = \sigma \cup \{(r, b)\}}{(b, \sigma, \emptyset, \mathcal{F}) \mapsto (b, \sigma', \emptyset, \mathcal{F}, r)} \text{ AM-BOOL} \\ v \in \text{dom}(\sigma) \sigma(v) \notin \text{Loc} \quad \frac{}{(v, \sigma, \emptyset, \mathcal{F}) \mapsto (\sigma(v), \sigma, \emptyset, \mathcal{F}, v)} \text{ AM-VAR-BASE} \\ v \in \text{dom}(\sigma) \sigma(v) \in \text{Loc} \quad \frac{}{(v, \sigma, \emptyset, \mathcal{F}) \mapsto (\mathcal{F}(\sigma(v)), \sigma, \emptyset, \mathcal{F}, v)} \text{ AM-VAR-LOC} \\ (x, \sigma, \mathcal{F}, h_1) \mapsto (x', \sigma_x, h'_1, \mathcal{F}, v_x) \quad (y, \sigma_x, \mathcal{F}, h_2) \mapsto (y', \sigma_y, h'_2, \mathcal{F}, v_y) \\ r \text{ fresh } h = h_1 \circ h_2 \quad h' = h'_1 \circ h'_2 \quad z = x' + y' \quad \sigma' = \sigma_y \cup \{(r, z)\} \quad \frac{}{(x + y, \sigma, h, \mathcal{F}) \mapsto (z, \sigma', h', \mathcal{F}, r)} \text{ AM-ADD} \\ (A[x] (C a_1 \cdots a_n) := H) \in \Sigma \quad (e, \sigma_0, h_0) \mapsto (C e_1 \cdots e_n, \sigma_1, h_1, y_1) \\ (e_i, \sigma_i, h_i) \mapsto (e'_i, \sigma_{i+1}, h'_i, v_i) \text{ for each } 1 \leq i \leq n \\ h' = h'_1 \circ h'_2 \circ \cdots \circ h'_n \quad h = h_0 \circ h_1 \circ \cdots \circ h_n \quad \sigma' = \sigma_{n+1} \cup \{(r, \ell)\} \\ \ell \text{ fresh } r \text{ fresh} \\ H' = H[x := \ell][a_1 := \sigma_2(v_1)][a_2 := \sigma_3(v_2)] \cdots [a_n := \sigma_{n+1}(v_n)] \\ \mathcal{F}' = \mathcal{F} \cup \{(\ell, (C e'_1 \cdots e'_n))\} \quad \frac{}{(\text{lower}_A(e), \sigma_0, h, \mathcal{F}) \mapsto ((C e'_1 \cdots e'_n), \sigma', h' \cdot [H'], \mathcal{F}', r)} \text{ AM-LOWER} \\ (A[x] (C a) := H) \in \Sigma \quad (f (C b) := e_f) \in \Sigma \\ (e, \sigma, h) \mapsto (C e_1, \sigma_1, h_1, y) \\ (e_1, \sigma_1, h_1) \mapsto (e'_1, \sigma_2, h_2, r) \\ \ell \text{ fresh } r \text{ fresh } y \text{ fresh} \\ H' = H[x := \ell][a := e'_1] \quad h' = h_1 \cdot [H'] \quad \sigma' = \sigma_f \cup \{(r, \ell)\} \\ \mathcal{F}' = \mathcal{F} \cup \{(\ell, (C e'_1))\} \\ \frac{(\text{lower}_B(e_f[b := y]), \sigma_2, h') \mapsto (e'_f, \sigma_f, h'', r)}{(\text{inst}_{A,B}(f)(e), \sigma, \mathcal{F}, h) \mapsto (e'_f, \sigma', h'', \mathcal{F}', r)} \text{ AM-INSTANTIATE} \end{array}$$

Figure 8 Abstract machine semantics rules.

$$\begin{array}{c} h \cdot [\text{emp}] = h \text{ L-EMP} \quad \frac{h' = h \cdot [H] \quad a \in \text{Val}}{h \cdot [\ell : \rightarrow a, H] = h'[\ell \mapsto a]} \text{ L-POINTSTO} \\ \frac{e \in \text{Val}}{h \cdot [A[x](e), H] = h \cdot [H]} \text{ L-APPLY} \end{array}$$

Figure 9 Rules for layout bodies acting on heaps.

In the first group, consider S-ADD. In the result of the translation, we've included $v == v_1 + v_2$ in the list of conjuncts in the pure part. Here, v_1 and v_2 are the results of the two subexpressions in the addition. In the pure part, we also include the pure parts of the two subexpressions as conjuncts. These are p_1 and p_2 . The spatial part of the translation consists of the spatial parts of the two subexpressions, s_1 and s_2 .

Now, in the second group, consider S-LOWER-CONSTR. This translates a Pika constructor application expression using a specific layout (which is provided by using the `lower_-` construct). It takes the specific branch of the layout corresponding to the constructor in question and puts the right-hand side of that branch into the spatial part, after applying the appropriate substitutions for the arguments given to the constructor in the application. The right-hand side of the layout branch is H and, after the substitution, it is called H' .

The S-INST-INST rule is used to translate a function application being applied to the result of another function application, given particular layouts for each application. In SuSLik, it does not make sense to directly apply a predicate to another predicate application. Therefore, we must do an ANF-like translation, where the result does not have “compound” applications like this. This translation is exactly what S-INST-INST is doing.

► **Lemma 1** ($\mathcal{T}[\cdot]$ function). $(\cdot, V) \Downarrow (\cdot, \cdot, \cdot, r)$ is a computable function $\text{Expr} \rightarrow (\text{Pure} \times \text{Spatial} \times \mathcal{P}(\text{Var}))$, given fixed V and r where $r \notin V$.

By throwing away the third element of the tuple in the codomain, we obtain a function $\text{Expr} \rightarrow (\text{Pure} \times \text{Spatial})$ from expressions to SSL propositions.

Call this function $\mathcal{T}[\cdot]_{V,r}$. That is, we define the function as follows where $r \notin V$:

$$\mathcal{T}[e]_{V,r} = (p; s) \iff (e, V) \Downarrow (p, s, V', r) \text{ for some } V'$$

We highlight the computability of this function to emphasise the fact that it can be used directly in an implementation of this subset of Pika.

3.3.2 Translating Function Definitions

The next step is to define the translation for Pika function definitions. In order to do this, we must first figure out how to determine the appropriate layout branch to use when unfolding a layout, a problem we highlighted earlier. Once this is accomplished, the rest of the translation can be defined. When this problem was solved for the abstract machine semantics, it was possible to simply evaluate the Pika expression until a constructor application expression was reached. From there, it is possible to just look at the constructor name and match it against the appropriate layout branch.

For the translation, however, we do not have the luxury of being able to evaluate expressions. Instead, we must instead rely on the fact that, in SSL, a “pure” (Boolean) condition can determine which inductive predicate branch to use. The question becomes: *Given an algebraic data type and a layout for that ADT, how do we generate an appropriate Boolean condition for a given constructor for the ADT?*

The solution is to find a Boolean condition which, given that the inductive predicate holds, is true if and only if the layout branch corresponding to that ADT constructor is satisfiable. In more detail, to define the branches of an inductive predicate $\mathcal{I}_A(x)$, given an ADT α , a constructor $C : \beta_1 \rightarrow \beta_2 \rightarrow \dots \rightarrow \beta_n \rightarrow \alpha$, a layout $A : \alpha \rightarrow \text{layout}[x]$ with a branch $A[x] (C a_1 \dots a_n) := H$ and given that $\mathcal{I}_A(x)$ holds, find a Boolean expression b with one free variable x such that $b \iff \exists \sigma, h. (\sigma, h) \models H$.

$$\begin{array}{c}
 \frac{i \in \mathbb{Z} \quad v \text{ fresh}}{(i, V) \Downarrow (v == i, \text{emp}, V \cup \{v\}, v)} \text{ S-INT} \\
 \frac{b \in \mathbb{B} \quad v \text{ fresh}}{(b, V) \Downarrow (v == b, \text{emp}, V \cup \{v\}, v)} \text{ S-BOOL} \\
 \frac{v \in \text{Var}}{(v, V) \Downarrow (\text{true}, \text{emp}, V, v)} \text{ S-VAR} \\
 \frac{(e_1, V_0) \Downarrow (p_1, s_2, V_1, v_1) \quad (e_2, V_1) \Downarrow (p_2, s_2, V_2, v_2) \quad v \text{ fresh}}{(e_1 + e_2, V_0) \Downarrow (v == v_1 + v_2 \wedge p_1 \wedge p_2, s_1 * s_2, V_2 \cup \{v\}, v)} \text{ S-ADD} \\
 \frac{v \in \text{Var}}{(\text{lower}_A(v), V) \Downarrow (\text{true}, A(v), V \cup \{v\}, v)} \text{ S-LOWER-VAR} \\
 \frac{(A[x] (C a_1 \cdots a_n) := H) \in \Sigma \quad (e_i, V_i) \Downarrow (p_i, s_i, V_{i+1}, v_i) \text{ for each } 1 \leq i \leq n \quad v \text{ fresh}}{V' = V_{n+1} \cup \{x\} \quad H' = H[a_1 := v_1] \cdots [a_n := v_n] \quad (\text{lower}_A(C e_1 \cdots e_n), V_1) \Downarrow (p_1 \wedge \cdots \wedge p_n, H' * s_1 * \cdots * s_n, V', x)} \text{ S-LOWER-CONSTR} \\
 \frac{v \in V \quad r \text{ fresh}}{(\text{inst}_{A,B}(f)(v), V) \Downarrow (\text{true}, \mathcal{I}_{A,B}(f)(v, r), V \cup \{r\}, r)} \text{ S-INST-VAR} \\
 \frac{(A[x] (C a_1 \cdots a_n) := H) \in \Sigma \quad (e_i, V_i) \Downarrow (p_i, s_i, V_{i+1}, v_i) \text{ for each } 1 \leq i \leq n \quad x \text{ fresh}}{V' = V_{n+1} \cup \{x\} \quad H' = H[a_1 := v_1] \cdots [a_n := v_n] \quad (f (C b_1 \cdots b_n) := e_f) \in \Sigma \quad e'_f = e_f[b_1 := v_1] \cdots [b_n := v_n] \quad (\text{lower}_B(e'_f), V_{n+1}) \Downarrow (p, s, V', r)} \text{ S-INST-CONSTR} \\
 \frac{(\text{inst}_{A,B}(g)(e), V) \Downarrow (p_1, s_1, V_1, r_1) \quad (\text{inst}_{B,C}(f)(r_1), V_1) \Downarrow (p_2, s_2, V_2, r_2)}{(\text{inst}_{B,C}(f)(\text{inst}_{A,B}(g)(e)), V) \Downarrow (p_1 \wedge p_2, s_1 * s_2, V_2, r_2)} \text{ S-INST-INST}
 \end{array}$$

Figure 10 Expression Translation Rules.

$V = \{v_1, \dots, v_n\}$ where v_1, \dots, v_n are distinct variables

$r \in \text{Var} \quad r \notin V \quad c = \text{cond}(A, C, x) \quad p_1 \cdots p_n \text{ fresh}$

$$\frac{(p, s) = \mathcal{T}[\text{inst}_{A,B}(f)(C p_1 \cdots p_n)]_{V,r} \quad (f (C a_1 \cdots a_n) := e) \xrightarrow{\text{fn-def}}_{A,B} (\mathcal{I}_{A,B}(f)(x, r) : c \Rightarrow \{p; s\})}{(f (C a_1 \cdots a_n) := e) \xrightarrow{\text{fn-def}}_{A,B} (\mathcal{I}_{A,B}(f)(x, r) : c \Rightarrow \{p; s\})} \text{ FNDEF}$$

Figure 11 Translation rule for function definitions.

► **Lemma 2** (cond function). *There is a computable function $\text{cond}(\cdot, \cdot)$ that takes in any layout $A : \alpha \rightarrow \text{layout}[x]$ with a branch $A[x]$ ($C a_1 \cdots a_n := H$ for a given constructor $C : \beta_1 \rightarrow \beta_2 \rightarrow \cdots \rightarrow \beta_n \rightarrow \alpha$ and it produces a Boolean expression with one free variable x such that the following holds under the assumption that $\mathcal{I}_A(x)$ holds.*

$$\text{cond}(A, C) \iff \exists \sigma, h. (\sigma, h) \models H$$

Here, $\mathcal{I}_A(x)$ is the name of the generated inductive predicate corresponding to the layout A .

With this function in hand, we are now ready to define the translation for Pika function definitions. This definition is in Figure 11. In this rule, the fresh variables p_1, \dots, p_n will be substituted for a_1, \dots, a_n .

3.4 Typing Rules

Typing rules for Pika expressions are given in Figure 12. These rules differ from standard typing rules for a functional language due to the existence of layouts and their associated constructors, like `instantiate` and `lower`. If an expression is well-typed, then each use of `instantiate` and `lower` only uses layouts together with the ADT that they are defined for.

The rules also make use of a *concreteness judgment*. The rules for this judgment are given in Figure 13a. The intuition of this judgment is that a type is “concrete” iff values of that type can be directly represented in the heap machine semantics. For example, an ADT type is *not* concrete because a layout has not been specified. However, once a particular layout is specified for the ADT type, it becomes concrete. Base types, like `Int`, are also concrete.

Rules for the ensuring that global definitions are well-typed are given in Figure 13b. In this figure, Δ is the set of all (global) constructor type definitions.

3.5 From Pika to SLL Specifications: Soundness of the Translation

We want to show that our abstract machine semantics and our SLL translation fit together. In particular, our abstract machine semantics should generate models that satisfy the separation logic propositions given by our SLL translation. Figure 14 gives a high-level overview of how these pieces fit together. We will give a more specific description of this in Theorem 3.

► **Theorem 3** (Soundness). *For any well-typed expression e , if $\mathcal{T}\llbracket e \rrbracket_{V,r}$ is satisfiable for $V = \text{dom}(\sigma')$ and $(e, \sigma, h, \mathcal{F}) \mapsto (e', \sigma', h', \mathcal{F}', r)$, then $(\sigma', h') \models \mathcal{T}\llbracket e \rrbracket_{V,r}$. That is, given an expression e with a satisfiable SLL translation, any heap machine state that e transitions to (by the abstract machine semantics) will be a model for the SLL translation of e (cf. Figure 14).*

Proof. See the Appendices in the extended version of the paper [14]. ◀

The fact that, at the top level, we only translate function definitions suggests an additional theorem. We want to specifically show that any possible function application is sound, in the sense just described. This immediately follows from Theorem 3.

Abbreviating $\text{inst}_{A,B}(f)$ as $f_{A,B}$, we can state the following theorem:

► **Theorem 4** (Application soundness). *For any well-typed function application $f_{A,B}(e)$, if $\mathcal{T}\llbracket f_{A,B}(e) \rrbracket_{V,r}$ is satisfiable for $V = \text{dom}(\sigma')$ and $(f_{A,B}(e), \sigma, h, \mathcal{F}) \mapsto (e', \sigma', h', \mathcal{F}', r)$, then $(\sigma', h') \models \mathcal{T}\llbracket f_{A,B}(e) \rrbracket_{V,r}$.*

Proof. This follows immediately from Theorem 3. ◀

$$\begin{array}{c}
 \frac{i \in \mathbb{Z}}{\Gamma \vdash i : \text{Int}} \text{-INT} \quad \frac{b \in \mathbb{B}}{\Gamma \vdash b : \text{Bool}} \text{-BOOL} \quad \frac{(v : \alpha) \in \Gamma}{\Gamma \vdash v : \alpha} \text{-VAR} \\
 \\
 \frac{(f : \alpha \rightarrow \beta) \in \Sigma}{\Gamma \vdash f : \alpha \rightarrow \beta} \text{-FN-GLOBAL} \\
 \\
 \frac{\Gamma \vdash x : \text{Int} \quad \Gamma \vdash y : \text{Int}}{\Gamma \vdash x + y : \text{Int}} \text{-ADD} \\
 \\

 \\
 \frac{(C : \alpha_1 \rightarrow \dots \rightarrow \alpha_n \rightarrow \beta) \in \Sigma \quad (B : \beta \rightsquigarrow \text{layout}[x]) \in \Sigma}{\Gamma \vdash e_i \text{ concrete}_{\alpha_i} \text{ for each } i \text{ with } 1 \leq i \leq n} \text{-LOWER-CONSTR} \\
 \\
 \frac{(A : \alpha \rightsquigarrow \text{layout}[x]) \in \Sigma \quad (B : \beta \rightsquigarrow \text{layout}[y]) \in \Sigma}{\Gamma \vdash f : \alpha \rightarrow \beta \quad \Gamma \vdash e : A} \text{-INSTANTIATE} \\
 \\
 \frac{(C : \alpha_1 \rightarrow \dots \rightarrow \alpha_n \rightarrow \beta) \in \Sigma \quad \Gamma \vdash e_i : \alpha_i \text{ for each } i \text{ with } 1 \leq i \leq n}{\Gamma \vdash C e_1 \dots e_n : \beta} \text{-CONSTR}
 \end{array}$$

Figure 12 Typing rules.

4 Extensions of SuSLik

We have shown the translation from the functional specifications into SSL specifications. However, some of the SSL specifications are not supported in the original SuSLik and existing variants. In this section, we show how to extend the SuSLik to support more features to make the whole thing work. We will show the extensions on the following three aspects:

- How to describe and call an existing function within SSL predicates.
- How to make the result of one function call as the input of another function call.
- How to synthesise programs with inductive predicates without the help of pure theory.

$$\begin{array}{c}
 \frac{\Gamma \vdash e : \text{Int}}{e \text{ concrete}_{\text{Int}}} \text{C-INT} \quad \frac{\Gamma \vdash e : \text{Bool}}{e \text{ concrete}_{\text{Bool}}} \text{C-BOOL} \\
 \\
 \frac{(A : \alpha \rightsquigarrow \text{layout}[x]) \in \Sigma \quad \Gamma \vdash e : A}{e \text{ concrete}_{\alpha}} \text{C-LAYOUT} \quad \frac{\begin{array}{c} (C : \alpha_1 \rightarrow \alpha_2 \rightarrow \dots \rightarrow \alpha_n \rightarrow \beta) \in \Delta \\ b_1 : \alpha_1, b_2 : \alpha_2, \dots, b_n : \alpha_n \vdash e : \gamma \end{array}}{(f(C b_1 \dots b_n) := e) \Rightarrow f : \beta \rightarrow \gamma} \text{G-FN}
 \end{array}$$

(a) Concreteness judgment rules.

(b) Global definition typing.

Figure 13 Rules for concreteness judgement and typing global definitions.

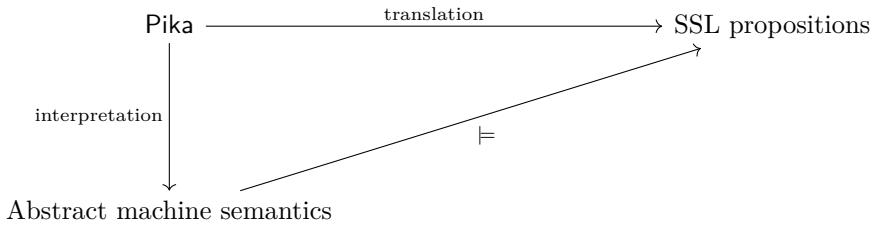

Figure 14 The relationship between the two Pika semantics given by the soundness theorem.

4.1 Function Predicates

Without any modification upon the implementation, we find the SSL predicate with some restrictions can be used to describe function relations other than data structures (named function predicates). The definition of **function predicates** is as follows:

► **Definition 5 (Function Predicates).** Given any non-higher-order n-ary function $f(x_1, \dots, x_n)$ in the functional language, the function predicate to synthesise f has the following format:

```
predicate predf(T x1, ... ,T xn, T output){...}
```

where $T \in \{\text{loc}, \text{int}\}$. The type of x_i (and output) is decided by the type of f . If it is an integer in f , then its type is int ; otherwise, it is loc (for any data structure in Pika).

Since the input of the whole workflow is functional programs, the “output” in the definition is to provide another location for the output of the function. And the specification to synthesise function f should have the following format:

```
void f(loc x1, ... ,loc xn)
{x1 :-> v1 ** x2 :-> 12 ** s11(12) ** ... ** xn :-> vn ** output :-> 0}
{x1 :-> v1 ** x2 :-> 12 ** ... ** xn :-> vn ** output :-> output0 **
 predf(v1, 12, ..., vn, output0)}
```

4.2 SSL Rules for *func* Structure

As we show in previous examples, the reason we can have *func* structure is that the points-to structure in the post-condition is always eliminated after write operations. For example, the in-placed *inc1* functions specification is satisfied via the WRITE (Figure 15) on the location.

```
void inc_y(loc y, loc x)
{x :-> vx ** y :-> vy}
{x :-> vx + vy ** y :-> vy}
```

The core insight of *func* structure is: since the function synthesised by function predicate behaves like the pure function, it is the same as the WRITE rule in the sense that only the output location is modified. Thus, we add the new FUNCWRITE rule into the zoo of SSL rules (see Figure 15). To make the *func* structure correctly equal to some “write” operation, the following restrictions should hold, which are achieved by the translation:

- If $\text{func } f(x_1, \dots, x_n, \text{output})$ appears in a post-condition, then no write rule can be applied to any x_i . This is to avoid the ambiguity of the *func*.
- The type of function f is consistent.

$$\begin{array}{c}
 \text{WRITE} \\
 \frac{\text{Vars}(e) \subseteq \Gamma \quad e \neq e' \quad \{\phi; x \mapsto e * P\} \rightsquigarrow \{\psi; x \mapsto e * Q\} | c}{\{\phi; x \mapsto e' * P\} \rightsquigarrow \{\psi; x \mapsto e * Q\} | *x = e ; c} \\
 \\
 \text{FUNCWRITE} \\

 \end{array}$$

Figure 15 The WRITE and new FUNCWRITE rules in SSL.

Note that based on the setting of the function predicate, the parameters of the function call are pointers, while the parameters of the function predicate are content to which pointers point. Furthermore, we have the *func* generated from function predicates and with the format defined in Subsection 4.1. As a result, the equivalent original SSL that duplicates points-to of one location is not a problem, since they can be merged as one.

4.3 Temporary Location for the Sequential Application

Though richly expressive, SSL has difficulty in expressing the sequential application of functions. For example, given the *func* structure available, the following function is not expressible within one function predicate:

```
f x y = g (h x) y
```

If we attempt to express it, we will have the following part in the predicate:

```
predicate f(loc x, loc y, loc output)
{... ** func h(x, houtput) ** func g(houtput, y, output)}
```

However, *houtput* is not a location in the pre-condition, which is not allowed in SSL. Thus, we introduce a new keyword *temp* to denote the temporary location for the sequential application. The new definition of *func* is as follows:

```
predicate f(loc x, loc y, loc output)
{... ** temp houtput ** func h(x, houtput) ** func g(houtput, y, output)}
```

Roughly speaking, the *temp* structure will help to allocate a new location for the output of the first function, and then use it as the input of the second function. After all appearances of *houtput* is eliminated, we will deallocate the location.

