Regular Papers

A Sound Type System for Secure Currency Flow <i>Luca Aceto, Daniele Gorla, and Stian Lybeck</i>	1:1–1:27
Runtime Instrumentation for Reactive Components <i>Luca Aceto, Duncan Paul Attard, Adrian Francalanza, and Anna Ingólfssdóttir</i>	2:1–2:33
A Dynamic Logic for Symbolic Execution for the Smart Contract Programming Language Michelson <i>Barnabas Arvay, Thi Thu Ha Doan, and Peter Thiemann</i>	3:1–3:26
Dynamically Generating Callback Summaries for Enhancing Static Analysis <i>Steven Arzt, Marc Miltenberger, and Julius Näumann</i>	4:1–4:27
Behavioural Up/down Casting For Statically Typed Languages <i>Lorenzo Bacchiani, Mario Bravetti, Marco Giunti, João Mota, and António Ravara</i>	5:1–5:28
Cross Module Quickening – The Curious Case of C Extensions <i>Felix Berlakovich and Stefan Brunthaler</i>	6:1–6:29
HOBBIT: Hashed OBject Based InTegrity <i>Matthias Bernad and Stefan Brunthaler</i>	7:1–7:25
Understanding Concurrency Bugs in Real-World Programs with Kotlin Coroutines <i>Bob Brockbernd, Nikita Koval, Arie van Deursen, and Burcu Kulahcioglu Ozkan</i> ..	8:1–8:20
A Language-Based Version Control System for Python <i>Luis Carvalho and João Costa Seco</i>	9:1–9:27
Indirection-Bounded Call Graph Analysis <i>Madhurima Chakraborty, Aakash Gnanakumar, Manu Sridharan, and Anders Møller</i>	10:1–10:22
Regrading Policies for Flexible Information Flow Control in Session-Typed Concurrency <i>Farzaneh Derakhshan, Stephanie Balzer, and Yue Yao</i>	11:1–11:29

Mutation-Based Lifted Repair of Software Product Lines <i>Aleksandar S. Dimovski</i>	12:1–12:24
Pure Methods for roDOT <i>Vlastimil Dort, Yufeng Li, Ondřej Lhoták, and Pavel Parízek</i>	13:1–13:29
The Performance Effects of Virtual-Machine Instruction Pointer Updates <i>M. Anton Ertl and Bernd Paysan</i>	14:1–14:26
Rose: Composable Autodiff for the Interactive Web <i>Sam Estep, Wode Ni, Raven Rothkopf, and Joshua Sunshine</i>	15:1–15:27
Mover Logic: A Concurrent Program Logic for Reduction and Rely-Guarantee Reasoning <i>Cormac Flanagan and Stephen N. Freund</i>	16:1–16:29
Fair Join Pattern Matching for Actors <i>Philipp Haller, Ayman Hussein, Hernán Melgratti, Alceste Scalas, and Emilio Tuosto</i>	17:1–17:28
A CFL-Reachability Formulation of Callsite-Sensitive Pointer Analysis with Built-In On-The-Fly Call Graph Construction <i>Dongjie He, Jingbo Lu, and Jingling Xue</i>	18:1–18:29
Fearless Asynchronous Communications with Timed Multiparty Session Protocols <i>Ping Hou, Nicolas Lagaillardie, and Nobuko Yoshida</i>	19:1–19:30
Taking a Closer Look: An Outlier-Driven Approach to Compilation-Time Optimization <i>Florian Huemer, David Leopoldseder, Aleksandar Prokopec, Raphael Mosaner, and Hanspeter Mössenböck</i>	20:1–20:28
Learning Gradual Typing Performance <i>Mohammad Wahiduzzaman Khan, Sheng Chen, and Yi He</i>	21:1–21:27
CONSTRICtor: Immutability as a Design Concept <i>Elad Kinsbruner, Shachar Itzhaky, and Hila Peleg</i>	22:1–22:29
InferType: A Compiler Toolkit for Implementing Efficient Constraint-Based Type Inference <i>Senxi Li, Tetsuro Yamazaki, and Shigeru Chiba</i>	23:1–23:28
Qafny: A Quantum-Program Verifier <i>Liyi Li, Mingwei Zhu, Rance Cleaveland, Alexander Nicollellis, Yi Lee, Le Chang, and Xiaodi Wu</i>	24:1–24:31
Compositional Symbolic Execution for Correctness and Incorrectness Reasoning <i>Andreas Lööw, Daniele Nantes-Sobrinho, Sacha-Élie Ayoun, Caroline Cronjäger, Petar Maksimović, and Philippa Gardner</i>	25:1–25:28
Matching Plans for Frame Inference in Compositional Reasoning <i>Andreas Lööw, Daniele Nantes-Sobrinho, Sacha-Élie Ayoun, Petar Maksimović, and Philippa Gardner</i>	26:1–26:20
The Fault in Our Stars: Designing Reproducible Large-scale Code Analysis Experiments <i>Petr Maj, Stefanie Muroya, Konrad Siek, Luca Di Grazia, and Jan Vitek</i>	27:1–27:23