Note that the temporary variable is possible to appear in two different structures: recursive function predicates or *func* call. The reason we don't need to consider the basic arithmetic operations is that the integer will be directly used as the predicate parameter, instead of the location as the parameter. For example, the sum of a list can be expressed as:

```
predicate sum(loc l, int output){
| l == 0 => {output == 0; emp}
| l != 0 => {output == output1 + v; [l, 2] ** l :-> v ** l + 1 :-> lnxt **
sum(lnxt, output1)} }
```

Such sequential application is common in functional programming, especially in the recursive function. For example, it is not elegant to flatten a list of lists without the sequential application.

$$\text{TEMPFUNCALLOC} \quad \frac{\{\phi; x \mapsto a * P\} \rightsquigarrow \{\psi; \text{func } f(e_1, \dots, e_n, x) * \text{temp}(x, 1) * Q\} | c}{\{\phi; P\} \rightsquigarrow \{\psi; \text{func } f(e_1, \dots, e_n, x) * \text{temp}(x, 0) * Q\} | \text{let } x = \text{malloc}(1); c}$$

$$\text{TEMPFUNCFREE} \quad \frac{\{\phi; P\} \rightsquigarrow \{\psi; Q\} | c}{\exists x \in Q \wedge \{\phi; P\} \rightsquigarrow \{\psi; \text{temp}(x, 1) * Q\} | \text{let } x_0 = *x; \text{type_free}(x_0); \text{free}(x); c}$$

■ **Figure 16** New allocating and deallocating rule for `temp` in SSL.

```
flatten :: [[a]] -> [a]
flatten [] = []
flatten (x:xs) = x ++ flatten xs
```

We can express this function, but with some strange structure to store all temporary lists.

```
predicate flatten(loc x, loc output){
| x == 0 => {output :-> 0}
| x != 0 => {[x, 2] ** x :-> x0 ** sll(x0) ** x + 1 :-> xnxt **
[output, 2] ** func append(x, outputnxt, output) ** output + 1 :-> outputnxt **
flatten(xnxt, outputnxt)} }
```

With such a function predicate, though we can synthesise the function whose result stored in `output` is the flattened list, the list `output` is containing a lot of intermediate values, which is neither consistent with the definition in the source language nor space efficient.

The new rules consist of allocating and deallocating rules (Figure 16). Based on the definition of the `func` structure and the function predicate, the allocated locations are different, where the `temp` location for `func` is directly used; while the `temp` location for function predicate should allocate a new location for function predicates. As for the deallocation, not only the `temp` location(s) but also the content they point to should be deallocated. That is the reason we have the `type_free` function, which is syntax sugar to deallocate the content of a location based on the type information. For example, if the type of the location is `tree`, then the `type_free` will deallocate the content of the location via `tree_free` function, which is synthesised based on the SSL predicate `tree` as follows.

```
void tree_free(loc x)
{tree(x)}
{emp}
```

Specifically, if the location contains the value with type `int`, then the `type_free` will do nothing. Thus, the function predicate with `temp` is much better, in the sense that no extra space is used, and the synthesised function is consistent with the source language.

```
predicate flatten(loc x, loc output){
| x == 0 => {output :-> 0}
| x != 0 => {[x, 2] ** x :-> x0 ** sll(x0) ** x + 1 :-> xnxt ** temp outputnxt **
** flatten(xnxt, outputnxt) ** func append(x, outputnxt, output)} }
```

4.4 Avoiding Excessive Heap Manipulation with Read-Only Locations

The existing SuSLik depends on the set theory to express the pure relation. However, it is not trivial to automatically generate the pure part of SSL specifications from the functional specifications. To see why the set theory is needed, the following simple example shows the functionality of the set theory, with `sll_n` being the single-linked list with `no` set.

```

predicate sll_n(loc x) {
| x == 0      => {true; emp}
| not (x == 0) => { [x, 2] ** x :-> v ** (x + 1) :-> xnxt ** sll(xnxt) } }
predicate copy(loc x, loc y) {
| x == 0      => {y == 0; emp}
| not (x == 0) => { [y, 2] ** y :-> v ** (y + 1) :-> ynxt ** [x, 2] ** x :-> v
                     ** (x + 1) :-> xnxt ** copy(xnxt, ynxt) } }

```

While the intent of the function predicate `copy` is to copy the list `x` to `y`, without the set theory, the output program will be somewhat surprising to see:

```

{sll_n(x)}
void copy (loc x, loc y) {
  if (x == 0) {
  } else {
    let n = *(x + 1); copy(n, y); let y01 = *y; let y0 = malloc(2); *y = y0;
    *(y0 + 1) = y01; let vy = *y0 *x = vy; } }
{copy(x, y)}

```

The problem here is that, when we have the pure relation in the predicate to indicate that the values are the same, the synthesiser finds another possible way: instead of copying the value of `x` to `y`, we can just change the value of `x` to initial value `vy` after `malloc`. This is not the user intent, and the output program is not correct. Turns out, the solution is not that difficult: we simply need add a new kind of heaplet in the specification language, call *constant points-to*, which has a similar idea as read-only borrows [2]. The only difference of the constant points-to from the original *points-to* heaplet is that the value of the location is constant, which means that the WRITE rule in SSL is not applicable. By this way, the extended SuSLik will not consider the modification of the input location, thus provides the correctness mechanism (in Subsection 3.5) for the translation of Pika.

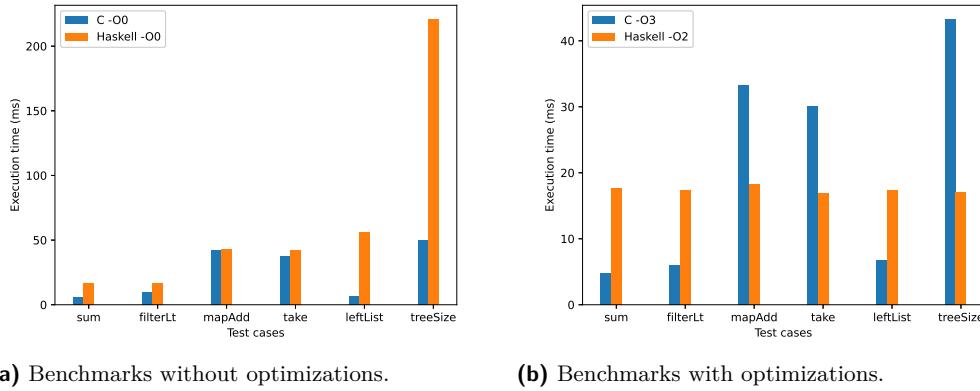

5 Evaluation

In this section, we evaluate Pika’s expressiveness. A secondary objective is to evaluate Pika’s performance. The performance evaluation is done largely to put Pika into context by comparing it to a prominent functional programming language (Haskell). The main purpose of Pika is to increase the expressiveness of SuSLik, which is the reason for the primary evaluation objective. Towards these goals, we answer the following research questions:

- **RQ1:** Is the performance of the synthesised code competitive with code generated from traditional functional language compilers?
- **RQ2:** In concrete terms, how does the tool’s expressivity compare with the expressivity of SuSLik specifications for programs written in a functional style?
- **RQ3:** What are the failure modes of our approach?

Our implementation and benchmarks are available in supplementary material. The experiments were conducted on a 2021 MacBook Pro with an M1 processor and 32 GB of RAM. We used GHC version 9.8.1 and Apple Clang version 13.0.0.

For **RQ1**, we run benchmarks and compare execution time. The benchmarks we selected are a series of functions that manipulate data structures such as lists and trees, which covers different common abstract operations (like `map`, `filter`, `fold`). The comparison is between Haskell functions based on user-defined data structures and C functions generated from Pika’s specifications (via the extended SuSLik), parameterised with the data structures of large size. We recorded both execution time with and without optimisation of compilers.

(a) Benchmarks without optimizations. (b) Benchmarks with optimizations.

Figure 17 Performance of C functions generated by Pika compared to Haskell/GHC.**Table 1** Statistics on the benchmarks: Pika spec size v, generated SSL spec size, translator performance, and synthesiser performance. All times are in seconds.

#	Task Name	Pika AST	SuSLik AST	$\frac{ \text{Pika AST} }{ \text{SuSLik AST} }$	Compile Time	Synthesis Time
1	cons	76	123	0.618	0.012	5.134
2	plus	46	91	0.505	0.002	5.992
3	add1Head	64	109	0.587	0.006	5.114
4	listId	62	107	0.579	0.005	4.906
5	add1HeadDLL	74	146	0.507	0.007	10.618
6	even	19	42	0.452	0.001	3.999
7	foldr	63	113	0.558	0.005	5.454
8	sum	58	103	0.563	0.004	5.125
9	filterLt	84	147	0.571	0.009	6.104
10	mapAdd	71	116	0.612	0.007	5.031
11	leftList	116	156	0.744	0.008	7.722
12	treeSize	78	126	0.619	0.007	5.980
13	take	119	212	0.561	0.012	10.447

The results are shown in Figure 17. Our findings are as follows:

- When compiled to an executable run without optimisations, the C programs generated by Pika are faster than Haskell programs. And we can also observe that the speed difference is larger for functions with more complex data structures.
- When compiled to an executable with optimisations:
 - For functions with complex data structures, the comparison is similar to the case without optimisation.
 - For functions for the singly-linked list GHC's optimisation is very powerful, resulting in much better performance than C programs generated by Pika. With more tests, we found out the performance after GHC's optimisation is similar to the one using Haskell's built-in list. We believe this is because GHC's optimisations are fine-tuned to optimise code manipulating list-like data structures and use the same optimisation as for Haskell's built-in list. That said, similar observations regarding GHC do not hold on other complex data structures, such as trees.

```

selfAppend : List -> List;
selfAppend xs := instantiate [S11, S11] S11 append xs xs;

append : List -> List -> List;
append (Nil) ys := ys;
append (Cons x xs) ys := instantiate [Int, S11[mutable]] S11 cons
                           (addr x) (append xs ys);

```

 **Figure 18** A Pika specification not supported by SuSLik.

To answer **RQ2**, we first find some common patterns for Pika programs in the benchmarks shown in Table 1: (1) pattern matching on ADTs (#9, 10, etc.), (2) code reusability (#3 vs 5, #7 vs 8). Those features are not directly expressible in SuSLik because of the low-level nature of SSL. For example, the `add1Head` and `add1HeadDLL` functions share the same function definition, where the only difference is the type layout used; but the SuSLik specifications need to be treated separately, which makes the codes more complex. To make some objective observations on the expressivity, we measure the number of nodes in the input Pika AST and find it consistently fewer than the number of AST nodes in the generated SuSLik specification.

To address **RQ3**, note that a particular failure mode occurs when Pika source code reuses a variable in a way that violates SSL constraints. For example, see the `selfAppend` example in Figure 18 which uses its argument twice. We could have addressed this issue by introducing a lightweight linear type system to Pika, but have not carried out this exercise yet. Another kind of failure occurs when SuSLik fails to synthesise an implementation of the generated specification: handling these failures is beyond the scope of this work.

6 Discussion

We have given a translation from a high-level functional language into SSL specifications to be given to a program synthesiser.

In doing so, we have revealed a close connection between, on one hand, algebraic data types and recursive pattern-matching functions and, on the other hand, SSL inductive predicates. The soundness of this connection is demonstrated by Theorem 3 in Section 3.

Beyond the theory, this connection can be exploited in three directions:

- Increased type safety: Algebraic data types allow you to distinguish between types that have the same runtime heap representation.
- More reusability: An algebraic data type can have multiple layouts, each of which gives a different possible runtime heap representation for the ADT. As Pika functions are defined only in terms of algebraic data types, they naturally get the *polymorphism* of the ADT by being able to work with any layout of the ADT.
- Greater succinctness: When working at this higher level of abstraction, it generally takes less code as you are not frequently manipulating heap locations. The only mention of heap locations is in reusable layout definitions. This can also give greater clarity.

7 Related Work

Pika is built upon the SuSLik synthesis framework. SuSLik provides a synthesis mechanism for heap-manipulating programs using a variant of Separation Logic [9]. However, it does not have any high-level abstractions. In particular, writing SuSLik specifications directly involves a significant amount of pointer manipulation. Further, it does not provide abstraction over specific memory layouts. As described in Subsection 2.2, Pika addresses these limitations.

Dargent language [1] also includes a notion of layouts and layout polymorphism for a class of algebraic data types, which differs from our treatment of layouts in two primary ways:

1. In **Pika**, abstract memory locations (with offsets) are used. In contrast, **Dargent** uses offsets that are all relative to a single “beginning” memory location. The **Pika** approach is more amenable to heap allocation, though this requires a separate memory manager of some kind. This is exposed in the generated language with `malloc` and `free`. On the other hand, the technique taken by **Dargent** allows for greater control over memory management. This makes dealing with memory more complex for the programmer, but it is no longer necessary to have a separate memory manager.
2. Algebraic data types in the present language include *recursive* types and, as a result, **Pika** has recursive layouts for these ADTs. This feature is not currently available in **Dargent**.

Furthermore, layout polymorphism also works differently. While **Dargent** tracks layout instantiations at a type-level with type variables, in the present work we simply only check to see if a layout is valid for a given type when type-checking. In particular, we cannot write type signatures that *require* the same layout in multiple parts of the type (for instance, in a function type `List -> List` we have no way at the type-level of requiring that the argument `List` layout and the result `List` layout are the same). This more rudimentary approach that **Pika** currently takes could be extended in future work. Overall, the examples in the **Dargent** paper tend to focus on the manipulation of integer values. In contrast, we have focused largely on data structure manipulation, which follow the primary motivation of **SuSLik**.

Synquid is another synthesis framework with a functional surface language. While **Synquid** allows an even higher-level program specification than **Pika** through its liquid types, it does not provide any access to low-level data structure representation. [8] In contrast, **Pika**’s level of abstraction is similar to that of a traditional functional language but, similar to **Dargent**, it also allows control over the data structure representation in memory.

8 Future Work and Conclusion

We make the following observations based on our experience of developing and using **Pika**.

By allowing layouts to use multiple SSL parameters, we would be able to give a greater variety of layouts associated with an ADT. For instance, the `List` data type used in the examples could have a doubly-linked list layout in addition to the singly-linked list layout `S11`. Note that any existing **Pika** function defined over `List` will continue to work with no modification with these new layouts. Defunctionalisation and lambda lifting can also be used to implement true higher-order functions.

It is possible to do inference of some layouts, for example in `mapAdd1` we would usually want to use the same layout as the argument layout, but we leave this for future work. Another approach is to introduce type variables that correspond to layouts, as done in the series of works on the **Dargent** tool [1]. We leave this approach for future work as well.

Reverse transformation deserves further investigation: if we go from an SSL specification to **Pika** program and then compile to, *e.g.*, C, can we synthesise additional programs that traditional SSL synthesisers would struggle with? What are the limitations of this approach?

We may be able to expose more of the synthesis mechanism in the **Pika** language. For example, generate an SSL specification given only a **Pika** type signature (and corresponding `%generate` directive). This could combine well with additional polymorphism, as we could utilise the free theorems that are given by a polymorphic type signature to further constrain the resulting specification.

Finally, is it possible to derive translations for languages such as Pika from abstract machine semantics? In this paper, we have given a language with abstract machine semantics. We then give a translation of that language into SSL. We then show that the final states given by the abstract machine semantics are models for the SSL propositions produced by our translation. But is it possible to begin by specifying the abstract machine semantics and then mathematically (or automatically) *derive* an appropriate translation into SSL, with the requirement that the translation satisfies the soundness theorem?

In conclusion, we have presented Pika: a high-level functional specification language that paves the way for the efficient synthesis of a verifiably correct imperative code with in-place memory updates that is comparable in efficiency to the handwritten C.

Abstract

Timing channel attacks are emerging as real-world threats to computer security. In cryptographic systems, an effective countermeasure against timing attacks is the constant-time programming discipline. However, strictly enforcing the discipline manually is both time-consuming and error-prone. While various tools exist for analyzing/verifying constant-time programs, they sacrifice at least one feature among precision, soundness and efficiency.

In this paper, we build CtChecker, a sound static analysis for constant-time programming. Under the hood, CtChecker uses a static information flow analysis to identify violations of constant-time discipline. Despite the common wisdom that sound, static information flow analysis lacks precision for real-world applications, we show that by enabling field-sensitivity, context-sensitivity and partial flow-sensitivity, CtChecker reports fewer false positives compared with existing sound tools. Evaluation on real-world cryptographic systems shows that CtChecker analyzes 24K lines of source code in under one minute. Moreover, CtChecker reveals that some repaired code generated by program rewriters supposedly remove timing channels are still not constant-time.

1 Introduction

Modern cryptographic systems are vulnerable to timing attacks [21, 10, 26, 6], which can quickly reveal confidential keys by analyzing the encryption/decryption time of those systems. While the threat has been well-known for decades, identifying timing channel vulnerabilities in cryptographic systems is a daunting task, as timing channels result from implementation details such as data and instruction cache effects, branch prediction buffers and memory controllers. As all of those hardware features are invisible in the source code, manually identifying timing channel vulnerabilities is extremely challenging, if possible at all, as doing so precisely requires a crystal clear view of the whole software-hardware stack and how secret information flows throughout the stack.

To make it feasible to mitigate timing channels, one common practice is to identify and rule out *dangerous code patterns* that lead to timing channels. Notably in cryptographic systems, a common countermeasure against timing attacks is to follow *constant-time disciplines* [1, 11], which rules out (1) branching on secret-dependent data, as well as (2) accessing memory with secret-dependent offset (e.g., an array access with a secret-dependent index). For example, a secret-dependent branch `if s[i] then x = 2` may be identified by noting that `s[i]` is the i -th bit of the private key, hence violating the first constant-time discipline. We might further replace it with `x = s[i]*(2-x)+x`, or `x = (-s[i]&2)|((s[i]-1)&x)`, which are both functionally equivalent to the original code. While the violation in this example is easy to spot as it directly uses the secret value s , detecting constant-time violations and rewriting them in a secure way in general is still error-prone, as evidenced by timing leak in manually validated code [27] as well as a sequence of timing-related patches where early patches introduce new vulnerabilities that are fixed by later ones [36]. Hence, more rigorous and automated techniques are necessary for security.

Motivated by the need for rigorous and automated tools, designing and developing automated tools for detecting and sometimes repairing constant-time violations has been an active research area. Observing the relation between constant-time disciplines and non-interference [16], most automated tools rely on some form of information flow analysis to detect constant-time violations (i.e., to detect “tainted” branch conditions and memory addresses). For example, ct-verif [1] uses a sound and complete reduction on the source code to verify constant-time disciplines as a safety problem, via off-the-shelf verification tools. FACT [11] is a domain-specific language that uses a static information flow type system to detect constant-time violations. Constantine [7] deploys a dynamic taint analysis [7], while FlowTracker [32] uses an optimized program dependence graph (PDG) to identify constant-time violations. If we narrow down the scope further and focus on *cache-based* timing channels only, it is also common to identify constant-time violations first, before further refining the results to those that are vulnerable to cache-based attacks only. For instance, SC-Eliminator [46] uses a static taint analysis to identify “leaky conditional statements” (i.e., sensitive branches) and “leaky lookup-table accesses” (i.e., sensitive memory addresses via array accesses) before applying a (more costly) static cache analysis on leaky lookup-table accesses to filter out the ones that are not vulnerable to cache-based timing attacks (though they might still be vulnerable to other variants of timing attacks; see Section 2.3). The same applies to SpecSafe [9] and oo7 [43], which used static and dynamic taint analysis respectively before applying more costly cache analysis to refine their results.

With ample tools that use information flow analysis to detect constant-time violations, the *precision issue of those tools* is still under-investigated to the best of our knowledge. Yet, to be practical, the precision issue is just as important as soundness, especially given the common wisdom that static information flow analysis usually comes with high false positive rates when being applied to real-world applications [33]. To be more concrete, the following research questions still linger when cryptographic library developers plan to develop or adopt an information flow analysis for the purpose of detecting constant-time violations:

- RQ1:** To analyze cryptographic libraries, what are the impacts of various design decisions (e.g., field-sensitivity, declassification, context-sensitivity) on the analysis precision?
- RQ2:** Which approach (e.g., logic-based formal verification, PDG-based analysis) should they follow in order to achieve better trade-offs between precision and performance?
- RQ3:** Is it possible to improve the precision of existing tools without sacrificing soundness and performance?

To address these research questions, we start from a baseline PDG-based static information flow analysis called PIDGIN [18], with minor extensions that use its resulting sensitivity of registers and memory blocks to detect violations of constant-time disciplines. With the baseline implementation, we thoroughly study the root causes of false positives produced by the baseline and improve it with various features such as field-sensitivity, declassification and flow-sensitivity to reduce its false positive rate. The precision study is performed on a benchmark consisting of various implementations of modular exponentiation used in popular cryptographic systems (Libgcrypt, OpenSSL, mbedTLS and BearSSL), which are known to be vulnerable to timing attacks, as well as a set of automatically repaired code from Constantine [7], which are expected to be constant-time. The precision study shows that field-sensitivity and declassification are the most effective features. As a result from the precision study, we built CtChecker, a precise, sound and efficient information flow analysis for constant-time programming. CtChecker was implemented based on PIDGIN, with several precision improving features introduced. CtChecker targets LLVM intermediate representation (IR), which allows it to analyze various source code languages with compatible compiler front-ends. In summary, CtChecker reduces the false positives of the baseline by 67.6%, and we observed that the remaining ones are mainly due to imprecision in the sound points-to analysis used by CtChecker. Moreover, CtChecker detects true positives in 6 repaired programs produced by Constantine, which was not revealed before to the best of our knowledge.

A1: Field-sensitivity and declassification are the most effective features that can improve analysis precision, while the precision of point-to analysis (used by sound information flow analysis) has a considerable impact on the overall precision.

To study the remaining two research questions, we first compare the precision of CtChecker with respect to ct-verif [1], which first transforms source code to target code via a sound and complete reduction, and then verifies safety properties on the target code via off-the-shelf verification tools. Despite the fact that the reduction is sound and complete, and the common wisdom that logic-based formal verification generally offers superior precision than static program analyses that are built on approximation of program semantics, CtChecker turns out to be both more precise and more efficient compared with ct-verif [1]. Digging into the results, we found that ct-verif uses *loop invariant heuristics* to verify the code after reduction, which introduced higher false positive rates than CtChecker. Moreover, PDG-based approach is more appealing for detecting constant-time violations as it can pinpoint those violations in the code, while verifiers only produce a binary result of the existence or absence of violations.

A2: Based on our empirical study on state-of-the-art tools, we found that PDG-based information flow analysis offers the best trade-off between precision and performance compared with logic-based approach.

We further compare CtChecker with CacheS [44] and SC-Eliminator [46] on the benchmarks that those tools were evaluated on. Both tools are *soundy* as CacheS is built on lightweight but unsound memory model, and SC-Eliminator assumes no information flow via aliasing. Though CtChecker is built on a sound points-to analysis, we found that CtChecker reports very similar positives with those reported by CacheS [44], even though CacheS is built on complex abstraction interpretation with an unsound memory model. Compared with the static taint analysis used by SC-Eliminator, CtChecker reports fewer positives in 6 programs and the same positives in 9 programs in the SC-Eliminator benchmark. CtChecker reports more positives in 2 programs, but they are all true positives missed by SC-Eliminator, since it does not propagate information flows via aliasing.

A3: CtChecker improves the precision of existing tools without sacrificing soundness and performance. Compared with CtChecker, existing solutions either fall short on the high false positive rates with sound static method [1], or inherit the unsoundness of dynamic

method [45, 37], or simplified but unsound memory model [44, 46]. Notably, the precision of CtChecker is close to those built on unsound memory models, even though they have the advantage of possibly reporting fewer false positives by sacrificing soundness.

In summary, this paper makes the following contributions:

- Design and implementation of CtChecker, a precise, sound and efficient static information flow analysis for constant-time programming. The source code is made publicly available¹.
- Identification of the imprecision sources (e.g., field-sensitivity, declassification and flow-sensitivity) of constant-time analysis on cryptographic libraries (Section 3), and improvement of overall analysis precision based on the findings. Overall, field-sensitivity and declassification are the most effective features that improve precision, while combining multiple features enables CtChecker to reduce the total false positives compared to the baseline by 67.6% (Section 4).
- Comparison between CtChecker and state-of-the-art tools with similar goals. Evaluation results suggest that PDG-based information flow analysis offers the best trade-off between precision and performance compared with logic-based approach (e.g., ct-verif [1]) and abstract interpretation (e.g., CacheS [44]). Moreover, its precision is close to tools that are built on unsound memory models (Section 4).
- Evaluation of CtChecker on automatically repaired code from Constantine [7] reveals new timing channels that are not reported before (Section 4).

2 Background

2.1 Information Flow Analysis

Information flow analysis tracks interactions of information throughout a program. Given the confidentiality of program inputs, an information flow analysis tracks which data have been computed from confidential information or its derivatives. In general, information flow analysis handles complex confidentiality and/or integrity policies which can be formalized as a security lattice [13], while its simplest setting, known as *taint analysis*, only handles a two-level confidentiality lattice with “public” and “secret” labels only. A *sound* information flow analysis typically enforces *non-interference* [16] or its variants. Intuitively, non-interference guarantees that information labeled with higher confidentiality (or lower integrity) has no influence on information labeled with lower confidentiality (or higher integrity).

Listing 1 Example of Explicit and Implicit Information Flow.

```
// key = sensitive information
x = key + 1;
y = 0;
if (key > 100) {
    y = 1;
}
```

There are two kinds of information flows: explicit and implicit, as illustrated in the example shown in Listing 1. In this simple example, `key` is the only confidential input. We can see that `x` is directly computed from `key`, forming an *explicit* information flow. On the other hand, the variable `y` is assigned to a public constant in the true branch. However, due to the fact that the assignment occurs only in a branch whose condition is dependent on `key`, an attacker with the ability to observe the value of `y` can infer if the value of `key` is above 100 or not. In this case, the confidential data *implicitly* flows into `y`.

¹ <https://github.com/psuplus/CtChecker>

A variety of information flow analyses have been implemented with different methodical approaches. The utilization of program dependence graph (PDG) to detect the flow of information inside a program can be found in works such as PIDGIN [18] and FlowTracker [32]. Another approach is to use reduction techniques such as self-composition [5, 1] and product programs [4, 48] to reduce the information flow problem to safety properties, which can be verified by formal methods. Type-based approach, another more traditional method, can be found in various implementations [23, 42, 30]. Besides the static sound approaches above, dynamic taint analysis tracks information flow [14, 24, 39] at program execution time.

In this paper, we focus on the PDG-based approach and logic-based approach as they have been used in existing *automated and sound* tools that detects timing channels [1, 32]. Some prior work uses type-based approach to detect timing channels in software [49] and hardware [51] designs, but the precision of type systems is usually limited [33, 20]. They require type annotations from programmers, which is time-consuming, and pinpointing the root cause of type errors is a nontrivial task [50, 25, 34].

2.2 Timing Channels in Cryptosystems

A timing channel is a side channel in which an attacker uses program execution time to learn information about sensitive data. In some implementations of sliding window exponentiation, for example, the sequences of squares and multiplies can be measured due to differences in each method's execution time. This attack can be illustrated in the source code from an old OpenSSL implementation of sliding window exponentiation, shown in Listing 2.

Listing 2 Square and Multiply Timing Channel.

```

1  for (i = 1; i < bits; i++) {
2      if (!BN_sqr(v, v, ctx))
3          goto err;
4      if (BN_is_bit_set(p, i))
5          if (!BN_mul(rr, rr, v, ctx))
6              goto err;
7 }
```

The for-loop here iterates through each bit in the confidential exponent p . In each iteration, it first computes the square of v , and if the i -th bit of p is set, an additional multiplication computation is executed before proceeding to the next loop iteration. Since the extra multiplication computation is *only performed* when the i -th bit of p is set, the code is vulnerable to a timing attack which utilizes the “side effects” of the extra computation on timing to rebuild the entire private key (e.g., [6]).

Another common kind of timing channels in cryptography algorithm implementations root from array accesses being indexed with an offset derived from secret. The reason is that when accessing the memory, different indices may cause the loading or eviction of data into or from different cache lines in the data cache. By observing such behaviors, an attacker could reveal secret data; this variant of timing attacks is also known as *cache attacks*. The code snippet below is an example which is vulnerable to cache attack, where a public array $Sbox$ is accessed with secret key RK :

```
RK[4] = RK[0] ^ Sbox[(RK[3] >> 8) & 0xFF];
```

As different values of $RK[3]$ can lead to different cache lines to be fetched, a cache-probing attack can be launched to learn the value of $RK[3]$. The code snippet represents real timing vulnerabilities in encryption algorithms such as AES [17].

2.3 Constant-Time Disciplines and Cache-Specific Analysis

As timing channels are revealed by the execution time of a program, and many hardware features (e.g., data/instruction cache, CPU pipeline and cache bank) can affect timing, manually reasoning about timing channel vulnerabilities is extremely challenging, if possible at all. So as a practical countermeasure against timing channels, the threat model of constant-time discipline [1, 11] defines two constant-time violations of programs which can be exploited by attackers: (1) secret-dependent branch conditions, and (2) secret-dependent memory addresses. The constant-time disciplines are widely adopted in security-critical cryptographic systems [1, 11] due to a few benefits:

- It is *agnostic* to hardware configurations (e.g., cache configuration and replacement policy and features (e.g., cache, pipeline and cache bank) that are utilized by timing attacks).
- It provides a security abstraction that is more attractable both for programmers and for rigorous program analysis. For example, it is a common practice to use information flow analysis [1, 7, 11, 32] to detect constant-time discipline violations: it is sufficient to tag branches and memory accesses that use tainted values.

We note that under a *weaker threat model* that focuses on cache-based timing attacks only, various cache analyses [8, 35, 46] has been developed to detect if confidential information has impact on the cache hit/miss behaviors. For instance, SC-Eliminator [46] assumes a weaker threat model where an attacker only observes the number/type of instructions and cache hits/misses. Consider `preload A; A[secret]`, where `preload A` loads the whole array `A` into the cache. The code is secure per SC-Eliminator’s threat model since `A[secret]` always hits the cache. But it is insecure against other sophisticated attacks, such as the CacheBleed attack [47] that exploits cache-bank conflicts, and traffic analysis on the memory bus.

Despite the differences in their threat models, we note that cache analysis sometimes performs a static taint analysis first to identify array indices that are potentially tainted by sensitive data. Then, with the results from the taint analysis, a more costly cache analysis is performed to determine cache hits/misses. A positive from the taint analysis is removed if the cache analysis decides that this positive is a cache must-hit [35, 46]. Hence, precision improvements in sound and efficient static taint analysis, the focus of this paper, could also improve the precision of existing cache analysis, despite their very different threat models.

3 CtChecker Design

In this section, we depict the design details of CtChecker. We first describe the general workflow of CtChecker. Then we highlight the unique challenges and their solutions, and finally discuss the precision of CtChecker.

3.1 General Workflow

CtChecker first captures information flows by identifying the information flow introduced by each instruction according to its semantics. The captured flows are represented as a set of constraints, where each constraint element represents the sensitivity of registers or memory blocks. A least solution that satisfies all constraints is then computed. Lastly, all branch conditions and memory accesses are checked against the least solution to see if any sensitive information was used in them, resulting in violations of constant-time discipline.

```
<pointer> = getelementptr inbounds <ty>, ptr
    <ptrval>{}, [inrange] <ty> <idx>}*
```

Flow: $V(\text{ptrval}) \rightarrow V(\text{pointer})$

```
store <ty> <value>, ptr <pointer>
```

Flow: $V(\text{value}) \rightarrow D(\text{pointer})$

```
<result> = load <ty>, ptr <pointer>
```

Flow: $V(\text{pointer}) \cup D(\text{pointer}) \rightarrow V(\text{result})$

■ **Figure 1** Memory-Related Specification for LLVM IR.

3.1.1 Capturing Information Flows

The information flow specification of each instruction describes the sources (i.e., where information come from) and the sinks (i.e., where information go to). Based on the semantics of each instruction, the sources and sinks are usually easy to identify: instruction operands being read are sources and operands that are written to are sinks. However, since pointers can point to different data (in the memory) and the data to which they point to can change, a concrete information flow specification needs to distinguish three categories of elements, namely 1) the operand itself (e.g., a register), 2) the memory location that a pointer directly points to, and 3) all memory locations that are reachable from a pointer (through pointer arithmetics). Hence, we define three functions (V, D, R) which return the elements to be constrained for a value, respective to the three categories.

- $V(x)$, the value associated with the operand x .
- $D(p)$, the memory block that a pointer p points to.
- $R(p)$, the set of all reachable (i.e., accessible) memory blocks from a pointer p .

In order to correctly compute D and R , a sound points-to analysis is employed. Formally, the points-to analysis creates a directed graph $G = (P, M, E)$ from the code being analyzed, where node set P represents all pointer values, node set M represents all memory blocks being allocated, and edge set E links nodes in P to nodes in M (i.e., the points-to relation), as well as links connecting memory blocks, as a memory block can also hold a pointer.

To compute the function $D(p)$, we locate $p \in P$ and return the set $\{m \mid m \in M \wedge (p, m) \in E\}$. Similarly, to compute the function $R(p)$, we return the set of memory blocks that are *reachable* from p in G . For example, assume a pointer p_1 pointing to a pointer field of a data structure, $D(p_1)$ will be the memory block storing the pointer only, while $R(p_1)$ contains all the memory blocks that can be recursively reached by p_1 through node traversal, which include both the memory block storing the pointer and the data that the pointer points to.

For most IR instructions, information flow is captured by a simple value flow, $V(\text{source}) \rightarrow V(\text{sink})$. For memory-related instructions (e.g., the `getelementptr` (GEP), `store` and `load` instructions in LLVM IR), the more complicated specification is given in Figure 1. Specifically, for GEP instruction that calculates the memory address of a subelement in an aggregate data structure (i.e., array and structure) from the base pointer and the index of the target subelement, the sink $V(\text{pointer})$ is the address directly pointed to by p . For `store` and `load`, function D is used to specify the source and destination of the memory write and read respectively. Function R is used for function calls, which we discuss in Section 3.2.4.

3.1.2 Constraints and Their Least Solution

With the information flow specification, CtChecker creates a set of *constraints* from sources to sinks for each instruction. For each register and memory block $m \in M$, a distinguished *constraint element* is created (i.e., a one-to-one mapping). For an information flow $source \rightarrow sink$, a constraint is generated as $E_{source} \leq E_{sink}$ where E_{source} and E_{sink} are the corresponding constraint element of the *source* and *sink* respectively. The \leq symbol represents a partial ordering on the constraint elements and each constraint element can either be L (public) or H (secret), where $L < H$ and $H \not\leq L$. Additionally, CtChecker identifies the initial sensitive data m (e.g., secret keys) and generates constraints of the form $H \leq E_m$. For example, code snippet “`k=secret; x=k; y=0;`” will generate three constraints $H \leq E_k$, $E_k \leq E_x$ and $0(\text{constant}) \leq E_y$. These generated constraints are then added to the set of constraints, which are used to find the least solution.

The least solution, if exists, can be computed with linear-time algorithms, such as the Rehof-Mogensen algorithm [31]. By definition, the *least solution* provides the *least* confidentiality level of each constraint element, where the set of constraint elements with the least level H are considered to contain sensitive information. For the code snippet above, the least confidentiality level of `k`, `x` and `y` are H , H , and L , respectively. As a result, `k` and `x` are considered containing sensitive information.

3.1.3 Checking the Constant-Time Discipline

With the least solution at hand, CtChecker can check whether the analyzed program adheres to the constant-time discipline by examining all branch conditions and memory accesses, where a violation is found if a branch condition has level H , or a memory address being loaded from or stored to has level H . CtChecker reports all locations in terms of the line number in the source code regarding violations of the constant-time discipline.

3.2 Challenges and Solutions

The general workflow above presents the foundation of a *sound* analysis of constant-time programs. However, to develop an *useful* analysis, we need to address the following challenges.

3.2.1 Field-Sensitivity

In the naive analysis above, function D is modeled as $D(\text{pointer})$, the aggregated data structure that `pointer` points to. However, it is common for cryptographic libraries to store secret and public information in the same structure. In Listing 3, consider the `gcry_mpi` struct of Libgcrypt, where the array under `expo->d` in the modular exponentiation function holds secret value, while all other metadata fields are public. The naive approach would constrain `expo` as a single entity, reporting both branches at lines 8 and 9 as secret-dependent branches. However, the branch on `expo->flags` is not secret, resulting in a false positive.

To address the issue, both the sound points-to analysis and information flow analysis need to be *field-sensitive*, meaning that they both need to differentiate different fields in a structure. In particular, points-to analysis creates one separate memory block for each *subelement* in aggregate data structures, and correspondingly, CtChecker creates one distinct constraint element for each memory block from points-to analysis. By retrieving the offset and size information when possible (using `idx` operand from the corresponding GEP instruction of a `store` or `load` instruction as well as type information), CtChecker refines function D as $D(\text{pointer}, \text{offset}, \text{size})$, providing the necessary lookup information into the memory nodes in G , constructed by a field-sensitive points-to analysis. Function R is refined in a similar way.

■ **Listing 3** Field-Sensitivity Issues.

```

1 struct gcry_mpi {
2     ...
3     unsigned int flags;
4     mpi_limb_t *d;           // secret value
5 };
6
7 struct gcry_mpi *expo;
8 if (expo->flags) ... // not secret-dependent
9 if (expo->d[i]) ... // secret-dependent
10 if (expo->d) ... // not secret-dependent

```

One remaining subtlety is to distinguish pointer values and the memory blocks that they point to. For example, it is common to store private keys at the public memory address (i.e., revealing the addresses of the keys does not reveal their values). To prevent CtChecker from over-tainting these addresses (e.g., line 10 in Listing 3), CtChecker follows a two-phase approach. In the first phase, CtChecker propagates the addresses that are potentially storing sensitive information. In the second phase, when the data in these addresses is accessed, the tainted information will then be tracked from these accesses.

We note that while field-sensitivity can be enabled on many cases, a sound analysis inevitably needs to sacrifice field-sensitivity in cases where type information is missing, or aliases have inconsistent types, for instance. In these cases, refined function $D(\text{pointer}, \text{offset}, \text{size})$ resorts to its basic version without `offset` and `size` (i.e., D retrieves all fields in the structure that `pointer` points to).

3.2.2 Declassification

In real-world applications, strict information flow analysis should be relaxed to allow information flows that reveal limited or intended amount of sensitive information. This relaxation is known as *declassification*. CtChecker supports a *whitelisting* mechanism, where a user-provided whitelist (often provided by a programmer with domain knowledge) consists of variables that are derived from tainted data but are considered harmless. For all cryptographic libraries, we add variables storing *key sizes* but nothing else to the whitelist. These variables are manually checked to make sure that they do not contain key content themselves.

With a whitelist, CtChecker removes constraints that are associated with whitelisted variables after constraint generation. This way, not only the whitelisted variables are considered public, but also variables derived from them. The branches based on whitelisted variables or their derivatives are not reported by CtChecker.

3.2.3 Flow-Sensitivity

A variable might store both sensitive and public values at different program points, leading to imprecision issues. Consider the code snippet where both branches are dependent on `i`.

```

1 int i = key;
2 if (i == 0) ... // secret-dependent
3 i = 10;
4 if (i == 0) ... // not secret-dependent

```

A naive information flow analysis generates the constraints $H \leq E_i$ and $L \leq E_i$, where `i` throughout the program shares the same constraint element E_i . The least solution of the constraints is $E_i = H$, meaning that `i` is potentially sensitive. As a consequence, both branch conditions at lines 2 and 4 are marked as violations of constant-time discipline.

```
declare <RetType> @<FnName> ([arg list])
```

Flow: $V_{args} \cup R_{args} \rightarrow T_{ret} \cup R_{args}$

$$V_{args} = \bigcup_{i=0}^N V(arg_i)$$

$$R_{args} = \bigcup_{i=0}^N \{R(arg_i) : type(arg_i) = \text{pointer}\}$$

$$T_{ret} = \begin{cases} V(\text{retval}) & \text{RetType = primitive} \\ R(\text{retptr}) & \text{RetType = pointer} \end{cases}$$

 **Figure 2** Unknown Function Specification for LLVM IR.

Observing that the root cause of the issue above is lacking flow-sensitivity, CtChecker utilizes existing compiler support to improve flow-sensitivity. In LLVM, all registers are in static single-assignment (SSA) form. Hence, CtChecker can utilize LLVM’s `mem2reg` pass, which transforms the IR code by turning the standard `alloca-store-load` instruction sequences on memory (e.g., assignment and use of `i` in the example above) into simple register assignments. With the code transformation, the two `i`’s are named as `i.0` and `i.1`, respectively. Hence, two constraints are generated: $H \leq E_{i.0}$, $L \leq E_{i.1}$, and the least solution is $E_{i.0} = H, E_{i.1} = L$. Therefore, only the branch at line 2 which uses `i.0` is marked.

However, we note that due to aliasing and other subtleties in C language’s memory model, enabling flow-sensitivity on pointer-based accesses while maintaining soundness is much more challenging, which is beyond the scope of this paper.

3.2.4 Unknown Functions

The analyzed code often calls to external functions whose source code is either unavailable, or not covered by the analysis. To soundly capture information flows with the absence of some function definitions, we need to constrain possible flows in those missing functions. Obviously, input arguments can flow to return values. Moreover, if an argument or the return value is a pointer, any value that is *reachable* from the pointer-argument might flow to all *reachable* values from the pointer-return (e.g., through pointer arithmetics and memory writes). Hence, the information flows with absent function implementation is specified as the rule in Figure 2, where reachable memory from pointer-arguments are both sources and sinks of information flow, while reachable memory from pointer-return are sinks.

3.3 Precision of CtChecker

While CtChecker is empowered by various techniques above to improve its precision while maintaining soundness, false positives are still unavoidable like any nontrivial static program analysis.

One potential source is from a sound points-to analysis. To be sound, the points-to analysis must mark memory nodes as collapsed when the type information is inconsistent or missing. Once a node is collapsed in the points-to analysis, field-sensitivity is lost on the memory node. Moreover, whenever the points-to analysis fails to distinguish two different pointers’ corresponding memory nodes, it merges them into one node, resulting in an over-approximation of the taint analysis.

Second, CtChecker is a context-sensitive interprocedural analysis. However, when a callee function is invoked multiple times within the same caller function with different arguments, CtChecker only creates one context for all calls. This leads to the same indexed arguments of the multiple calls being aliased in the points-to analysis. As a result, a similar over-approximation is observed.

Furthermore, the adoption of LLVM’s `mem2reg` pass only enables flow-sensitivity on non-aggregate type memory. Memory accesses involving GEPs are still flow-insensitive.

While the above limitation prevents us from removing all false positives, we observe that CtChecker is able to outperform existing sound analysis. We provide the evaluation details next in Section 4.

4 Evaluation

4.1 Implementation

We implement CtChecker on PIDGIN [18], a static information flow analysis that integrates a query language into program dependence graphs (PDGs). However, PIDGIN lacks the precision-enhancing features discussed in Section 3.2, which we implement with an additional 2100 LOC in C++.

One implementation choice of static information flow analysis is the points-to analysis to derive sound approximation of memory blocks that a pointer might point to. The two mainstream points-to analysis algorithms are the unification-based Steensgaard’s algorithm [38] and the inclusion-based Andersen’s algorithm [2]. Both algorithms have implementations that are both context- and field-sensitive in order to gain better precision. For example, DSA [22] is a field- and context-sensitive points-to analysis based on Steensgaard’s algorithm with heap cloning. On the other hand, Andersen’s algorithm is generally considered more precise but also costly. Tools such as SVF [40] provide precision from context- and field-sensitivity without sacrificing much performance. Noting that DSA is used in our baseline PIDGIN and ct-verif [1], a representative logic-based tool, CtChecker is also built on top of DSA to make fair comparison with them (see the comparison with PIDGIN in Section 4.4 and ct-verif in Section 4.5). We leave the study of the impact of points-to analysis on constant-time analysis as future work.

4.2 Benchmarks

We evaluated CtChecker on two sets of benchmark programs. The first benchmark set consists of code taken from four cryptographic libraries, i.e., BearSSL v0.6 [29], Libgcrypt v1.10.1 [12], mbedTLS v3.2.1 [41] and OpenSSL v1.1.1q [15]. Among the four libraries, Libgcrypt and OpenSSL have widespread use, mbedTLS is built for embedded platforms, and BearSSL is less popular but it claims to be a constant-time cryptographic library [28]. In particular, the code consists of the modular exponentiation implementations of each library, where 4 implementations are taken from OpenSSL, as it is the only library that has various implementations for the same functionality. In the benchmark, the exponents in the modular exponentiation computation is marked as confidential sources. According to the definition of constant-time discipline, the sinks of the analysis are simply branch conditions and memory addresses.