Static Basic Block Versioning <i>Olivier Melançon, Marc Feeley, and Manuel Serrano</i>	28:1–28:27
Generalizing Shape Analysis with Gradual Types <i>Zeina Migeed, James Reed, Jason Ansel, and Jens Palsberg</i>	29:1–29:28
Verifying Lock-Free Search Structure Templates <i>Nisarg Patel, Dennis Shasha, and Thomas Wies</i>	30:1–30:28
Ozone: Fully Out-of-Order Choreographies <i>Dan Plyukhin, Marco Peressotti, and Fabrizio Montesi</i>	31:1–31:28
Tenspiler: A Verified-Lifting-Based Compiler for Tensor Operations <i>Jie Qiu, Colin Cai, Sahil Bhatia, Niranjan Hasabnis, Sanjit A. Seshia, and Alvin Cheung</i>	32:1–32:28
Compiling with Arrays <i>David Richter, Timon Böhler, Pascal Weisenburger, and Mira Mezini</i>	33:1–33:24
Pipit on the Post: Proving Pre- and Post-Conditions of Reactive Systems <i>Amos Robinson and Alex Potanin</i>	34:1–34:28
Partial Redundancy Elimination in Two Iterative Data Flow Analyses <i>Reshma Roy, Sreekala S, and Vineeth Paleri</i>	35:1–35:19
Scaling Interprocedural Static Data-Flow Analysis to Large C/C++ Applications: An Experience Report <i>Fabian Schiebel, Florian Sattler, Philipp Dominik Schubert, Sven Apel, and Eric Bodden</i>	36:1–36:28
Java Bytecode Normalization for Code Similarity Analysis <i>Stefan Schott, Serena Elisa Ponta, Wolfram Fischer, Jonas Klauke, and Eric Bodden</i>	37:1–37:29
Optimizing Layout of Recursive Datatypes with Marmoset: Or, Algorithms + Data Layouts = Efficient Programs <i>Vidush Singhal, Chaitanya Koparkar, Joseph Zullo, Artem Pelenitsyn, Michael Vollmer, Mike Rainey, Ryan Newton, and Milind Kulkarni</i>	38:1–38:28
Formalizing, Mechanizing, and Verifying Class-Based Refinement Types <i>Ke Sun, Di Wang, Sheng Chen, Meng Wang, and Dan Hao</i>	39:1–39:30
Information Flow Control in Cyclic Process Networks <i>Bas van den Heuvel, Farzaneh Derakhshan, and Stephanie Balzer</i>	40:1–40:30
Refinements for Multiparty Message-Passing Protocols: Specification-Agnostic Theory and Implementation <i>Martin Vassor and Nobuko Yoshida</i>	41:1–41:29
Failure Transparency in Stateful Dataflow Systems <i>Aleksey Veresov, Jonas Spenger, Paris Carbone, and Philipp Haller</i>	42:1–42:31
Inductive Predicate Synthesis Modulo Programs <i>Scott Wesley, Maria Christakis, Jorge A. Navas, Richard Trefler, Valentin Wüstholtz, and Arie Gurfinkel</i>	43:1–43:30

Type Tailoring Ashton Wiersdorf, Stephen Chang, Matthias Felleisen, and Ben Greenman	44:1–44:27
Higher-Order Specifications for Deductive Synthesis of Programs with Pointers David Young, Ziyi Yang, Ilya Sergey, and Alex Potanin	45:1–45:26
CtChecker: A Precise, Sound and Efficient Static Analysis for Constant-Time Programming Quan Zhou, Sixuan Dang, and Danfeng Zhang	46:1–46:26
Defining Name Accessibility Using Scope Graphs Aron Zwaan and Casper Bach Poulsen	47:1–47:29

■ Message from the Program Chairs

Started in 1987, ECOOP is Europe's oldest programming conference, welcoming papers on all practical and theoretical investigations of programming languages, systems, and environments that provide innovative solutions to real problems as well as evaluations of existing solutions. Papers were submitted to one of four categories: *Research* for papers that advance the state of the art in programming; *Replication* for empirical evaluations that reconstruct a published experiment in a different context in order to validate the results of that earlier work; *Experience* for applications of known techniques in practice; and *Pearl/Brave New Idea* for papers that either explain a known idea in an elegant way or unconventional papers introducing ideas that may take some time to substantiate. The chairs thank the Program Committee for their dedication to ensuring a quality program and providing constructive feedback to authors: Alvin Cheung, Eva Darulova, Jenna DiVincenzo (Wise), Werner Dietl, Jens Dietrich, Sebastian Erdweg, Patrick Eugster, Carla Ferreira, Simon J. Gay, Jeremy Gibbons, Elisa Gonzalez Boix, Arjun Guha, Suresh Jagannathan, Ranjit Jhala, Yu David Liu, Mira Mezini, Heather Miller, Ragnar Mogk, David Naumann, Marianna Rapoport, António Ravara, Manuel Serrano, Peter Thiemann, Emilio Tuosto, and Elena Zucca.