The second benchmark set consists of code generated by a constant-time rewriter Constantine [7], which automatically identifies timing channels in the source code and repair them to follow the constant-time discipline². To the best of our knowledge, this is the first work to analyze the rewritten code by constant-time rewriters. Due to an incompatible LLVM version used by Constantine [7], we used an off-the-shelf C-backend [19] to translate their rewritten IR back to C source code whenever possible.

4.3 Evaluation Setup

We answer four research questions with the evaluation:

- Q1: Impact of separate features.** How do field-sensitivity, declassification and flow-sensitivity affect the analysis precision as separate features? Will including additional source code improve the analysis precision? Does CtChecker improve the precision of its baseline (i.e., PIDGIN)?
- Q2: Comparison with state-of-the-art.** Does CtChecker improve the precision when compared with ct-verif [1], a sound verifier for constant-time programming? Does CtChecker produce comparable or even more precise results when compared with CacheS [44] and SC-Eliminator [46]), both are built on simplified but unsound memory model?
- Q3: Precision.** How many false positives does CtChecker produce? What are the origins of the remaining false positives?
- Q4: Scalability.** Does CtChecker scale to real-world codebase with moderate size?

4.4 Impacts of Analysis Features

To answer Q1, we first create three variants of CtChecker, where only one feature among field-sensitivity (FS), white-list (WL) and flow-sensitivity (FL) is enabled. One extra feature, which is external to CtChecker, is how much code does it cover in the analysis. To study the impact of code coverage, we create two versions of each library implementation: one only includes the essential code that is necessary to compile the modular exponentiation implementation, while the other version (SRC) includes utility functions such as the multi-precision integer (mpi) or big number (bn) libraries³. The evaluation results are summarized in Table 1.

The improvement for field-sensitivity alone (column FS) is smaller than expected: while all implementations allocate secret and non-secret values in same structures, only four implementations (Libgcrypt, mbedTLS, BearSSL and OpenSSL-MontConstTime) observe some improvements. The reason is largely due to the lack of utility function implementations: both points-to analysis and information flow analysis remain very conservative without callee’s implementation, making it hard to differentiate read/write effects on each individual data field.

All four libraries saw a considerable reduction in positives when whitelist was used (column WL). The removed positives only leak key sizes, which are explicitly declassified in the whitelist. OpenSSL and mbedTLS saw a slight reduction with flow-sensitivity enabled (column FL).

² We pick Constantine [7] instead of other available rewriters such as SC-Eliminator [46], Lif [35] as they both assume a weaker threat model that only tackles cache attacks (see Section 2.3). In particular, their rewritten code with prefetching technique still violates constant-time disciplines.

³ The only exception is on BearSSL, which remains the same for both versions for two reasons: (1) the modular exponentiation function only contains high-level code that makes up fewer than 20 lines of code. An analysis on it alone does not generate any meaningful result, and (2) BearSSL has a much smaller codebase compared with other libraries.

Table 1 Number of positives based on features. Each column represents the analysis result with some features enabled. *Base*: the baseline analysis, *FS*: field-sensitivity, *WL*: whitelist, *SRC*: adding extra source code, *FL*: flow-sensitivity, and *All*: all features enabled. *TP* represents the true positives and *Reduction* computes the reduction rate of false positives, i.e., $(\text{Base} - \text{All}) / (\text{Base} - \text{TP})$.

Library	Base	FS	WL	SRC	FL	All	TP	Reduction
Libgcrypt 1.10.1	66	46	55	76	66	30	6	60.0%
mbedTLS 3.2.1	50	45	48	33	45	10	4	87.0%
BearSSL 0.6	18	15	6	18	16	3	1	88.2%
OpenSSL 1.1.1q								
Reciprocal	14	14	3	20	13	9	2	41.7%
Mont	45	45	36	37	44	25	2	46.5%
MontConstTime	36	27	28	29	34	18	0	50.0%
MontWord	4	4	2	15	4	12	1	-267%
binsec/aes_big	0	0	—	—	0	0	0	—
binsec/des_tab	51	26	—	—	51	26	24	92.6%
binsec/tls-rempad-luk13	7	6	—	—	7	6	6	100%
appliedCryp/3way	41	0	—	—	41	0	0	100%
appliedCryp/des	72	62	—	—	72	62	62	100%
appliedCryp/loki91	75	72	—	—	75	72	56	15.8%
ghostrider/findmax	0	0	—	—	0	0	0	—
ghostrider/matmul	4	0	—	—	4	0	0	100%
libg/des	448	432	—	—	448	432	432	100%
pycrypto/ARC4	20	19	—	—	20	19	19	100%
Overall	951	813	178	228	940	724	615	67.6%

Including additional source code (column SRC) does not necessarily reduce false positives: doing so in fact increases positive numbers for Libgcrypt, OpenSSL-Reciprocal and OpenSSL-MontWord. This somewhat surprising degradation comes from the imprecision of the underlying points-to analysis. The points-to analysis, using heap cloning technique, will merge distinct nodes that are processed by a common function. The analysis also merges nodes that are found to be in the same equivalence class. In the case of Libgcrypt, nodes that were considered distinct in the baseline test, end up aliased to the same node in the full source benchmark.

CtChecker enables all features and analyzes more than the essential code (i.e., it also covers utility function implementations), whose result is shown under the column “All”. For most libraries, CtChecker delivers the most precise result, with the exceptions of OpenSSL-Reciprocal and OpenSSL-MontWord. By inspecting the differences, we concluded that the reason is also due to undesirable effects in the points-to analysis when additional code is being analyzed.

4.5 Comparison with ct-verif

ct-verif [1] is one of the first sound tools for verifying constant-time properties; it uses the self-composition technique [5] to convert the constant-time property into a classical program verification problem. One reason for comparing with ct-verif is that it is also built on top of the DSA [22] points-to analysis; hence, the comparison focuses on the advantages of each approach, rather than some engineering details, such as the difference in the points-to analysis, in their implementations.

Table 2 Comparison with ct-verif. “Full-SRC” corresponds to full source in Table 1. “No-Undefined-Function” is the version where all function calls without sources are removed. “ct-verif-Verified” stands for all positives in ct-verif are removed, while “CtChecker-Verified” stands for all positives in CtChecker are removed.

Library	ct-verif				CtChecker			
	Full SRC	No Undefined Function	ct-verif Verified	CtChecker Verified	Full SRC	No Undefined Function	ct-verif Verified	CtChecker Verified
Libgcrypt 1.10.1	–	20	0	10	30	6	0	0
mbedTLS 3.2.1	OOM	5	0	1	10	4	0	0
BearSSL 0.6	3	3	0	0	3	3	0	0
OpenSSL 1.1.1q								
Reciprocal	–	2	0	0	9	2	0	0
Mont.	–	4	0	2	25	2	0	0
Mont. Const. Time	–	2	0	3	18	0	0	0
Mont. Word	–	1	0	0	12	1	0	0

One challenge in the comparison is that as a verification tool, ct-verif only reports whether the input program is constant-time or not⁴. To find the exact lines that ct-verif deems constant-time violations, a line-by-line check on the source code is needed. Whenever ct-verif reports a positive, we log the current line, modify it with some constant-time code, and run ct-verif again. The same strategy is applied to function calls that lead the control flow to other functions.

Even though we carefully make the changes so that the information flow remains the same, there is still a chance that the information flow might be changed while rewriting the code that has constant-time violations. For a fair comparison, both tools are running on the same rewritten code.

4.5.1 Results

Both ct-verif and CtChecker are sound analyses and we did observe that both tools report all true positives. The differences are on false positives. To evaluate the false positive reported by each tool, we consider four variants of the cryptographic libraries that we evaluated in Section 4.3. The results are summarized in Table 2.

Full-SRC contains the full source code of the libraries, including mpi libraries. ct-verif was only able to analyze BearSSL in this setting (recall that BearSSL has the smallest codebase among all libraries). ct-verif fails with an out-of-memory error on mbedTLS. As for Libgcrypt and OpenSSL, full source introduces a huge amount of source code. Since we have to manually go through the source code line by line with ct-verif to find offending lines. It is a prohibitive amount of work to get all positives. On the contrary, CtChecker could get all four libraries’ results, where the result on BearSSL is the same as what ct-verif reports.

No-Undefined-Function corresponds to the minimal source in Table 1. The difference here is that a function call will be removed if it calls an undefined function. The reason is to accommodate the difference in how the tools treat excluded sources. ct-verif treats a return value as sensitive even if there is no tainted argument used in this function call. CtChecker taints all reachable memory in the presence of pointer-values (even if the pointer itself is

⁴ When verification fails, ct-verif does generate some error messages. However, it is hard to decipher those messages and link them to the source code.

not tainted, see Section 3.2). Removing undefined function calls allows a fair comparison between the two tools. We note that for all libraries, CtChecker is consistently at least as precise as ct-verif, where CtChecker reports fewer positives in 4 out of 7 libraries.

ct-verif-Verified was created from column *No-Undefined-Function* by removing all positives reported by ct-verif, resulting in fully verified code that is constant time. Any positive reported by CtChecker on this version is expected to be a false positive. That being said, CtChecker reported no positive when all positives are removed in ct-verif.

CtChecker-Verified was created similarly from column *No-Undefined-Function* by removing all positives that are reported by CtChecker. Each program is a piece of verified constant-time code. Hence, the positives reported by ct-verif on this version are false positives (we also manually confirmed). ct-verif reports 16 false positives in total on the constant-time code.

To understand the possible causes for these false positives reported by ct-verif, we analyzed its output IR code and results. One reason is that memory nodes within an array are marked public with a constant length by annotation in ct-verif. When a loop is encountered, memory could be accessed with a loop variable. Then, ct-verif fails to determine whether a piece of accessed memory is within the public area or not, because it cannot infer how many iterations at most the loop will be executed. Loop invariants could be automatically computed to verify the range of loop variables. However, the loop invariant generation in ct-verif, based on a simple heuristic, might fail to verify secure code. Another series of false positives originates from how ct-verif handles `memcpy`, for which it will show arbitrary behaviors. For example, in the code snippet below, the addresses of `s`, `p1`, `p2` and `p3` are set to public. The contents of `p1`, `p2` and `p3` are also public.

```

1 int test(int *s, int *p1, int *p2, int *p3) {
2     int a=32;
3     memcpy(p1, p2, a);
4     if (p3[0]) dummy++;
5 }
```

After calling `memcpy`, the content of `p3` is tainted and line 4 will be reported, even though `p3` is neither an argument nor the return of `memcpy`.

In summary, CtChecker exhibited a considerable improvement in precision over ct-verif, a result apparent in the difference between the number of positives reported by each tool in the last three columns. Moreover, as discussed above, CtChecker is more user-friendly as it reports all positives in one shot, whereas using ct-verif to find all positives in source code is cumbersome.

4.6 Comparison with CacheS

CacheS [44] uses abstract interpretation to verify constant-time property. Notably, CacheS is a “soundy” analysis where “the implementation is unsound for speeding up analysis and optimizing memory usage, due to its lightweight but unsound treatment of memory”, quoted from the same paper. Also, it operates on a platform independent IR called REIL IR, which is lifted from x86 assembly code. We compare CtChecker against CacheS to show how the memory model and IR code could affect analysis results, see Table 3.

For Libgcrypt, CacheS reports line 19 in Listing 4 (line 682 in *mpi-pow.c*), where `e0` is derived from `secret`. But CtChecker ignores this line. The reason is that in LLVM IR, this line is neither compiled into a branch nor accesses memory with sensitive index. However, in REIL IR, `cmove` instruction is lifted to a branch with a condition that is derived from the `secret`, the reason that CacheS reports it.

■ **Table 3** Comparison with CacheS (★: low-risk positives; †: extra positive reported by CacheS).

Library	File	CtChecker Positives	CacheS Positives
Libgcrypt 1.10.1	mpi-pow.c	440	440
		559★	749★
		617	617
		641	—
		667	—
		—	682†
		702★	—
mbedTLS 3.2.1	bignum.c	2124	2124
		2127	2127
		2173	2173
		2182★	2182★
BearSSL 0.6	i32_sub.c	36	N/A
OpenSSL 1.1.1q			
Reciprocal	bn_exp.c	242	N/A
Mont.		262	
Mont. Word		398	
		419	
		1240	

We also observe that CacheS ignores a few high-risk positives reported by CtChecker. In Libgcrypt, two high-risk positives are overlooked, namely, lines 7 and 13 in Listing 4 (lines 641 and 667 in *mpi-pow.c*). In LLVM IR, the branch conditions at these lines are derived from the secret value and they are inside a loop, which leads to multiple-bit leakage. Similar to the previous case, the difference between two tools’ analysis targets leads to discrepancies in results. CacheS observes a `bsr` instruction in the assembly code, which is a constant-time instruction on most architectures.

CacheS employs a lightweight but unsound memory model, which avoids one issue of CtChecker: 69% of false positives of CtChecker are introduced by DSA. However, as a trade-off, this advantage may lead to false negatives in detecting high-risk vulnerabilities, though we did not observe any false negatives from CacheS in our evaluation.

4.7 Comparison with SC-Eliminator’s Taint Analysis

As discussed in Section 2.3, SC-Eliminator [46] and CtChecker assume different threat models. As a consequence, SC-Eliminator performs a taint analysis that identifies violations of constant-time disciplines first, before the results are further analyzed by a cache analysis. Here, we compare CtChecker with SC-Eliminator’s taint analysis as they both share the same functionality. The comparison is also meaningful as precision improvements in the taint analysis could help cache-analysis tools like SC-Eliminator to rewrite less code, which improves the performance of the product rewritten code.

Listing 4 Code snippet from Libgcrypt (*mpi_pow.c*).

```

1 count_leading_zeros (c0, e);
2 e = (e << c0);
3 c -= c0;
4 j += c0;
5
6 e0 = (e >> (BITS_PER_MPI_LIMB - W));
7 if (c >= W)
8     c0 = 0;
9 ...
10 count_trailing_zeros (c0, e0);
11 e0 = (e0 >> c0) >> 1;
12
13 for (j += W - c0; j >= 0; j--)
14 {
15     base_u_size = 0;
16     for (k = 0; k < (1<< (W - 1)); k++)
17     {
18         ...
19         base_u_size |= ( precomp_size[k] & (OUL - (k == e0)) );
20     }
21     ...
22 }
```

We build SC-Eliminator from source code⁵ with LLVM 8.0.1. The comparison was based on the benchmarks used in [46], see Table 4. Before analyzing the results, we note two major differences between CtChecker and SC-Eliminator’s taint analysis:

1. While CtChecker is built on a sound points-to analysis, SC-Eliminator’s taint analysis *does not* use any points-to analysis. The result is that the latter might miss taints that are propagated via aliasing.
2. While CtChecker is implemented as an interprocedural analysis, SC-Eliminator’s taint analysis is implemented as an *intraprocedural* analysis. Although an intraprocedural analysis is inherently free of context-sensitivity issues that we discuss further in Section 4.8, it requires manual efforts to label sensitive function parameters⁶, which is both time-consuming and error-prone.

Despite the differences above, both favor SC-Eliminator’s taint analysis in terms of precision, CtChecker reports fewer positives in 6 benchmark programs, while the two tools report the same number of positives on 9 of the benchmark programs. Surprisingly, SC-Eliminator reports less positives in two algorithm programs, namely, *anubis* and *cast5* in the Chronos library. The extra positives that CtChecker reports, as we investigate deeper, are true positives. *But due to the lack of a points-to analysis, SC-Eliminator missed them.* In other words, SC-Eliminator in fact has *false negatives*, which we elaborate next.

4.7.1 False Negatives in SC-Eliminator’s Taint Analysis

The lack of a points-to analysis sometimes breaks the propagation of information flow. The code snippet shown in Listing 5 contains a concrete true positive that is missed by SC-Eliminator. Here, the first parameter **key** of function **bar** is the tainted source. At line 8, the first element of **ctx->keys** is tainted by **key**. So, line 9 violates constant-time disciplines

⁵ <https://bitbucket.org/mengwu/timingsyn/src/master/>

⁶ To reduce the effort, with only a few hard-coded cases, SC-Eliminator’s taint analysis assumes that only the first parameter of every function to be tainted.

 **Table 4** Comparison with SC-Eliminator's Taint Analysis.

Library	SC-Eliminator		CtChecker
	Positives Reported	False Negatives	Positives Reported
appliedCryp/3way.c	4	0	3
appliedCryp/des.c	22	0	18
appliedCryp/loki91.c	8	0	7
chronos/aes.c	388	0	388
chronos/anubis.c	84	8	92
chronos/cast5.c	288	160	448
chronos/cast6.c	448	0	448
chronos/des.c	426	0	416
chronos/des3.c	400	0	390
chronos/fcrypt.c	128	0	128
chronos/khazad.c	40	0	40
libg/camellia.c	32	0	32
libg/des.c	144	0	144
libg/seed.c	8	0	8
libg/twofish.c	248	0	248
supercop/aes_core.c	412	0	409
supercop/cast-ssl.c	448	0	448

as the branch condition is tainted. However, SC-Eliminator misses the positive and leaves it unchanged in the rewritten code. Due to the lack of a points-to analysis, SC-Eliminator cannot infer that variable `keys` defined at line 7 and `ctx->keys` point to the same memory. This contrived example illustrates why SC-Eliminator misses those true positives in *anubis* and *cast5* in the Chronos library.

 **Listing 5** Example of a false negative in SC-Eliminator.

```

1 void do_something() {...}
2 typedef struct {
3     int **keys;
4     int n;
5 } CONTEXT_st;
6 void bar(int *key, CONTEXT_st *ctx){
7     int **keys = ctx->keys;
8     keys[0] = key;
9     if(ctx->keys[0][0] == 0)
10     do_something();
11 }
```

4.8 Analysis Precision

To answer Q3, we inspected each positive and categorized it into three kinds: low-risk, high-risk and false positive, where the first two are true positives, and their difference is in the severity of information leakage. In particular, a low-risk positive only reveals one bit of information while high-risk positives can leak multiple bits of secrets (e.g., a sensitive branch within a loop).

The classification result is shown in Table 5. CtChecker reports a total number of 724 positives, with 615 true positives and 109 false positives.

True Positives. CtChecker does find true positives in the rewritten code by Constantine. For example, line 5 in Listing 6 is a timing channel and line 17 is a cache side channel. At the beginning, `%idx` is an address calculated from `%sec`, which is derived from a secret

Table 5 Result Classifications. *Base* and *All* refer to the same columns in Table 1.

Library	Base	All	FP	Low-risk	High-risk
Libgcrypt 1.10.1	66	30	24	2	4
mbedTLS 3.2.1	50	10	6	1	3
BearSSL 0.6	18	3	2	0	1
OpenSSL 1.1.1q					
Reciprocal	14	9	7	0	2
Mont.	45	25	23	0	2
Mont. Const. Time	36	18	18	0	0
Mont. Word	4	12	11	0	1
binsec/aes_big	0	0	0	0	0
binsec/des_tab	51	26	2	24	0
binsec/tls-rempad-luk13	7	6	0	6	0
appliedCryp/3way	41	0	0	0	0
appliedCryp/des	72	62	0	62	0
appliedCryp/loki91	75	72	16	56	0
ghostrider/findmax	0	0	0	0	0
ghostrider/matmul	4	0	0	0	0
libg/des	448	432	0	432	0
pycrypto/ARC4	20	19	0	19	0

key. It is then cast to an integer type and is masked by 63. The result `%and` is tainted from the masking operation. At line 4, `%cmp`, the branch condition, is computed from `%and`, making the branch secret dependent. What makes the case more interesting is that the branch at line 5 *does not* exist in the original source code. Constantine adds the branch to check if `%and` satisfies certain property. If not, the execution will stop. For this reason, even though this branch is added into the main processing loop, it should be considered a low-risk positive. Later, `%and` is used to compute another address `%addptr` at line 11. Then, `%addptr` is accessed by `load` if the execution path comes from `forbody.pre`. This memory access is sensitive because the index is derived from secret even after the masking operation. All positives found in rewritten code follow the similar pattern.

Listing 6 Rewritten IR by Constantine from pycrypto/ARC4.

```

1 %idx = gep @stream_state, 0, %sec
2 %2 = ptrtoint %idx to i64
3 %and = and %2, 63
4 %cmp = icmp slt %and, and (sub (add (ptrtoint (@stream_state to i64),
319), ptrtoint (@stream_state to i64)), -64)
5 br %cmp, label %forbody.pre, label %exit
6
7 exit:
8 ...
9
10 forbody.pre:
11 %addptr = gep @stream_state, 0, %and
12 br label %forbody.body
13
14 forbody:
15 ...
16 %_ptr = phi [ %addptr1, %forbody ], [ %addptr, %forbody.pre ]
17 %3 = load volatile %_ptr

```

False Positives. While the overall false positive rate of CtChecker on all benchmarks appears low, we further studied the root cause of false positives in the cryptographic library benchmarks, which witness a higher rate of false positives, and found that the majority (63 of them) are caused by the imprecision of DSA, 26 by context-insensitivity, and 2 by

flow-insensitivity (see Section 3.3 for the major reasons of imprecision). Arguably, 69% of false positives due to DSA are unavoidable while we aim for a sound and scalable analysis. For example, when creating the data structure graph for the reciprocal method in OpenSSL, the structure representing the exponent p is collapsed. Without the field information, CtChecker have to conservatively taint the whole structure. Consequently, line 1 in Listing 7 (which corresponds to line 171 in `bn_exp.c`) is reported even though it only depends on `flag` field, not the data field.

Listing 7 False positives caused by collapsed memory and callsite-insensitivity in OpenSSL.

```

1 if (BN_get_flags(p, BN_FLG_CONSTTIME) != 0
2   || BN_get_flags(a, BN_FLG_CONSTTIME) != 0
3   || BN_get_flags(m, BN_FLG_CONSTTIME) != 0) {
4   BNerr(BN_F_BN_MOD_EXP_RECV, ERR_R_SHOULD_NOT_HAVE_BEEN_CALLED);
5   return 0;
6 }
```

29% of false positives are produced when a callee function is invoked multiple times within the same caller function with different arguments. In this case, DSA provides no callsite distinction. In Listing 7, `BN_get_flags` is called multiple times with p , a and m as the first parameter, respectively. Since p is tainted, lines 2 and 3 (lines 172 and 173 in `bn_exp.c`) are also reported. One fix is to distinguish all calling contexts in the static analysis, or inlining all function calls before the source code is being analyzed. However, both approaches will hurt the scalability of static analysis on large programs.

Other implementations of points-to analyses may be used to improve precision further in two different aspects: (1) to reduce the number of collapsed memory nodes, and (2) to provide finer-grained context-sensitivity on callsites. As an example, these improvements might remove false positives mentioned in the example of reciprocal method in OpenSSL above. However, as developing a more precise points-to analysis is beyond the scope of this paper, we leave it as future work.

The remaining 2 false positives are due to the lack of flow-sensitivity. As discussed in Section 3.2, LLVM's `mem2reg` pass only provides flow-sensitivity to some extent. For example, the tainted data in mbedTLS is the `d` field of variable `E`. Hence, line 1 in Listing 8 (line 1988 in `bignum.c`) is not key-dependent as it only returns the `s` field of E .

Listing 8 False positives caused by flow-insensitivity in mbedTLS.

```

1 if( mbedtls_mpi_cmp_int( E, 0 ) < 0 )
2   return( MBEDTLS_ERR_MPI_BAD_INPUT_DATA );
3 ...
4 while( 1 ) // Main processing loop
5 {
6   ...
7   MBEDTLS_MPI_CHK( mpi_select( &WW, W, (size_t) 1 << wsize, wbits ) );
8   ...
9 }
```

However, line 1 is falsely reported by CtChecker. Inside `mpi_select`, `s` field of `WW` is changed to the secret derived from `wbits` that is tainted. Since DSA treats `E` and `WW` as potential aliases, `s` field of `E` is also tainted. However, CtChecker is unable to distinguish *when* `s` field of `E` is tainted. Hence, it conservatively reports line 1 as a positive.

4.9 Scalability

To answer Q4, we evaluate the scalability of CtChecker on benchmark programs from Table 1 on a PC equipped with 2.30GHz Intel Core i7-11800H and 16 GB memory.

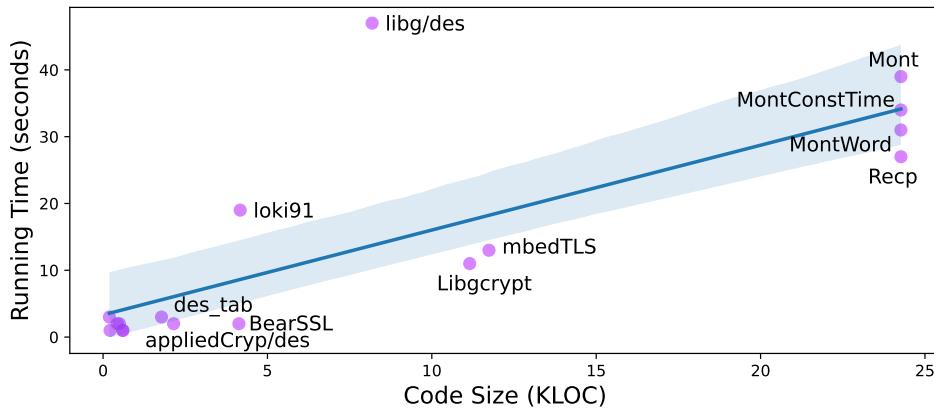

Figure 3 Running Time vs. Code Size of Benchmarks. Unlabeled data points are from Constantine rewritten code with smaller size.

For each cryptographic library, the experiment was done with both the full source (i.e., the SRC version) and the minimal source (i.e., the modular exponentiation code only). Among the tested benchmarks, BearSSL has the smallest codebase of about 4 KLOC, whereas the largest codebase is OpenSSL with around 24 KLOC for its full source version. The running time for these two libraries are 2 and 39 seconds, respectively. The comparison shows that processing time is small even for larger libraries. The libg/des code rewritten by Constantine, which has around 8.6 KLOC, had the longest running time of 48 seconds. Overall, the running time against code size of all benchmark programs being analyzed shows a close to linear trend, as shown in Figure 3.

In terms of memory consumption, the peak usage is around 150 MB when OpenSSL is being analyzed, during the constraint solving step. The result shows that CtChecker is scalable in both the spatial and temporal dimensions.

4.9.1 Running Time of Other Tools

We did not compare the running time and memory usage of CtChecker quantitatively with other tools since the underlying techniques are very different, making a direct comparison unfair. However, we discuss other tools' running time and memory consumption below.

ct-verif: For moderate-sized codebase like mbedTLS, the full source code makes ct-verif run out-of-memory (OOM) after several hours. Moreover, ct-verif stops execution once the first violation is found, making it hard to gauge its execution time if it were reporting all positives in one shot.

CacheS: As reported in [44], the running time for CacheS is at least 33.2 seconds when there is only one function being analyzed, up to 179.2 seconds if the execution runs successfully without timeout, and more than 5 hours if timeout occurs. The memory consumption is also significantly larger than CtChecker, where at least 620 MB of space was used. That said, we note that their reported numbers are collected from different experimental settings than ours, e.g., physical machine, analyzed code base, etc. Therefore, the performance numbers are not directly comparable.

SC-Eliminator: Its taint analysis is the fastest among all tools, which takes around 1 second for each of their benchmarks. The reasons are two-fold however. On the one hand, it does not utilize a points-to analysis, which sacrifices its soundness as we mentioned in Section 4.7.

On the other hand, it simply propagates taints when each instruction is analyzed, which leads to soundness issues in corner cases. For instance, given `x:=y; y:=secret` in a loop, SC-Eliminator fails to taint `x`, as the taint on `y` is discovered later in the analysis. CtChecker is built on more rigorous information flow analysis with constraint generation and solving. The points-to analysis and constraint generation/solving collectively consume most of the time for CtChecker.

Although a fair comparison on efficiency is infeasible, it is safe to conclude that CtChecker’s efficiency is better or at least comparable to other tools employing similar sub-components. SC-Eliminator is more efficient than ours and other competitors with a loss of soundness, as discussed above.

5 Related Work

5.1 Detecting Timing Side Channels

Both static and dynamic approaches are widely adopted to detect constant time violations. VirtualCert [3] and FlowTracker [32] are static tools built with formal methods. VirtualCert is flow-insensitive and is specially used for virtualized systems. FlowTracker focuses on optimizing the representation of implicit flows and is flow-sensitive. Almeida et al. [1] propose ct-verif, a static tool that employs self-composition for verifying constant-time property. It either accepts or rejects programs being verified, but it does not pinpoint the source code where the violations occur. Both VirtualCert and ct-verif require additional annotations to work. SecVerilog [51] is a language-based approach for checking hardware-level information flow violations. Somorovsky [37] presents a dynamic tool using fuzzing technique to detect implementation with constant-time violations. Dynamic methods could avoid false positives but are limited by their search space, which leads to unsoundness. Compared to these tools, CtChecker is a sound and generic non-constant-time code detection tool that does not require additional annotations.

5.2 Detecting Cache Side Channels

Cache-based side channels are another type of covert channel that could leak sensitive information to unintended parties. CacheD [45] is a trace-based analysis that identifies cache-based timing channels using taint tracking and symbolic execution. However, symbolic execution might not have the full coverage of execution paths. Brotzman et al. [8] propose a cache-aware symbolic execution (CaSym) that works on LLVM IR. CaSym is able to cover all execution path by introducing a technique that could transform a program with loops to its loop-free version. Both works report the location of vulnerabilities to make it easier for developers to fix them. CacheS [44] is a static analysis that could detect timing channels and cache-based channels. A novel abstract domain called Secret-Augmented Symbolic domain (SAS) is proposed to track sensitive information with high precision while remaining efficient. However, the unsound memory model it uses may cause false negatives. For comparison, CtChecker employs a sound points-to analysis, which makes it both sound and efficient.

5.3 Mitigating Side Channels

Another line of work involves mitigating side channels after vulnerabilities are detected. Cauligi et al. [11] propose a C-like DSL called FaCT. Its compiler is claimed to be able to compile secret-sensitive source code into constant-time LLVM bitcode. However, FaCT

requires libraries to be rebuilt in this language, making it impractical for existing libraries and legacy systems. Wu et al. [46] propose SC-Eliminator, a program rewriter that can eliminate both timing- and cache-based side channels. A constant time select function is proposed for secret-dependent branches. Cache-side channels are removed by preloading all elements in a lookup table. Soares et al. [35] point out that SC-Eliminator introduces out-of-bound memory accesses when doing the transformation. They put forward another rewriter called lif that ensures memory safety at the same time. Preloading methods fail when an attacker could evict cache lines after preloading and before accessing the data. Constantine [7] adopts a radical full linearization design. It focuses on how to maintain efficiency under the radical design. CtChecker does not repair programs when vulnerabilities are found. However, it could help the rewriters to identify problematic code locations more precisely, hence reducing the overhead of mitigation. Moreover, as we demonstrated in the evaluation, it can also serve as an efficient verifier for the code generated by those program rewriters.

6 Conclusion and Future Work

In this work, we build CtChecker, a sound, precise and scalable static information flow analysis for constant-time programming. Compared with traditional information flow analysis, CtChecker is equipped with various features to improve analysis precision on cryptographic code. The features effectively reduce false positive rates while maintaining analysis soundness. By inspecting remaining false positives, we observed that the majority is due to imprecision in the sound points-to analysis that CtChecker is built on.

For future work, a fraction of remaining false positives is due to a callee function being invoked multiple times within the same caller function with different arguments. We plan to investigate how to identify the instances where inlining such code might improve precision, with the insight that heterogeneous arguments to the callee function are the root cause of the imprecision issue. The selective inlining strategy likely will strike a good balance between precision and performance.

Defining Name Accessibility Using Scope Graphs

Aron Zwaan 

Delft University of Technology, The Netherlands

Casper Bach Poulsen 

Delft University of Technology, The Netherlands

Abstract

Many programming languages allow programmers to regulate *accessibility*; i.e., annotating a declaration with keywords such as `export` and `private` to indicate where it can be accessed. Despite the importance of name accessibility for, e.g., compilers, editor auto-completion and tooling, and automated refactorings, few existing type systems provide a formal account of name accessibility.

We present a declarative, executable, and language-parametric model for name accessibility, which provides a formal specification of name accessibility in Java, C#, C++, Rust, and Eiffel. We achieve this by defining name accessibility as a predicate on *resolution paths* through *scope graphs*. Since scope graphs are a language-independent model of name resolution, our model provides a uniform approach to defining different accessibility policies for different languages.

Our model is implemented in Statix, a logic language for executable type system specification using scope graphs. We evaluate its correctness on a test suite that compares it with the C#, Java, and Rust compilers, and show we can synthesize access modifiers in programs with holes accurately.

1 Introduction

Many programming languages, especially object-oriented ones, support *information hiding*, i.e., regulating from which positions in a program a declaration can be accessed. Information hiding is used to enforce invariants of particular code units, implement design patterns (e.g. the singleton pattern), improve modularization, limit public APIs to offer guidance to library users and guarantee forward compatibility. Support for information hiding is usually provided using *access modifier keywords*¹ (*access modifiers* for short), such as `public`, `protected`, `internal` and `private`. Each of these corresponds with a particular accessibility policy that is validated by the type checker.

Although recent research has not paid much attention to access modifiers, there are still good reasons to study their semantics. First, understanding access modifiers is required to implement (alternative) compilers and editor services correctly. In particular, disregarding accessibility may result in incorrect name binding, and hence incorrect program behavior. Second, formalizing access modifiers enables reasoning about the meaning of programs.

¹ Other common names include “access specifier” or “visibility modifier”.

47.2 Defining Name Accessibility Using Scope Graphs

```

package p1;
class A {
    int x;
}

package p2;
class B extends p1.A { }

package p1;
class C extends p2.B {
    int y = x;
}

```

(a) Inheritance through Packages.

```

package p;
class A {
    protected int x;
}

class B extends A {
    private int x;
}

class C extends B {
    int y = x;
}

```

(b) Inaccessible or Shadowed?

```

package p;
class A {
    private int x = 0;
    protected int y = 1
}

class B {
    int x = 3;
    int y = 4;
    class C extends A {
        int z = x + y
    }
}

```

(c) Accessibility and Shadowing.

 **Figure 1** Examples of intricate Access Modifier semantics. Classes are assumed to be public.

Finally, program transformation tools, such as automated refactorings, must handle the semantics of accessibility correctly. This is especially relevant for research on large-scale automated transformations, aimed at dealing with large (legacy) codebases. It is often infeasible to check transformations performed with such tools manually. Thus, the correctness of these transformations must be guaranteed through other means.

The meaning of access modifiers can be intricate in corner cases. We illustrate that using the examples in Figure 1. In Figure 1a, there is an inheritance chain, where class C extends class B, which itself extends A. Classes A and C reside in package p1, while B is in p2. Class A defines a package-accessible field x, which is accessed in C. The question here is whether that access is actually allowed. One could reason that it is correct, as the access occurs in the same package as the declaration, so a package-level declaration should be visible. On the other hand, one could consider x not inherited by B [11, §8.2], and thus not inherited by C either. In fact, the Java language designers chose the second option, rejecting this program [23, §4.2]. Using ((A) `this`).x is accepted however.

Something similar happens in Figure 1b. Here, one can consider the reference x in class C to be invalid, as the field in class B is inaccessible. Alternatively, under the assumption that B.x is *out of scope*, the reference can be valid, pointing to A.x. In this case, Java checks accessibility *after shadowing*, so this program is again rejected. However, in Figure 1c, accessibility does influence the binding. The reference x binds to the field of the *enclosing* class B, as the field inherited from class A is inaccessible. However, reference y binds to the field inherited from A. Thus, in this case, the *accessibility* of the inherited fields determines the resolution of x and y; i.e., accessibility is checked *before shadowing*. This shows that specifying accessibility is essential to defining the name binding of a language correctly.

Unintuitive semantics of accessibility occurs in non-object-oriented languages as well. For example, the accessibility scheme of Agda seems simple: definitions are either public or module-private, and imported definitions can be re-exported. However, issue #5461² reports that re-exports in a private block are still exposed to the outside world. While this intuitively seems wrong to most commenters, an argument is made that this is actually the intended behavior. The discussion stalls shortly after a remark that talking about intended behavior is “meaningless without a specification”.

² <https://github.com/agda/agda/issues/5461>

These examples show that the meaning of access modifiers is not always obvious. Hence, language designers should define their semantics unambiguously. Ideally, that is done through *specifications* containing *inference rules*. Inference rules allow unambiguous interpretation of the meaning of programming language constructs, including name binding. However, perhaps surprisingly, a general model for defining access modifiers has never been proposed.

Perhaps closest is the work of Steimann and Thies [25] (later incorporated in the JRRT refactoring tool [23]). They propose a constraint-based approach to automating refactorings in Java, by collecting and solving *accessibility constraints*. These constraints are generated using *constraint generation rules*, which cover the access rules the Java compiler enforces. By solving these constraints, changes in accessibility implied by the refactoring can be inferred, yielding type- and behavior-preserving refactorings.

Steimann and Thies' work solves the problem of making refactorings in Java sound regarding accessibility. However, it does not yet give a high-level explanation of the meaning of access modifiers. This is partly because the constraint generation rules need several low-level details to catch some intricate corner cases, but also because the function that computes the minimal required accessibility level is not given, as it was “unpleasant to specify” and “of no theoretical interest” [25, §5.2]. Therefore, their work cannot easily be adapted to a different language or a different application (e.g., a type checker).

To advance the state of the art, we pursue the following goals:

- Explain the meaning of access modifiers.
- Explain the (subtle) differences between access modifiers in different languages.
- Provide a framework for experimenting with feature combinations that do not (yet) exist in other languages.

To this end, we do not fully formalize one particular language, but rather define a toy language that incorporates and combines a large number of accessibility features. To abstract over low-level name resolution details, we use *scope graphs* [18, 27, 22, 38]. In this paper, we demonstrate this is a natural fit, because accessibility can be expressed as a predicate over paths in a scope graph. The specification is written in the logic language Statix [27, 22], which has a well-defined declarative semantics and also supports generating executable type-checkers automatically.

We compare these executable type checkers with reference compilers of Java, C#, and Rust, showing that we accurately captured the semantics of access modifiers in some real-world languages. Moreover, using Statix/scope graphs as a basis for (*language-parametric*) *refactorings* is an active topic of research [16, 29, 15, 3]. We envision that this will provide accessibility-aware refactorings similar to Steimann et al., without requiring significant additional effort. This is substantiated by the fact that Statix-based code completion [19] proposes an access modifier if and only if it would not cause accessibility errors elsewhere in the program.

In summary, the contributions of this paper are as follows:

- We provide a systematic classification of accessibility features (Section 2);
- we apply our taxonomy to Java, C++, C#, Rust, and Eiffel (Section 2);
- we present a specification of (various versions of) accessibility on modules (Section 5), subclasses (Section 6), and their conjunctive and disjunctive combination (Section 7);
- we extend our specification with accessibility-restricting inheritance (Section 8);
- we prove some theorems about our model, showing it is well-behaved (Section 9); and
- we implement our specification in Statix, and compare it with the standard compilers of Java, C#, and Rust. Moreover, we show access modifiers can be synthesized accurately using Statix-based Code Completion [19] (Section 10).

This paper comes with an artifact that allows reproducing the evaluation [35], and appendices containing a full specification of the access modifiers and proofs of the stated theorems [36].

2 Access Modifiers in Real-World Languages

In this section, we explore the design space of access modifiers as they occur in real-world languages. We first motivate why languages have access modifiers (Section 2.1). After that, we discuss common accessibility features (Section 2.2), summarizing them in a feature model (Section 2.3).

2.1 Why Accessibility?

Most programming languages allow programmers to define entities (variables, functions, types, etc.), and assign a name to them. That name can then be used to refer to the introduced entity from other positions in the program. However, as there is typically a large number of entities within a software project, most languages offer a notion of modularization to group related definitions. Equally named definitions in different modules can be distinguished by qualifying them with the name of the module in which they reside. Unqualified (or partially qualified) names by default resolve within their enclosing module, or imported modules. Details of this scheme differ from language to language, but generally aim to make definitions easy to refer to (e.g., by minimizing the number of required qualifiers), while trying to be unambiguous to the compiler and the programmer.

However, these rules may often be too lenient with respect to the intention of the programmer. A definition may be accessible from scopes where it is not intended to be used. This can have detrimental effects on the quality of a software artifact. For example, exposing all internal definitions of a library makes it (1) less intuitive to its users, (2) prone to forward compatibility issues and technical debt (e.g. strong coupling).

For these reasons, many programming languages provide constructs that give *the programmer* control over the regions of code where a definition can be accessed. For example, in many object-oriented languages, a class can access fields from its ancestor classes by default (language-controlled). However, if the programmer does not want a field to be accessible from subclasses, they can add a `private` access modifier. This modifier *prevents* access from all other classes (programmer-controlled). Although many constructs that provide access control to the programmer can be envisioned, most languages settle on a limited set of keywords that can be attached to a definition. In practice, this relatively simple scheme has proven powerful enough to cover most use cases.

2.2 Accessibility in Practice

Next, we explore how languages typically provide modularization and accessibility features.

Modules. A common feature that provides modularization is *modules* (also called “package” or “namespace”). A module is a syntactic construct that introduces a named collection of definitions. Members of modules can be accessed using the name of the module, for example in a preceding import statement, or as a qualifier to the name of the member that is accessed.

Hiding a definition from other modules is the simplest accessibility restriction that can be applied with respect to modules. For example, Java declarations without an access modifier can only be accessed within the same package. Rust items without a modifier behave similarly, except that declarations can still be accessed from submodules.

Some languages have multiple notions of modularization. For example, C# has assemblies, namespaces, and files, where a namespace can comprise multiple files, and/or a file can contain multiple namespaces. The `internal` keyword in C# restricts accessibility to the *assembly*, and the `file` keyword (introduced in C# 11 [32]) to the current file. Similarly, Java 9 introduces *modules* [21], with features to restrict access from external modules.

```

mod outer {
    mod inner {
        pub x = 42;
    }
    pub use inner::x;
}

fn main() {
    // ERROR: inner is inaccessible:
    // let x = outer::inner::x;
    let x = outer::x;
    println!("{}")
}

```

Figure 2 Re-exports can change Accessibility.

Some languages give some more control over *which* modules a declaration can be accessed from. For example, Rust has the `pub(in path)` access modifier, where *path* refers to some enclosing module. This enables programmers to expose items to an arbitrary ancestor.

Imports usually do not affect the visibility of a declaration. A notable exception to this rule is *re-exporting* (e.g., as implemented in Rust), which can actually *change* the visibility of a declaration, as shown in Figure 2. In this program, the module `inner` is accessible in `outer`, but not in its parent (the root scope). Therefore, the function `main` cannot access its field `x`. However, `outer` re-exports `inner::x`, which gives rise to a new definition `outer::x`. As `outer` is accessible in the root scope, so is this definition. Hence, via the re-export, `main` can access `x`, although the original declaration was hidden.

From an accessibility point of view, re-exporting can typically be considered as a combination of an import and a declaration, where the declaration always points to the imported member. The re-exported item (`inner::x` in the example) should be accessible from the location of the *re-export*. References to the re-export should have access to the location of the re-export, but not necessarily to the location of the original declaration. In fact, for any access path, it does not matter whether the declaration is a re-export or not.

Classes. A special modularization concept is the notion of *classes*, which represent composite data types with associated operations (methods). Where simple modules only have a static interpretation, an arbitrary number of class instances can exist at runtime.³ While modules can implicitly be related to each other by their relative position, such a relation does not exist for classes. However, classes can extend other classes, ensuring the subclass inherits the fields of its parent class. This creates an inheritance hierarchy orthogonal to the module hierarchy.

Object-oriented languages usually provide modifiers to control accessibility over the inheritance chain. For example, Java and C# have a `private` keyword, which prevents access outside the defining class. Additionally, the `protected` keyword allows access from subclasses, but prevents access from any other location.

In Java and C#, the accessibility level is inherited with the field. That means, if a field in the superclass is `protected`, it will be protected in the subclass as well. However, C++ allows restricting the accessibility of members of the parent class. A `private` modifier on extends-clauses will make all inherited public/protected members private on instances of the subclass. Similarly, a `protected` modifier will make all inherited public members protected.

Finally, some languages allow specifying “friend” classes, which grant the friend access to its members. This enables fine-grained access control, independent from module and class hierarchies. While discouraged in C++, Eiffel provides only this access control mechanism.

³ At this point, we slightly over-simplify the reality. For example, neither parameterized modules (ML) nor `objects` (e.g. Scala/Kotlin) fit in this scheme. We made this choice deliberately, to cover the most prevalent cases. We conjecture that the techniques we develop for classes can be applied to parameterized modules (and vice versa for modules and objects) but leave explicating that to future work.

Interaction. Accessibility restrictions on modules and classes can be combined. This is very explicit in C#, which has `protected internal` and `private protected` as additional modifiers. The former permits access from within the assembly (similar to `internal`) *and* to subclasses (similar to `protected`), even if they live outside the assembly. Analogously, `private protected` grants access to subclasses in the same assembly only, which is equivalent to the conjunction of `internal` and `protected`.

2.3 Classification

These concepts are organized and related in the feature model in Figure 3. Following the previous discussion, the main features are modules and classes. We have only a single feature for modules, because the different variants are (apart from C#'s files and namespaces) typically not mutually nested. The `internal` keyword can either relate to the containing module (Direct) or an arbitrary parent module (Ancestor). We explore this further in Section 5.

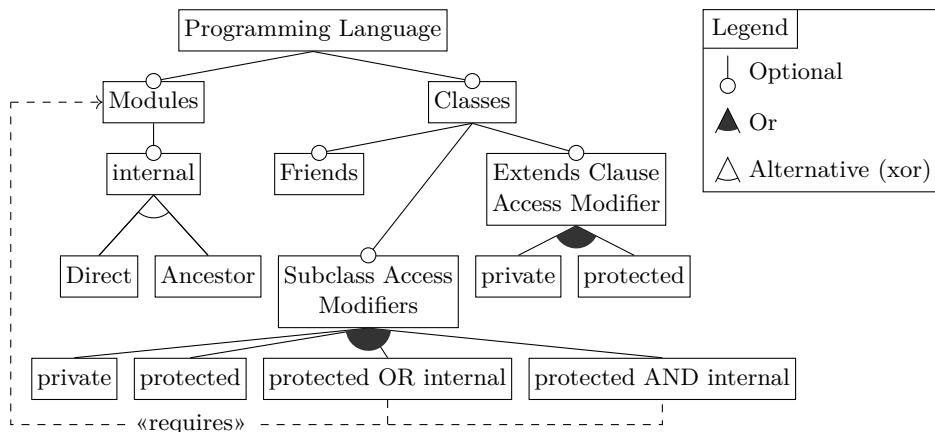

Figure 3 Feature Model for Access Control.

Table 1 Languages classified according to the feature model in Figure 3.

	Java	C#	C++	Eiffel	Rust
Modules	✓	✓	✓		✓
Internal	Direct	Direct ⁴	Direct		Ancestor
Classes	✓	✓	✓	✓	
Friends			✓	✓	
Subclass Acc. Mod.	✓	✓	✓	✓	
<code>private</code>	✓	✓	✓	✓	
<code>protected</code>		✓	✓		
<code>protected internal</code>	✓	✓			
<code>protected & internal</code>		✓	✓		
Extends Clause Acc. Mod.			✓		
<code>private</code>			✓		
<code>protected</code>			✓		

In the Classes category, the three subfeatures denote the three mechanisms for access control: Friends allow access to other classes by name, Subclass Access Modifiers are access modifiers on definitions that determine how it is accessible within the class hierarchy (Sections 6 and 7), and Extends Clause Access Modifiers (Section 8) are access modifiers on extends clauses, as seen in C⁺⁺. The latter two have subfeatures for each concrete keyword associated with the access control mechanism. For that reason, `private` and `protected` occur twice: once on definitions and once on extends clauses. Table 1 classifies several languages according to this scheme. In the remainder of this paper, we develop AML (Access Modifier Language), a language that covers all features. To this end, we first introduce scope graphs (Section 3), and a base language for AML (Section 4).

3 Using Scope Graphs to Model Name Binding in Programs

In the previous section, we sketched the landscape of access modifiers. This discussion was based largely on prose specifications as well as experiments with compiler implementations. No language specification we are aware of provides a more rigorous model of accessibility (or even non-lexical name binding). In this section, we introduce *scope graphs* [18, 27, 22, 38], and argue that they provide a suitable framework for such a model. Section 4 introduces AML (Access Modifier Language), a toy language with a type system defined using scope graphs. Sections 5–8 will extend this language with all accessibility features from Figure 3.

3.1 Scope Graphs as A Model for Name Binding

From a name binding perspective, classes and modules have some similarities. Each of these constructs can be thought of as introducing a “scope” (region of code), in which declarations live, and in which names can be resolved. Scopes are related to each other in various ways. First, modules are related according to their relative position in the abstract syntax tree. In addition, imports and extends clauses relate arbitrary modules and classes, respectively. Resolving a reference corresponds to finding a matching declaration in a scope that is reachable from the scope of the reference. For example, a reference may resolve to a declaration if it lives in a lexically enclosing scope, or in a module that is imported in an enclosing scope.

Scope graphs [18, 27, 22, 38] make this more precise. In this model, the name binding structure of a program is represented by a graph. Figure 4 (adapted from Poulsen et al. [20, Fig. 1]) gives an example program and its corresponding scope graph. A scope is represented by a circular node in the graph. For example, s_0 represents the global scope, and s_A , s_B and s_C represent the bodies of modules A, B, and C, respectively. Scopes are related using labeled, directed edges. For example, s_A is lexically enclosed by s_0 , and thus the graph contains an edge from s_A to s_0 with label `LEX`. Similarly, s_B imports s_A , and thus the graph contains an edge $s_B \xrightarrow{\text{IMP}} s_A$. Finally, scope graphs contain declarations. For example, a declaration of `i` in scope s_C is represented by the $s_C \xrightarrow{\text{VAR}} i : \text{int}$ edge/node pair. Similarly, the modules are declared in the root scope (e.g., $s_0 \xrightarrow{\text{MOD}} A \sim s_A$). The language specification determines which data is included in the declaration. Similarly, the labels for edges and declarations can be chosen to match the (binding) constructs of the language.

⁴ Either the most direct enclosing *file* (`file`), or most directly enclosing *assembly* (`internal`), possibly bypassing some namespaces.

47:8 Defining Name Accessibility Using Scope Graphs

```
module A {
    var i = 5
}
module B {
    import A
}
module C {
    import B
    var j = i
}
```

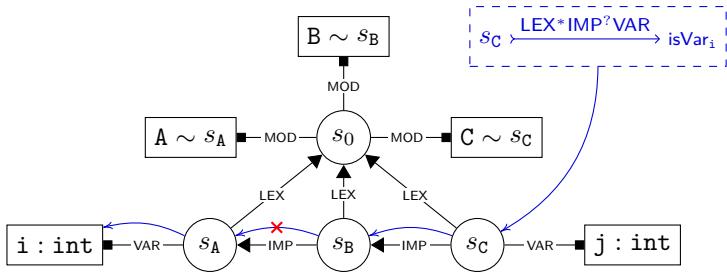

Figure 4 Reachability example. The $\text{IMP}^?$ part in the regular expression prevents traversal over the second IMP edge.

```
module D {
    var x = 3
    module E {
        import F
        var y = x
    }
}
module F {
    var x = 4
}
```

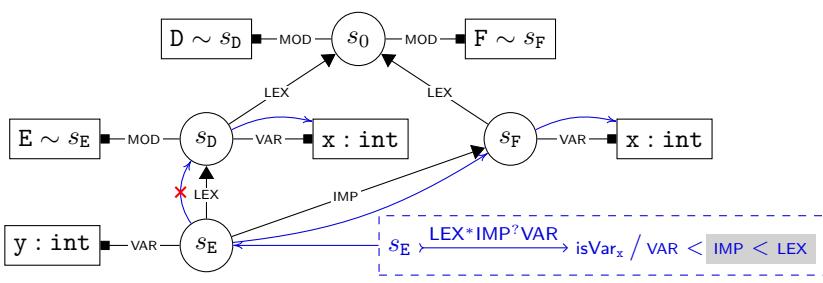

Figure 5 Shadowing example. The highlighted label order causes the edge to s_F to have priority.

Reachability. To resolve a reference, a *query* is executed to find a valid path in the scope graph from the scope of the reference to a matching declaration. Queries give specification writers several options to filter paths, to retain only valid paths. First, a unary predicate selects valid declarations. Usually, this predicate matches declarations with the name of the reference. Second, a *regular expression* over labels is used to select valid paths. This regular expression can, for example, be used to prevent transitive imports, or accessing members in a lexical parent of an imported module.

Figure 4 illustrates this with the query for i in module C (dashed blue box). The parameter on the arrow ($\text{LEX}^*\text{IMP}^?\text{VAR}$), is a regular expression that defines which paths to declarations are valid. The LEX^* indicates that a path may traverse an arbitrary number of LEX -edges. This corresponds to looking for variables in enclosing scopes. Next, the $\text{IMP}^?$ part indicates that zero or one IMP -edges can be traversed. Finally, the regular expression ends with VAR to ensure all paths resolve in variable declarations only, excluding e.g. modules. The isVar_i parameter matches all variable definitions with name i (isVar is defined in the next section). The candidate path (shown as blue edges) does not match this regular expression. Because IMP -labeled edges may only be traversed one time, the step to s_A cannot be made. In other words: the declaration of i in A is not *reachable* from C .

Visibility. Not every declaration that is reachable (i.e., for which a valid access path exists) can actually be referenced, due to *shadowing*. For example, in most languages, local definitions have higher priority than imported ones. We call reachable declarations that are not shadowed by any other declaration *visible*.

In scope graphs, visibility can be encoded using a partial order on labels. For example, an order $\text{VAR} < \text{IMP}$ encodes that (local) variable declarations shadow imported declarations. This is illustrated in Figure 5. The reference x in module F can refer to the declaration in

module D as well as the one in module E. Because the label order (third argument) indicates that imports shadow lexically enclosing scopes ($\text{IMP} < \text{LEX}$). Thus, the variable resolves to the declaration in s_F . Alternatively, if $\text{LEX} < \text{IMP}$, it would resolve to x in s_D . Finally, if neither $\text{LEX} \not\prec \text{IMP}$ nor $\text{IMP} \not\prec \text{LEX}$, both paths would be included in the query result.

In summary, scope graphs model the name binding structure of a program using nodes for scopes and declarations, and edges for relations between those. Queries can be used to model reference resolution. A query selects a declaration when (1) it matches some predicate, and (2) there exists a path to it of which the labels match a regular expression, and (3) no other paths that traverse labels with higher priority exist. The result of a query is a set of paths that lead to these matching declarations.

Accessibility. We can model extensibility using plain scope graphs by including accessibility information in the *declaration*. In other words, a declaration of a variable in a scope graph contains not only a name and a type, but also its accessibility level. *After resolution*, we check if the path that the query returns is actually valid according to the accessibility level of the declaration. For example, if a variable is private, but an `EXT`-edge (for class *extension*) is traversed, an error is emitted. With this pattern, we can model all accessibility features.

Notation. Figures 4 and 5 introduce the graphical notation of scope graphs. In text, variable s ranges over scopes, and S over sets of scopes. Moreover, we use the following notation for assertions on scope graphs: $s_1 \xrightarrow{L} s_2 \in \mathcal{G}$ means “scope graph \mathcal{G} has an L-labeled edge from s_1 to s_2 ”, and $s \xrightarrow{D} d \in \mathcal{G}$ means that \mathcal{G} has a declaration with data d under label D in scope s . Moreover, we write queries in the following way:

$$\text{query}_{\mathcal{G}} s \xrightarrow{R} \mathcal{P} / \mathcal{O} \mapsto R$$

where \mathcal{G} is the scope graph in which the query is resolved, s is the scope in which the resolution starts, R is the regular expression that paths must adhere to, and \mathcal{P} is the predicate that declarations must match. \mathcal{O} is the strict partial order on labels used for shadowing. It is usually written as $L_1 < L_2 < \dots < L_n$. We omit the label order when there is no shadowing. R is the result set containing tuples of paths and declarations. When we expect a single result, we use $\{(p, d)\}$ to match on the value in the set. Paths are alternating sequences of scopes and labels, written as $s_1 \xrightarrow{L_1} s_2 \dots s_m$. Paths do not include the declaration it resolved to, but stop at the scope in which the declaration occurs. The functions `src(p)`, `tgt(p)` refer to the source and target scope of a path, respectively. `scopes(p)` denotes all scopes in a path.

4 AML: The Base Language

In the next sections, we show how scope graphs support intuitive formalization of accessibility. We will do so by defining *AML* (Access Modifier Language). The base syntax (which will be extended later) is given in Figure 6. In AML, a program consists of a list of modules. Each module can define other modules, import other modules, and contain class definitions. A class can optionally extend another class, and contains a list of field declarations. Each field has an access modifier, and is initialized by some expression. Possible expressions include references, integer constants, class instance creation, field access, and binary operations.

At the right-hand side of Figure 6, the scope graph parameters are shown. There are three labels that connect scopes. `LEX` denotes lexical scoping, `IMP` denotes imports, and `EXT` class extension. The other three labels are used for declarations. `MOD` is used for module declarations, `CLS` for classes, and `VAR` for variables/fields. Next, we assume that each *module*

47:10 Defining Name Accessibility Using Scope Graphs

$\langle \text{prog} \rangle ::= \langle \text{mod} \rangle^*$	$\langle l \rangle ::= \text{LEX} \mid \text{IMP} \mid \text{EXT}$
$\langle \text{mod} \rangle ::= \text{module } \langle x \rangle \{ \langle \text{md} \rangle^* \}$	$ \text{MOD} \mid \text{CLS} \mid \text{VAR}$
$\langle \text{md} \rangle ::= \langle \text{mod} \rangle \mid \text{import } \langle x \rangle \mid \langle \text{cls} \rangle$	$ \text{THIS}_M \mid \text{THIS}_C$
$\langle \text{cls} \rangle ::= \text{class } \langle x \rangle (:\langle \text{acc} \rangle \langle x \rangle)^? \{ \langle \text{cd} \rangle^* \}$	$\langle d \rangle ::= \text{mod } \langle x \rangle : \langle s \rangle$
$\langle \text{cd} \rangle ::= \langle \text{acc} \rangle \text{ var } \langle x \rangle = \langle e \rangle \mid \langle \text{cls} \rangle$	$ \text{cls } \langle x \rangle : \langle s \rangle$
$\langle \text{acc} \rangle ::= \text{public} \mid \dots$	$ \text{var } \langle x \rangle : \langle T \rangle @ \langle A \rangle$
$\langle e \rangle ::= \langle n \rangle \mid \langle x \rangle \mid \text{new } \langle x \rangle () \mid \langle e \rangle . \langle x \rangle \mid \dots$	$ \langle s \rangle$
	$\langle T \rangle ::= \text{int} \mid \text{inst } \langle s \rangle$
	$\langle A \rangle ::= \text{PUB} \mid \dots$

Figure 6 Syntax of AML. The highlighted positions indicate extensions in later sections. The syntax of the complete language can be found in Appendix A [35].

Data Matching Predicates

$$\begin{array}{ll} \text{isMod}_x(\text{mod } x' : s) \Leftarrow x = x' & \text{isCls}_x(\text{cls } x' : s) \Leftarrow x = x' \\ \text{isVar}_x(\text{var } x' : T @ A) \Leftarrow x = x' & \text{isScope}_s(s') \Leftarrow s = s' \end{array}$$

Class Members

$$\boxed{\mathcal{P}(d)}$$

$$\frac{\text{D-DEF} \quad s \vdash_{\mathcal{G}} e : T \quad s \vdash_{\mathcal{G}} \text{acc} \Rightarrow A \quad s \xrightarrow{\text{VAR}} (\text{var } x : T @ A) \in \mathcal{G}}{s \vdash_{\mathcal{G}} \text{acc var } x = e \text{ OK}}$$

Type of Expression

$$\boxed{s \vdash_{\mathcal{G}} e : T}$$

$$\frac{\text{T-VAR} \quad \text{query}_{\mathcal{G}} s \xrightarrow{\text{LEX}^* \text{EXT}^* \text{VAR}} \text{isVar}_x / \text{VAR} < \text{EXT} < \text{LEX} \mapsto \{ \langle p, \text{var } x : T @ A \rangle \} \quad s \vdash_{\mathcal{G}} p ! A}{s \vdash_{\mathcal{G}} x : T}$$

$$\frac{\text{T-FLD} \quad \text{query}_{\mathcal{G}} s_c \xrightarrow{\text{EXT}^* \text{VAR}} \text{isVar}_x / \text{VAR} < \text{EXT} \mapsto \{ \langle p, \text{var } x : T @ A \rangle \} \quad s \vdash_{\mathcal{G}} p ! A}{s \vdash_{\mathcal{G}} e.x : T}$$

Access Modifier

$$\boxed{s \vdash_{\mathcal{G}} \text{acc} \Rightarrow A}$$

Access Policy

$$\boxed{s \vdash_{\mathcal{G}} p ! A}$$

$$\text{A-PUB} \frac{}{s \vdash_{\mathcal{G}} \text{public} \Rightarrow \text{PUB}}$$

$$\text{AP-PUB} \frac{}{s \vdash_{\mathcal{G}} p ! \text{PUB}}$$

Module and Class References

$$\boxed{s \vdash_{\mathcal{G}} x \xrightarrow{M} s_m \quad s \vdash_{\mathcal{G}} x \xrightarrow{C} s_c}$$

$$\frac{\text{Q-MOD} \quad \text{query}_{\mathcal{G}} s \xrightarrow{\text{LEX}^* \text{MOD}} \text{isMod}_x / \text{MOD} < \text{LEX} \mapsto \{ \langle p, \text{mod } x : s_m \rangle \}}{s \vdash_{\mathcal{G}} x \xrightarrow{M} s_m}$$

$$\frac{\text{Q-CLS} \quad \text{query}_{\mathcal{G}} s \xrightarrow{\text{LEX}^* \text{IMP}^* \text{CLS}} \text{isCls}_x / \text{CLS} < \text{IMP} < \text{LEX} \mapsto \{ \langle p, \text{cls } x : s_c \rangle \}}{s \vdash_{\mathcal{G}} x \xrightarrow{C} s_c}$$

Figure 7 Typing Rules of AML. Accessibility is integrated at the highlighted positions. The full type system specification can be found in Appendix A [35].

scope has a THIS_M edge pointing to itself, and similarly, each class has a THIS_C scope pointing to itself. This will be used to resolve enclosing classes or modules. The sort $\langle d \rangle$ denotes the data that can be associated with scopes. Modules and classes are characterized by their name and the scope of their body. A field has a name, a type $\langle T \rangle$, and an accessibility level $\langle A \rangle$. Scopes that are not declarations implicitly map to themselves. To query declarations, we use the four predicates shown at the top of Figure 7, which each match a single kind of declaration. Depending on the type of access control we formalize, different access modifiers will be used. Therefore, we have left the $\langle acc \rangle$ and $\langle A \rangle$ productions partially unspecified. Each section will instantiate those appropriately.

Typing Rules. Figure 7 presents some typing rules of AML. The rules are written in a declarative style, where a scope graph \mathcal{G} that models the program is assumed. Constraints over the scope graph are used as premises. The highlighted premises show where accessibility is integrated into the type system. We now discuss each of the presented rules.

The **D-DEF** rule asserts a declaration is well-typed if the initialization expression e has some type T (first premise), the access modifier acc corresponds to some accessibility policy A (second premise), and an appropriate declaration exists in the scope graph (third premise). The accessibility policy is included in the declaration, which enables us to validate accessibility when type checking references.

Next, rule **T-VAR** defines how references are type checked in a current scope s . First, it performs a query that looks into the lexical context (LEX^*), parent classes (EXT^*), and eventually resolves to a variable declaration (VAR). It matches only variables with the same name as the reference (isVar_x). Regarding shadowing, it prefers local variables over variables from a parent class ($\text{VAR} < \text{EXT}$), and variables from parent classes over variables from enclosing classes ($\text{EXT} < \text{LEX}$). The query should return a single result, as the name would otherwise be ambiguous. From this result, the access path p , type T , and accessibility policy A are extracted. The path and the accessibility policy are used in the second (highlighted) premise ($(s \vdash_{\mathcal{G}} p ! A)$), which asserts that “accessibility policy A grants access via path p in scope s ”. In future sections, we will define new accessibility policy rules, that may prohibit access of a variable, even if the query premise resolved properly.

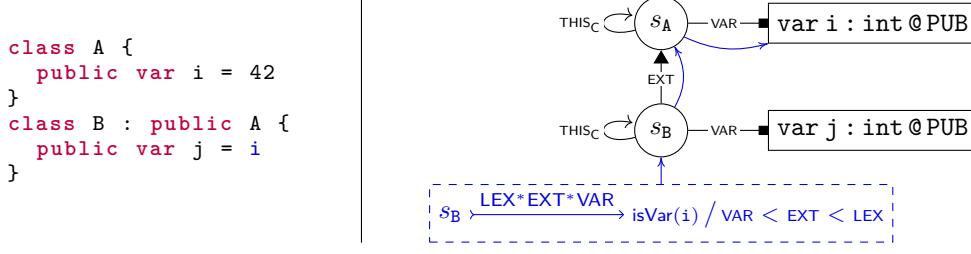

Note that, by having accessibility separated from the resolution, we do not capture the interaction between accessibility as shown in Figure 1c. We made this choice because the place where accessibility is integrated does not influence the access rules themselves, and this presentation allows more concise derivations, which makes the explanations more accessible. Appendix A.1 [35] shows how to integrate accessibility in the shadowing policy of a query, and is incorporated in the evaluation (Section 10).

For this base language, we only have the `public` access modifier. The **A-PUB** rule shows that this keyword corresponds to the PUB policy. The meaning of this policy is that access is allowed from any location, with any access path. This is encoded in the **AP-PUB** rule, which has no premises.

Finally, the last two rules define how references to classes and modules are resolved. Rule **Q-MOD** indicates that module reference x resolves to scope s_m if that scope is included in the closest module declaration with name x in the lexical context. Similarly, a class reference resolves to the scope of the closest class declaration s_c , preferring (non-transitively) imported classes over classes in the lexical context (**Q-CLS**).

Example. The example in Figure 8 shows two classes **A** and **B**. Both classes have a THIS_C -edge pointing to itself. Class **B** extends class **A**, which is represented by the $s_B \xrightarrow{\text{EXT}} s_A$ edge in the scope graph. Class **A** has a public field **i** with type `int`. The type as well as the corresponding

47:12 Defining Name Accessibility Using Scope Graphs

(a) Example program and (partial) scope graph.

$$\frac{\text{query}_G s_B \rightsquigarrow \text{isVar}_i / \dots \mapsto \{(s_B \xrightarrow{\text{EXT}} s_A, \text{var } i : \text{int} @ \text{PUB})\}}{s_B \vdash_G i : \text{int}}$$

(b) Part of typing derivation that shows how access is granted by the PUB accessibility policy.

Enclosing Modules

$$\vdash_G s \uparrow_M S \quad \vdash_G s \uparrow_M s$$

$$\text{ENC-M} \frac{\text{query}_G s \xrightarrow{\text{LEX*THIS}_M} \top \mapsto R \quad S_M = \{s_m \mid \langle p_m, s_m \rangle \in R\}}{\vdash_G s \uparrow_M S_M}$$

$$\text{ENC-MI} \frac{\text{query}_G s \xrightarrow{\text{LEX*THIS}_M} \top / \text{THIS}_M < \text{LEX} \mapsto \{\langle p, s_m \rangle\}}{\vdash_G s \uparrow_M s_m}$$

Enclosing Classes

$$\vdash_G s \uparrow_C S \quad \vdash_G s \uparrow_C s$$

$$\text{ENC-C} \frac{\text{query}_G s \xrightarrow{\text{LEX*THIS}_C} \top \mapsto R \quad S_C = \{s_c \mid \langle p_c, s_c \rangle \in R\}}{\vdash_G s \uparrow_C S_C}$$

$$\text{ENC-Cl} \frac{\text{query}_G s \xrightarrow{\text{LEX*THIS}_C} \top / \text{THIS}_C < \text{LEX} \mapsto \{\langle p, s_c \rangle\}}{\vdash_G s \uparrow_C s_c}$$

Figure 9 Auxiliary relations for AML scope graphs.

PUB access policy are included in the scope graph declaration. Similarly, class B has a field j. The initialization expression of j references i, which is represented with the query shown in the dashed box.

Figure 8b shows the part of the typing derivation that checks the highlighted reference. Reference i is type checked in scope s_B, and has type int. The first premise repeats the query shown in the scope graph, with the parameters and result made explicit. In particular, the resolution path is $s_B \xrightarrow{\text{EXT}} s_A$. The validity of this path is checked by the second premise, which is satisfied by the AP-PUB rule.

Auxiliary Relations. Finally, Figure 9 presents some auxiliary relations that we will use later. First, the $\vdash_G s \uparrow_M S_M$ relation asserts that S_M is the set of scopes of the enclosing modules of s. It is defined as a query that looks for a THIS_M edge in the lexically enclosing

scopes. There is no shadowing, so R can contain multiple results in the case of multiple nested modules. The result R is translated to the set of module scopes by discarding the access paths.

This relation is inhabited for any enclosing module scope. The second relation $\vdash_{\mathcal{G}} s \uparrow_M s_m$ is only inhabited for the *innermost* enclosing module s_m . The query in its definition finds the closest THIS_M -edge, which is enforced by the shadowing policy $\text{THIS}_M < \text{LEX}$. Thus, the query returns only one result, from which the module scope s_m is extracted. Analogously, $\vdash_{\mathcal{G}} s \uparrow_C S_C$ relates s to all enclosing *class* scopes S_C , and $\vdash_{\mathcal{G}} s \uparrow_C s_c$ is satisfied if s_c is the *innermost* enclosing class of s .

5 Defining Module Visibility

Some languages have access modifiers that regulate the visibility of a declaration in other modules. For example, in Rust, it is possible to write `pub(in ...)` to indicate in which module a declaration is visible. Similarly, some languages support giving particular classes access to an item. It is the primary accessibility mechanism for Eiffel, and C++'s `friend` modifier enables this as well. Less flexible approaches, such as Java's package visibility and C#'s `internal` keyword can be seen as special instances of this mechanism.

To demonstrate how these access policies can be encoded using scope graphs, we extend our base language as follows. Figure 10a introduces an additional modifier keyword `internal`, which can contain references to modules. The declaration is visible in these modules only. The corresponding accessibility policy `MOD` has a set of scopes, each corresponding to a name given in the keyword argument.

Next, we explain how this keyword is interpreted. An `internal` declaration is accessible if the reference occurs in a module that the arguments to the `internal` modifier give access to. This is formalized in the rules given in Figure 10b. Rule A-INT translates an `internal` access modifier to the `MOD` policy. Each module name argument to the modifier (x_i) is resolved relative to the current scope s . This yields a collection of module scopes s_i , which

$$\langle acc \rangle ::= \dots | \text{internal} (\langle x \rangle^*) \quad \langle A \rangle ::= \text{MOD } S$$

(a) Syntax of `internal` keyword.

$$\text{A-INT} \frac{}{s \vdash_{\mathcal{G}} \text{internal} (\bar{x}_{0..n}) \Rightarrow \text{MOD } S} \quad \text{AP-INT} \frac{\vdash_{\mathcal{G}} s \uparrow_M S_M \quad s_m \in S_M \quad s_m \in S}{s \vdash_{\mathcal{G}} p ! \text{MOD } S}$$

(b) Semantics of `internal` keyword.

$$\text{A-INT}' \frac{\vdash_{\mathcal{G}} s \uparrow_M S_M}{s \vdash_{\mathcal{G}} \text{internal} (\bar{x}_{0..n}) \Rightarrow \text{MOD } S} \quad \text{AP-INT}' \frac{\vdash_{\mathcal{G}} s \uparrow_M s_m \quad s_m \in S}{s \vdash_{\mathcal{G}} p ! \text{MOD } S}$$

(c) Variant 1: Ancestor module only.

(d) Variant 2: Innermost module.

$$\text{AP-INT}'' \frac{\dots [\vdash_{\mathcal{G}} s \uparrow_M S_{M_i} \quad s'_m \in S_{M_i} \quad s'_m \in S]_{s' \in (\text{scopes}(p) \setminus \{ \text{tgt}(p) \})}}{s \vdash_{\mathcal{G}} p ! \text{MOD } S}$$

(e) Variant 3: Definition exposed to all classes in path.

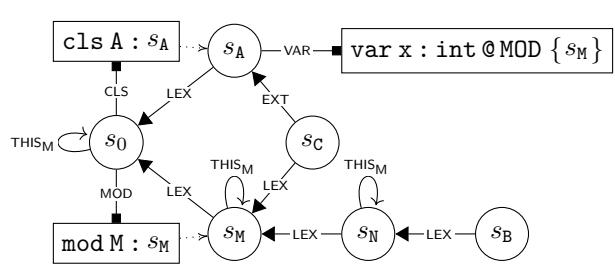

Figure 10 Extending AML (Figure 7) with module-level visibility.

47:14 Defining Name Accessibility Using Scope Graphs

```

class A {
    internal(M) var x = 42
}
module M {
    module N {
        class B {
            public var y =
                new C().x
        }
    }
    class C : public A { }
}

```

(a) Example program and partial scope graph demonstrating the `internal` access modifier.

$$\text{A-INT} \frac{s_A \vdash_G M \xrightarrow{M} s_M}{s_A \vdash_G \text{internal}(M) \Rightarrow \text{MOD}\{s_M\}}$$

(b) Part of typing derivation that shows how accessibility policy is derived.

$$\text{AP-INT} \frac{\dots \quad \vdash_G s_B \uparrow_M \{s_0, s_M, s_N\} \quad s_M \in \{s_0, s_M, s_N\} \quad s_M \in \{s_M\}}{s_B \vdash_G (s_C \xrightarrow{\text{EXT}} s_A) ! \text{MOD}\{s_M\}}$$

(c) Part of typing derivation that shows how access is granted by the `MOD` accessibility policy.

Figure 11 Example program demonstrating the meaning of the `internal` access modifier.

are included in the resulting policy. The `AP-INT` rule encodes that accessing an `internal` variable is valid if s_m , the scope of some enclosing module of s (the scope of the reference), is in the list of scopes to which access is granted.

Example. Figure 11 gives an example of an *internal* variable. Class A has a field x that can be accessed from module M. In the scope graph, this is indicated with the access policy `MOD {s_M}` on the corresponding declaration in s_A . The derivation of this policy is shown in Figure 11b. Module M contains a nested module N, which contains a class B. In class B, the field x is accessed on an instance of A. The (partial) typing derivation in Figure 11c shows this access is allowed by the `AP-INT` rule. The first premise asserts that s_0 , s_M and s_N are the enclosing modules of s_B . This can be seen in the scope graph, as those scopes are reachable via paths with regular expression `LEX*THIS_M` (Figure 9). As s_M occurs both in the enclosing modules and in the access policy, access is allowed.

Variant 1. Several variations on this scheme are conceivable. For example, languages can restrict the modules to which an `internal` modifier may expose a declaration. For example, Rust has the `pub(in <path>)` visibility modifier, similar to how we defined `internal`. However, at the $\langle path \rangle$ position, only “an ancestor module of the item whose visibility is being declared” is allowed [7, §12.6]. This is encoded in Figure 10c. Compared to `A-INT`, this rule adds premises (highlighted) that guarantee that the arguments of the `internal` modifier (x_i) resolve to an enclosing module ($s_i \in S_M$).

Note how these premises would make the example fail to type-check. Only s_0 is an enclosing module of s_A . In particular, the derivation in Figure 11b would have an additional premise $s_A \in \{s_0\}$, which is clearly unsatisfiable.

```

class A {
    private int x = 42;
    public int accessX(B b) {
        return b.x; // ERROR!
    }
}
class B extends A { }

class A {
    private int x = 42;
    public int AccessX(B b) {
        return b.x; // fine
    }
}
class B : A { }

```

Figure 12 Difference in `private` member access of subclass instances between Java and C#.

Variant 2. Next, consider the example in Figure 11a again. In the system above, `x` is accessible in `B`, because `x` is exposed to one of its enclosing modules (`M`). However, s_M is not its *innermost* enclosing module. Such a more lenient accessibility scheme might be desirable (e.g., Rust has this behavior), but languages such as Java do not allow this. To model these languages, we instead use the premise that asserts s_m is the *innermost* enclosing module scope. The rule for this variant is given in Figure 10d.

With this addition, the example would fail to type-check as well. The access validation (Figure 11c) would now have to satisfy $\vdash_G s_B \uparrow_M s_M$, which is impossible, as s_N is the innermost enclosing module.

Variant 3. Finally, consider example Figure 1a from the introduction again. In this example, the reference to `x` in class `C` was not valid, as `B` (by virtue of residing in a different package), did not inherit `x`. The (partial) rule in Figure 10e covers this case. For each scope in the path (apart from the target), it adds premises that assert that the definition is exposed to that scope (similar to s in Figure 10b).⁵ The target is excluded because it is not inheriting the accessed field, but rather defining it. (Recall that paths move from reference to declaration, so the target is the scope of the defining class.) For that reason, there is no need to assert it inherits the field.

When adding this rule fragment to the derivation in Figure 11c, there will be additional premises that validate that class `C` inherits `x`. This is the case, as `C` resides in module `M`.

6 Defining Subclass Visibility

Next, we consider how to define access modifiers that regulate access from other *classes*: the `private` modifier (Section 6.1), and the `protected` keyword (Section 6.2).

6.1 Private Access

The `private` access modifier is slightly challenging to define, as languages implement it differently. For example, C# allows accessing private variables on instances of *subclasses*, whereas Java does not. Consider the example programs in Figure 12. In the Java case, the access `b.x` is invalid, because it only allows access on instances of `A`.

On the other hand, Java exposes `private` members to the *outermost* enclosing class⁶, while C# only exposes members to the *defining* (i.e., innermost enclosing) class (including nested classes), as shown in Figure 13.

⁵ Alternatively, the premises of Figure 10d can be used when direct exposure is required.

⁶ “[When] the member or constructor is declared `private`, (...) access is permitted if and only if it occurs within the body of the top level class [sic!] that encloses the declaration of the member or constructor.” [11, §6.6.1]

47:16 Defining Name Accessibility Using Scope Graphs

```

class A {
    class B {
        private int x = 42;
    }
    int accessX(B b) {
        return b.x; // fine
    }
}

class A {
    class B {
        private int x = 42;
    }
    int AccessX(B b) {
        return b.x; // ERROR!
    }
}

```

Figure 13 Difference in `private` member access from enclosing class between Java and C#.

$$\langle acc \rangle ::= \dots \mid \text{private}\langle A \rangle ::= \dots \text{PRV} \quad \text{A-PRIV} \frac{}{s \vdash_{\mathcal{G}} \text{private} \Rightarrow \text{PRV}}$$

(a) Syntax of `private` keyword.

(b) `private` to PRV access policy.

$$\text{AP-PRIV} \frac{\vdash_{\mathcal{G}} s \uparrow_C S_C \quad \text{tgt}(p) \in S_C}{s \vdash_{\mathcal{G}} p ! A}$$

(c) Semantics of `private` keyword.

$$\text{AP-PRIV}, \frac{\dots \quad p \sim \text{LEX}^*}{s \vdash_{\mathcal{G}} p ! A}$$

(d) Prevent access on instances of subclasses.

$$\text{AP-PRIV''} \frac{\vdash_{\mathcal{G}} s \uparrow_C S_{C_{ref}} \quad \vdash_{\mathcal{G}} \text{tgt}(p) \uparrow_C S_{C_{decl}} \quad s_c \in S_{C_{ref}} \quad s_c \in S_{C_{decl}}}{s \vdash_{\mathcal{G}} p ! A}$$

(e) Allow access from enclosing classes.

Figure 14 Extending AML (Figure 7) with `private` visibility.

We start with modeling the C# semantics in Figures 14a–14c. Rule **AP-PRIV** states that the class in which the field is declared (which is the target of the path `tgt(p)`) should be an enclosing class of the scope in which the access occurs. This permits access from nested classes of `tgt(p)`, but does not expose it to enclosing classes. On the other hand, access on instances of subclasses is allowed, as there are no constraints on the structure of the path.

Note that we did not specify that this rule matches on the PRV policy specifically, but rather applies to *any* access policy A . This is a deliberate choice; it adds the possibility of using this rule as a fallback in case no other rule works. This ensures other accessibility policies will never be more strict than PRV, which corresponds to general intuition. By matching on an arbitrary A in **AP-PRIV**, we simplify the definition of the other policies, as they otherwise would need to define special rules for `private`-like access.

Current Instance. Now, we adapt these rules to match the Java semantics. First, Figure 14d shows how to prevent access to the private field on instances of subclasses (Figure 12). It uses a new type of constraint, $p \sim R$, which holds when the sequence of labels in path p is in the language described by the regular expression R . In this case, we assert that the access path p must adhere to the regular expression `LEX` * . This prevents access from instances of subclasses of the defining class, as that requires traversing an `EXT` edge. For example, the access path in Figure 12 would be $s_B \xrightarrow{\text{EXT}} s_A \sim \text{LEX}^*$, which is not satisfiable.

Outermost Class. Finally, Figure 14e shows how to expose `private` fields to the outermost enclosing class. In this rule, the set $S_{C_{ref}}$ contains the scope of the enclosing classes of the reference location, and $S_{C_{decl}}$ contains the scope of the enclosing classes of the class in which the declaration occurs. These sets should share a scope s_c , which represents the shared enclosing class of the reference and the declaration.

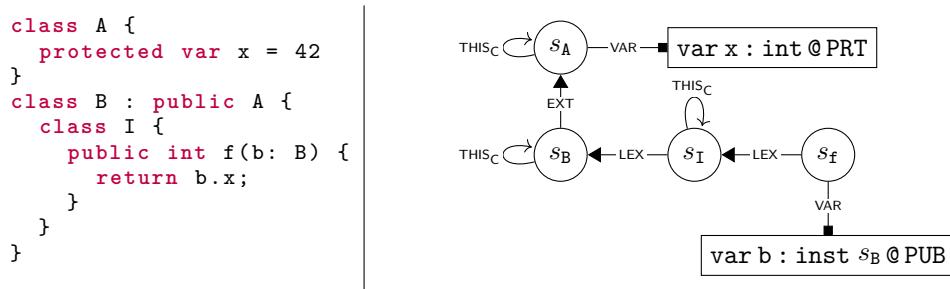

$$\langle acc \rangle ::= \dots \mid \text{protected} \quad \langle A \rangle ::= \dots \mid \text{PRT}$$

(a) Syntax of `protected` keyword.

$$\text{A-PROT} \frac{}{s \vdash_g \text{protected} \Rightarrow \text{PRT}} \quad \text{AP-PROT} \frac{\vdash_g s \uparrow_C S_C \quad s_c \in S_C \quad s_c \in \text{scopes}(p)}{s \vdash_g p ! \text{PRT}}$$

(b) Semantics of `protected` keyword.

■ **Figure 15** Extending AML (Figure 7) with `protected` visibility.

(a) Example program and partial scope graph demonstrating the `protected` access modifier.

$$\frac{\vdash_g s_f \uparrow_C \{ s_I, s_B \} \quad s_B \in \{ s_I, s_B \} \quad s_B \in \text{scopes}(s_B \xrightarrow{\text{EXT}} s_A)}{s_f \vdash_g (s_B \xrightarrow{\text{EXT}} s_A) ! \text{PRT}}$$

(b) Part of typing derivation that shows how access is granted by the PRT accessibility policy.

■ **Figure 16** Example program demonstrating the meaning of the `protected` access modifier.

Note how this rule enables type-checking the program in Figure 13. Using AP-PRIV does not work, as $\vdash_g s_A \uparrow_C \{ s_A \}$, which does not include $\text{tgt}(p) = s_B$. However, we can check it with AP-PRIV", as $\vdash_g \text{tgt}(p) \uparrow_C \{ s_B, s_A \}$, which includes the shared enclosing class s_A .

6.2 Protected Access

The `protected` access modifier (Figure 15a) grants access to subclasses of the defining class, including classes nested in subclasses. For field access expressions ($\langle e.x \rangle$), e must be an instance of a class that encloses the reference [11, §6.6.2.1]. This semantics (Figure 15b) can be modeled by asserting that there should be some class s_c that is both (a) an enclosing scope of the reference location ($\vdash_g s \uparrow_C S_C$), and (b) occurs in the in the access path ($s_c \in \text{scopes}(p)$). The last condition implies that the enclosing class s_c is a subclass of the *defining class*, which is the intuitive understanding of the `protected` keyword.

Figure 16 demonstrates how this rule works. In this program, there is a class A which has a subclass B. Class B has a nested class I, which has a method f with a parameter b of type B. The body of f accesses field x on the instance of B. On the right-hand side of the picture, a part of the corresponding scope graph is shown. The scopes for classes A and B are connected by an EXT-edge again. The fact that class I is nested in class B is represented by the $s_I \xrightarrow{\text{LEX}} s_B$ edge, similar to other lexically nested constructs. Likewise, scope s_f , which represents the body of the method f, has a LEX-edge to s_I .

Figure 16b shows how the access to $b.x$ is validated. The first premise states that s_I and s_B are the enclosing classes of s_f . The other premises assert that s_B is in the enclosing classes as well as in the access path. Together, this allows access to the protected member. Note how access to an instance of A in s_f would not be allowed. In that case, the access path would have been just s_A , which is not an enclosing class of s_f .

47:18 Defining Name Accessibility Using Scope Graphs

$\langle acc \rangle ::= \dots | \text{protected internal} (\langle x \rangle^*) | \text{private protected} (\langle x \rangle^*)$

$\langle A \rangle ::= \dots | \text{SMD } S | \text{SMC } S$

(a) Syntax of policy interaction keywords.

$$\text{A-PPROT} \frac{S = \left\{ s' \mid x_i \in \bar{x}_{0\dots n}, s \vdash_{\mathcal{G}} x_i \xrightarrow{\text{M}} s' \right\}}{s \vdash_{\mathcal{G}} \text{private protected}(\bar{x}_{0\dots n}) \Rightarrow \text{SMC } S}$$

$$\text{A-PINT} \frac{S = \left\{ s' \mid x_i \in \bar{x}_{0\dots n}, s \vdash_{\mathcal{G}} x_i \xrightarrow{\text{M}} s' \right\}}{s \vdash_{\mathcal{G}} \text{protected internal}(\bar{x}_{0\dots n}) \Rightarrow \text{SMD } S}$$

(b) Translation of composite keywords to their policies.

$$\text{AP-SMC} \frac{s \vdash_{\mathcal{G}} p ! \text{MOD } S \quad s \vdash_{\mathcal{G}} p ! \text{PRT}}{s \vdash_{\mathcal{G}} p ! \text{SMC } S}$$

$$\text{AP-SMD-PROT} \frac{s \vdash_{\mathcal{G}} p ! \text{PRT}}{s \vdash_{\mathcal{G}} p ! \text{SMD } S} \quad \text{AP-SMD-MOD} \frac{s \vdash_{\mathcal{G}} p ! \text{MOD } S^{(*)}}{s \vdash_{\mathcal{G}} p ! \text{SMD } S}$$

(c) Semantics of interaction policies.

Figure 17 Extending AML (Figure 7) with keywords to combine module-level and subclass-level accessibility.

7 Combining Subclass and Module Visibility

Access modifiers regulating both the module and subclass dimensions occur in real-world languages as well. For example (as noticed earlier), Java's `protected` keyword also exposes a definition in the same package, similar to C#'s `protected internal`. In addition, C# has a `private protected` modifier, which allows access to subclasses in the same assembly only. In fact, those two keywords denote the two main ways in which access modifiers can interact. First, `protected internal` denotes *disjunctive* interaction, where a declaration is accessible from the subclasses *or* the same module. Second, `private protected` denotes *conjunctive* interaction, where a declaration is accessible from the subclasses *in* the same module only. These interactions are straightforward to define, with one intricate case discussed below.

Figure 17a defines the syntax of the two new keywords (based on their name in C#) and policies. We add `SMD` (Subclass/Module, Disjunctive) and `SMC` (Subclass/Module, Conjunctive) policies, which each contain a list of module scopes to which they are exposed. The translation from keyword to policy is given in Figure 17b. Both rules resolve their module arguments, similar to `A-INT`. The `SMC` policy has one rule (`AP-SMC`), which simply asserts that access is granted by the module (`MOD`) and protected (`PRV`) policies. There are two rules for the `SMD` policy. The first one simply delegates to the `PRT` access policy, permitting access wherever a `protected` member would have been accessible. The other rule delegates to the `MOD` policy, but more careful attention must be paid here (hence the $(*)$ mark). Recall that the semantics of this policy has a variant that asserts that the whole inheritance chain has access to the declaration (Figure 10e). However, this extension should *not* be applied here, because the `protected` part of this modifier already grants access, regardless of the module-level exposure.

$$\begin{array}{c}
 \text{P-PUB} \frac{p \sim \text{LEX}^* \text{EXT}^*}{s \vdash_{\mathcal{G}} p \text{ i}} \quad \text{P-PRIV-PROT} \frac{\vdash_{\mathcal{G}} s \uparrow_C S_C \quad s_c \in S_C \quad \text{split-at}(s_c, p) = \langle p_1, p_2 \rangle}{p_1 \sim \text{LEX}^* \text{EXT}^* \quad p_2 \sim \text{EXT}_{\text{PRV}}^? (\text{EXT} | \text{EXT}_{\text{PRT}})^*} \\
 \end{array}$$

■ **Figure 18** Extending AML (Figure 7) with path-level visibility.

8 Defining Extends-Clause Accessibility Restriction

Until now, we have only considered inheritance as it exists in Java and C#. In this section, we shift our focus to C++, in particular the access modifiers on extends clauses. In C++, it is possible to add a `private` modifier to an extends clause, which reduces the accessibility of `public` and `protected` members to `private` in the derived class. Similarly, the `protected` keyword can be used to reduce the accessibility of `public` members to `protected`. For qualified accesses, C++ imposes the additional constraint that the inheritance chain leading to class in which the variable is declared should be accessible from the class in which the access occurs [8, §11.9.3 (4)].

Setup. In contrast to the previous sections, we cannot encode inheritance-imposed access control in our accessibility policy *A*. Instead, we encode it in the scope graph directly. For that purpose, we introduce two new labels: `EXTPRV` and `EXTPRT`, which model private and protected extension, respectively. Similar to the previous sections, `EXT` will model public extension; i.e. inheritance without access restriction.

Fortunately, we can validate path access independently from the declaration-level access policy.⁷ We require two adaptations to the rules **T-VAR** and **T-FLD** (Figure 7). First, the regular expressions of the queries must be changed to also traverse these new edges. Thus, in **T-VAR**, `LEX*EXT*VAR` must be changed to `LEX*(EXT|EXTPRT|EXTPRV)*VAR`. Similarly, **T-FLD** now has `(EXT|EXTPRT|EXTPRV)*VAR` as regular expression instead of `EXT*VAR`. Second, we add a premise $s \vdash_{\mathcal{G}} p \text{ i}$ to both rules. This premise asserts that the labels in the path p do not hide the accessed definition in scope s .

Path accessibility can be captured in two rules, shown in Figure 18. First, **P-PUB** asserts that a path is valid when there is only public inheritance. With this rule, the semantics of the programs that do not use private or protected inheritance has not changed. Second, rule **P-PRIV-PROT** covers the other two cases. This rule looks intricate, but the intuition behind it is not too complicated. Similar to the `private` and `protected` modifiers (Sections 6.1 and 6.2), access must occur within the class where the member is `private/protected`. This is now not necessarily the defining class, but rather the last class in the inheritance chain that has a non-public modifier on the extends clause. In the rule, this is encoded as follows. The first two premises introduce a scope s_c , which is an enclosing scope of the reference location s . The third premise asserts that the path p can be split into two segments at scope s_c . That is, p consists of two segments: a part p_1 from s_1 to s_c and a part p_2 from s_c to s_n . This implies that s_c is in the access path. To validate that all subclasses of s_c in the path have public inheritance, p_1 should match regular expression `LEX*EXT`.⁸ The path leading from the current class to the declaration (p_2) may start with a private inheritance step (`EXTPRV?`), but may have only public and protected inheritance higher in the access path.

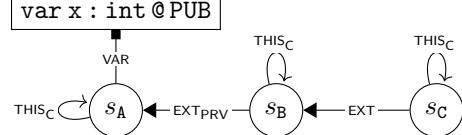

⁷ That also holds for the subtle interaction between `internal` and `protected` discussed in Section 7. `protected` or `private` inheritance in subclasses of the reference class can still compromise these access modes, and must therefore be validated.

⁸ Alternatively, one can encode the requirement that the instance type must be s_c itself by using `LEX*`, similar to Figure 14d.

```

class A {
    public var x = 42
}
class B : private A {
    public var y = new C().x
}
class C : public B { }

```

(a) Example program and partial scope graph demonstrating path access restrictions.

$$\frac{\dots}{\vdash_{\mathcal{G}} s_B \uparrow_{s_C} \{s_B\}} \quad s_B \in \{s_B\}$$

$$\text{split-at}(s_B, s_C \xrightarrow{\text{EXT}} s_B \xrightarrow{\text{EXT}_{\text{PRV}}} s_A) = \langle s_C \xrightarrow{\text{EXT}} s_B, s_B \xrightarrow{\text{EXT}_{\text{PRV}}} s_A \rangle$$

$$\frac{(s_C \xrightarrow{\text{EXT}} s_B) \sim \text{LEX}^* \text{EXT}^* \quad (s_B \xrightarrow{\text{EXT}_{\text{PRV}}} s_A) \sim \text{EXT}_{\text{PRV}}? (\text{EXT} | \text{EXT}_{\text{PRT}})^*}{s_B \vdash_{\mathcal{G}} (s_C \xrightarrow{\text{EXT}} s_B \xrightarrow{\text{EXT}_{\text{PRV}}} s_A) \downarrow}$$

(b) Part of typing derivation that shows how access is granted by the P-PRIV-PROT rule.

Figure 19 Example program demonstrating path accessibility.

Figure 19 gives an example that uses this rule. There is a class A with a field x. Class A is inherited privately by class B, which makes x private in B. Next, class C extends B publicly. In class B, x is accessed on an instance of C. This access should be allowed, as class B is the class in which x is private as well as the class in which the reference occurs. The partial derivation in Figure 19b asserts this. s_B is the scope that encloses the reference. Splitting the access path from s_C to s_A at that s_B yields two segments of a single step. The segment leading up to s_B ($s_C \xrightarrow{\text{EXT}} s_B$) does indeed match the regular expression $\text{LEX}^* \text{EXT}^*$. Likewise, the other segment also matches its regular expressions, showing that this access is valid. Note that, when class C would have extended class B with **protected** or **private** visibility instead, the premise on the first section would not hold anymore. This corresponds with the behavior in Section 6 (the field must be accessible as if it was defined on the instance type) as well as the specification of C++ cited above.

9 Analysis

A comprehensive model of accessibility can be made by composing the system fragments we discussed so far (Figures 7, 10, 14, 15, 17, and 18). In this section, we discuss a few properties that our system adheres to.

9.1 Soundness of Access Policies

First, we claim some soundness theorems for **private**, **protected** and **internal** access. There is no soundness theorem for **public**, as access is allowed unconditionally. Soundness theorems for **private** **protected** and **protected internal** are easily derived from Theorems 2 and 3, and hence omitted. In the theorems, $P_{\mathcal{G}}$ ranges over valid typing derivation for an AML program with scope graph \mathcal{G} , x_r over references, and x_d over declarations. Appendix D [35] defines the predicates used in these theorems, and proves them.

First, soundness for **private** access is stated as follows:

- **Theorem 1** (Soundness of private member access).

$$\begin{aligned} \text{resolve}_{P_G}(x_r) = x_d \wedge \text{private}_{P_G}(x_d) &\Rightarrow \\ \exists s_d. \text{definingClass}_{P_G}(x_d) = s_d \wedge \text{enclosingClass}_{P_G}(x_r, s_d) \end{aligned}$$

This should be read as “when x_r resolves to x_d , and x_d is private, then x_r must occur in the class s_c that defines x_d ”.

Likewise, soundness for **protected** access is stated as:

- **Theorem 2** (Soundness of protected member access).

$$\begin{aligned} \text{resolve}_{P_G}(x_r) = x_d \wedge \text{protected}_{P_G}(x_d) &\Rightarrow \\ \exists s_c, s_d. \text{definingClass}_{P_G}(x_d) = s_d \wedge \text{enclosingClass}_{P_G}(x_r, s_c) \wedge \text{subClass}_{P_G}(s_c, s_d) \end{aligned}$$

Compared to Theorem 1, this theorem states that x_r can occur in some arbitrary subclass s_c of s_d if x_d is **protected**.

Finally, **internal** access is specified correctly when:

- **Theorem 3** (Soundness of internal member access).

$$\begin{aligned} \text{resolve}_{P_G}(x_r) = x_d \wedge \text{internal}_{P_G}(x_d, \bar{x}) &\Rightarrow \\ (\exists x, s_m. \text{enclosingMod}_{P_G}(x_r) = s_m \wedge x \in \bar{x} \wedge \text{resolveMod}(x) = s_m) \vee \\ (\exists s_d. \text{definingClass}_{P_G}(x_d) = s_d \wedge \text{enclosingClass}_{P_G}(x_r, s_d)) \end{aligned}$$

This theorem states that references to declarations with modifier **internal** are valid if the enclosing module of the reference s_m is referred to in the arguments of the access modifier \bar{x} , or if it is accessed as a private variable.

9.2 Equivalence of Access Policies

The access policy language $\langle A \rangle$ we defined is not minimal. It is possible to define equivalent policies in multiple ways. To analyze that, we define equivalence of access policies as follows:

- **Definition 4** (Equivalence of Access Policies).

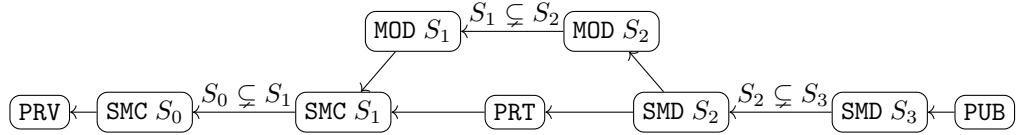

$$\frac{\forall \mathcal{G}, s, p. (s \vdash_{\mathcal{G}} p ! A) \Leftrightarrow (s \vdash_{\mathcal{G}} p ! A')}{A \equiv A'}$$

That is, two accessibility policies are equivalent when, for any scope s , path p , scope graph \mathcal{G} , either both policies admit access, or neither does.

The equivalences that hold in our model are: **PRT** \equiv **SMD** \emptyset and **PRV** \equiv **SMC** \emptyset \equiv **MOD** \emptyset . This follows from the fact that module access grants nothing if no module parameters are given. Thus, the **SMD** \emptyset policy reduces to **PRT**, while **SMC** \emptyset and **MOD** \emptyset do not elevate accessibility beyond **PRV**. Appendix B [35] gives proofs for each of these equivalences. Because of these equivalences, we did not include **PRT** and **PRV** in our implementation (Section 10).

9.3 Order of Access Policies

Intuitively, there exists an ordering between accessibility policies, where **PRV** is the bottom most restrictive, and **PUB** is the least restrictive. This order is partial, as the module-exposure dimension and subclass-exposure dimension are orthogonal. Assuming a subset relation on scope sets ($S \subset S'$), we can define a strict partial order $A <_A A'$ as follows:

where the edges indicate instances of the $<_A$ -relation. The edges with a condition indicate that SMC, MOD, and SMD become more permissive when more scopes are added to the policy.

The intuition behind this order is not arbitrary. In fact, we claim the following:

► **Theorem 5** (The order on access policies $<_A$ is well-behaved).

$$(A <_A A') \Rightarrow \forall \mathcal{G}, s, p. (s \vdash_{\mathcal{G}} p ! A) \Rightarrow (s \vdash_{\mathcal{G}} p ! A')$$

That is, when A is more restrictive than A' , and A permits access in scope s via a path p , then A' will permit that access too. A proof of this theorem can be found in Appendix C [35].

10 Evaluation

So far, we have motivated our specification with examples from real-world languages such as Java and C#, and stated some generic properties of our model. However, for our specification to be usable as a basis for practical tools, it must correspond with the behavior of the actual languages. To validate that, we evaluated our specification in two ways. First, we systematically compared our specification with reference compilers of Java, C#, and Rust. Second, we validated the compatibility of our framework with recent work on language-parametric code completion [19].

10.1 Comparison with Reference Compilers: Implementation

The comparison to compilers of real-world languages is implemented as follows:

1. Apply our type system on an AML program (the test case).
2. Translate the AML program to the target language.
3. Compile the translated program using a compiler of the target language.
4. Compare results: either both analyses should succeed, or both should give errors.

We discuss these steps in more detail below.

AML Type Checker. To compare our model with real-world compilers, we need a way to type check concrete AML programs. To that end, we implemented AML in the Spooftax language workbench [13, 31]. The actual type system is implemented using the Statix specification language [27, 22]. Statix is a suitable choice, as its declarativity allows an overall straightforward translation from our inference. For example, the Statix encoding of rule **T-VAR** in Figure 20a strongly corresponds to the original (Figure 7). Using this implementation, we can systematically check accessibility in concrete AML programs.

Compiling with Reference Compiler. Next, we implemented source-to-source translations from AML to each of Java, C# and Rust. This translation was straightforward by design, as otherwise the results of the type checkers can be different due to semantic differences introduced by the translation. For that reason, we do not support AML features that have no direct counterpart in the target language. For example, the translation to Java will error when the AML program uses the `private protected` access modifier, as Java does not support that accessibility policy. This way, we know that correspondence between the programs is guaranteed when the translation succeeds.

```

typeOfExpr: scope * Expr -> TYPE
typeOfExpr(s, Id(x)) = T :- fp A}
query var
filter LEX* EXT*
and { x' :- x' == x }
min $ < EXT, EXT < LEX
in s |-> [(p, (x, T, A))],
accessOk(s, p, A),
pathOk(s, p).

```

(a) Encoding of rule **T-VAR** in Statix.

```

test private - nested [[
class A {
private var x = 42
class B {
public var y = x
}
]]
analysis succeeds
run java-compat

```

(b) Example test case.

Figure 20 Overview of Approach to Comparison with Reference Compilers.

After translating, we invoke the reference compiler, observe its output (success or failure), and compare the given output with the result from our own type checker (step 1). If those are different (i.e., our type checker accepts the program, while the reference compiler emits errors, or vice versa), the test fails.

10.2 Comparison with Reference Compilers: Test Cases

To the best of our knowledge, there exists no test suite specifically aimed at verifying the semantics of access modifiers. For that reason, we manually created an extensive test suite. Each test contains a class **Def**, that defines some variable **x** with some access modifier **A**. Furthermore, each test contains a class **Ref**, in which a reference to **x** occurs. **Def** and **Ref** can be related in two different ways at the same time:

- By inheritance: either (1) **Def** and **Ref** are actually the same class, (2) have no mutual inheritance, (3) **Ref** inherits **Def**, or (4) **Def** inherits **Ref**.
- By module position: either **Def** and **Ref** (1) occur in the same module, or (2) **Ref** occurs in a parent/sibling/child module of **Def**.
- By class nesting: either (1) **Def** and **Ref** are top-level classes, (2) **Ref** is nested in **Def**, (3) **Def** is nested in **Ref**, or (4) **Def** and **Ref** have a shared enclosing class.

In addition, tests for member accesses (i.e., **recv.x**) have a receiver type **Recv**. This type must either be equal to **Def**, or inherit from it. However, it can be related in all possible other ways to **Def** and **Ref**. By systematically exploring all options, we derived our test suite.

We excluded cases that are (1) impossible (e.g., **Ref** cannot be nested in **Def** and live in a different module at the same time), (2) use features not supported by the target language, (3) invalid for another reason (i.e., inheriting from a nested class is not allowed by Java), or (4) do not bind properly (i.e., lexical access where **Ref** and **Def** do not inherit from each other, and are not nested in each other). To reduce the number of test cases, we restricted the cases that involved nested classes to have one module only. Additionally, we only used **private**, **protected** and **protected internal** as access modifiers in these cases. Table 2 summarizes the results of the test suite generation.

Figure 20b shows an example test case written in the Spooftax Testing Language (SPT) [12]. This test validates that a private field is accessible from a nested class. The test consists of a program (between double square brackets), and some *expectations*. In this case, we expect the (Statix-based) analysis to succeed. Moreover, we expect the **java-compat** transformation to succeed. This transformation is executing the steps in Section 10.1.

 **Table 2** Summary of Test Suite.

	Java	C#	Rust	Manual
<i>Acc. Mods.</i>	<code>public</code>	Same as Java, and	<code>public</code>	All
	<code>protected internal</code>	<code>protected</code>	<code>internal</code>	
	<code>internal, private</code>	<code>private protected</code>		
<i>Features</i>	class inheritance	class inheritance	structs, modules	advanced modules
	class nesting, and packages	class nesting, and assemblies		inheritance visibility
<i>#Cases</i>	433	522	60	168
<i>Compiler</i>	<code>javac 11.0.20.1</code>	<code>dotnet 7.0.401</code>	<code>rustc 1.73.0</code>	—

Results. There are several features present in AML that were not covered by any of the reference compilers, most notably *private/protected inheritance*, and module visibility beyond what Rust supports. To validate we cover these features to some extent, we have written 168 additional test cases. While initially exposing a lot of edge cases, in the end all test cases succeeded. This shows that our specification covers the languages it set out to model rather accurately.

10.3 Code Completion

One of our future goals is to use our framework to implement refactoring tools that are sound with respect to accessibility. The most recent work in this area is done by Pelsmaeker et al. [19]. They show how Statix specifications can be used to generate editor auto-completion proposals language-parametrically. We applied auto-completion to the access modifiers in the C#/Java and Rust tests (152, after deduplication), and validated soundness and completeness. That is, when the analysis succeeded, code completion should propose the current modifier at that position. Otherwise, if the access was invalid, the modifier should not be proposed, as only less restrictive ones are valid at that position.

We consider the fact that all completion tests pass a good indication that our specification can be applied with refactoring tools in the future. Apparently, the code completion framework is sound and complete with respect to our encoding of access modifiers. Accessibility errors introduced by a refactoring can be fixed by generating proposals for that position, and using the ordering from Section 9.3 to pick the most restrictive one.

10.4 Threats to Validity

In Section 4, we briefly mentioned that the specification as presented in the paper did not model the interaction between shadowing and accessibility correctly. Doing so would require a full path order, instead of ordering paths by a lexicographical order on labels. Appendix A.1 [35] explains how we think that could be done. However, Statix does not support full path orders. To work around that, we emulated this behavior using a few helper predicates. Our test suite gives confidence we modeled it correctly, but we did not prove that the specification in Statix and the full path order are semantically equivalent.

Finally, we might have modeled incorrect/unspecified behavior if the reference compilers were incorrect. Examples such as Figure 12 were derived from actual compiler behavior. However, we could not find our interpretation of the implementation behavior explicitly specified in the JLS [11, §6.6.1].

11 Related Work

In this section, we discuss previous work related to access modifiers and scope graphs.

11.1 Access Modifier Semantics and Implementations

The origin of access modifiers dates back to at least Simula 67, which around 1972 introduced `protected` and `hidden` access modifiers [4, §8] (the latter being equivalent to our `private`). Later, languages such as Java and C++ incorporated these keywords, making them well-known and often used. Design principles and patterns [9] using these keywords were developed, making contemporary software development heavily reliant on accessibility features the programming language provides.

Giurca and Savulea (2004) [10] apply object-oriented notions of `public`, `protected` and `private` to logic programs, with the purpose of better knowledge distribution and run time optimization. Moreover, Apel et al. [2, 1] introduce access modifiers in feature-oriented programming. Where we define accessibility for module nesting and class inheritance, they add the “feature refinement” dimension to this. In particular, the `feature` keyword restricts access to the “current feature” only (comparable to `private` in the class inheritance dimension), the `subsequent` keyword grants access to the current feature and later refinements (comparable to `protected`), and the `program` modifier allows access from any position (similar to `public`). In our terminology, their model supports “conjunctive” combination of the class and feature dimensions. As Section 7 shows that combining the module and class dimensions conjunctively is straightforward, we expect that integrating their work in our model will not pose major challenges (apart from a combinatorial explosion of policies).

Semantics. As access modifiers mainly originated from practical needs, it is not very surprising that little attention to them was paid from a more theoretical perspective. A few attempts to create a more formal account have been performed, however. In 1998, Yang [33] presented a formalization of Java access modifiers using attribute grammars. At that time, attribute grammars still lacked several convenience features, such as default attributes [30] and collection attributes [14]. For that reason, all members must be propagated explicitly to the scopes where they are accessible, which makes the specification rather verbose. Additionally, since fields and methods are not treated equally (shadowing vs. overriding), they are treated separately, doubling the specification size. In contrast, we specify the propagation of members queries in scope graphs, which is more concise. The additional requirements on methods (not explicitly discussed), can be handled at the definition site. Furthermore, we cover more features than just the Java ones. Pharkani et al. [6] present a generalized model of accessibility, where accessibility is modeled as a set of rules granting access of a member to another member (similar to Eiffel/`friends` in C++). In addition, rules can *deny* access to the named member, or apply to all members except the named ones.

Tools. Steimann et al. [25] observe that disregarding accessibility can result in a lot of subtle mistakes. For example, a method may silently fail to override another method when it is moved to a different package, which results in different dynamic dispatch. To capture these errors, they present nine constraint generation rules that model the accessibility semantics of Java. Refactoring tools can use these constraints to detect where the accessibility level of a member must be elevated. This work was incorporated in the JRRT refactoring tool [23], which was evaluated on a large number of real-world Java projects, showing the accuracy of their implementation. While their work also covers overriding-specific constraints, which our

specification treats rather superficially, we think our model is more comprehensible, and also gives insight in the differences between languages. Moreover, their work is applied in real refactoring implementations, while the quest for Statix-based refactorings is still ongoing. Meanwhile, a similar approach was applied to Eiffel accessibility [24, §6.3].

While these tools *elevate* accessibility if needed, a different line of research aims to *restrict* accessibility if possible [5, 17, 34]. The purpose of these tools is to detect access modifiers that are more lenient than needed, and restrict those. This is claimed to improve readability, enable optimizations, and increase modularity [17]. The exact underlying model is not the topic of these publications, and hence remains unclear. Despite that, the tools appear to be useful in practice. Zoller and Schmolitzky mention some challenges in porting their tool to other object-oriented languages [34, V.B]. A language-parametric model such as ours helps in that regard by (1) making differences between languages explicit, and (2) make implementations of these (kind of) tools language-parametric.

11.2 Scope Graphs

Scope Graphs (Section 3) have been introduced by Neron et al. [18], and later refined by Van Antwerpen et al. [27] and Rouvoet et al. [22]. In order to bridge the gap between language specification and implementation, scope graphs have been embedded into the NaBL2 constraint language [26]. Later, the Statix logic language was introduced [27, 22], which is more expressive than NaBL2. Both languages allow specifying type checking as constraint programs, giving the language a declarative appeal, but also yielding an executable type checker. Scope graphs are also available in a framework for concurrent and incremental type checkers [28, 39] and an embedded DSL in Haskell [20]. Finally, Statix specifications have been used for language-parametric code completion [19] and refactorings [16, 29]. Zwaan and Van Antwerpen provide a detailed overview of the development history of scope graphs, their embeddings in type system specification DSLs, and their applications [38].

12 Conclusion

Access modifiers occur in many real-world languages. To implement high-quality tooling for these languages, a good understanding of access modifiers is required. In this paper, we presented a model for access validation based on scope graphs. Our model covers the most important accessibility features in contemporary languages, including module accessibility, and inheritance accessibility, both on declarations and extends-clauses. Variations between different languages, both in supported features and their semantics, are made explicit in our model. Our specification is quite declarative, partly because scope graphs abstract over low-level name resolution and scoping details. Our model was validated using an extensive test suite, using Java, C#, and Rust compilers as oracles. This test suite was also used to show that we can synthesize access modifiers accurately using previous work on code completion [19].

Our main motivation for this work is twofold. First, we aim to provide a “language-transcendent” model for accessibility that enables comparison of different languages regarding accessibility. To this end we identify and formalize differences in the semantics of several access modifiers. In addition, we formulate soundness theorems of several access modifiers, and prove them. As such, we consider our specification accurate enough to serve as a reference for future tool implementations. Second, we aim to use our model in language-parametric refactorings, ensuring they respect accessibility properly. As these refactoring tools are still in development, actual validation of this application is still future work.