This year, we continued a number of innovations that were first introduced in 2022:

- **Multiple rounds.** ECOOP has two main rounds of submissions per year (Jan 17 and Apr 17). Each round supports both minor and major revisions. Major revisions are handled in the next round (either the same year or the next) by the same reviewers. In the second round we gave as many papers as possible the chance to try revising by the minor revision deadline so that they could make the 2024 program; all of these resubmissions were accepted.
- **No format or length restrictions.** In order reduce friction for authors, papers can come in any format and at any length. This applies to submissions. Final versions must abide by the publisher's requirements.
- **Artifacts and Papers together.** Every submitted paper can be accompanied with an artifact, submitted a few days after the paper. Both submissions are evaluated in parallel by overlapping committees as members of the artifact evaluation committee were invited to serve on the conference review committee.
- **Journal First/Last.** Papers can be submitted either one of three associated journals and be invited to present at the meeting. Furthermore, some accepted papers can be forwarded to journals.

In addition, this year we introduced a new review process, in which all papers were rated on each of the following criteria:

- **Soundness:** How well the paper's contributions are supported by rigorous application of appropriate research methods;
- **Significance:** The extent to which the paper's contributions are novel, original, and important, with respect to the existing body of knowledge;
- **Presentation:** Whether the paper's quality of writing meets the high standards of ECOOP.

0:x Message from the Program Chairs

After the author response and reviewer discussions, papers were accepted if the PC decided that the paper meets our high bar for Soundness and Presentation, and if at least one reviewer judges the paper to meet the bar for Significance. The goal of this process is to ensure quality of writing and confidence in results, while assuming that if one reviewer finds the paper to be significant then there will be readers who do so as well.

Overall, we found that most of these innovations to have worked well. The new reviewing criteria helped focus the reviewer discussion on what are the main issues with each paper. The acceptance criteria did not affect many papers but made a difference for a few; we believe the result is a more diverse program than might have been accepted based on a traditional, one-dimensional quality rating.

Overall, 59 papers were submitted in the first round and 53 in the second round. Each of these included some resubmissions of papers that received a reject or major revision judgment in prior reviewing rounds. In the end 47 papers were accepted, in many cases after a final round of checking for papers that initially received a conditional accept rating. As is common with journals, the ability to resubmit improved versions of a paper allowed the conference to accept a larger percentage of papers overall than in prior editions of ECOOP, while maintaining a high quality threshold.

We hope that future chairs will continue to experiment with more, and perhaps, different innovations that will enrich the ECOOP community further.

■ Message from the Artifact Evaluation Chairs

ECOOP has a long-standing tradition of offering artifact evaluation dating back to 2013. Following the process introduced in 2022, the artifact evaluation involved every single paper submission to ECOOP 2024, rather than just accepted papers. As such, it happened in parallel with the paper review process. This approach has two benefits: all authors who submitted an artifact received feedback (independently from paper acceptance), and evaluation results were made available to the reviewers of the papers. In addition, senior artifact evaluation committee members (representing half of the members) contributed to an average of 2 paper reviews to the technical research track as members of the extended review committee, improving the information sharing between the two processes. Artifact submissions could, thus, provide more insights into the technical contributions described in the papers and help to improve the overall review process.

To handle the high review load that such a process entails, we recruited a large artifact evaluation committee that included a total of 61 artifact reviewers. The artifact submissions were due around one week after the paper deadline, for both submission rounds of ECOOP. We received a total of 64 submissions (41 for R1 and 23 for R2). After a kick-the-tires review and author response phase, during which authors had the opportunity to clarify or address technical issues with their submissions, each submitted artifact was reviewed by three committee members.

We have followed ACM's badging policy¹ since 2023; details about the evaluation process are provided in the preface to the Artifact volume.² Out of the 64 submissions, the artifact evaluation committee awarded the highest qualification (available, functional and reusable badges) to 19 artifacts, the available and functional badges to 18 artifacts, and the available badge to 23 artifacts. Out of those 64 submissions, 33 were associated with papers accepted for presentation at ECOOP 2024.

The smooth and thorough artifact evaluation process would have not been possible without the members of the committee, who handled the artifact review workload and contributed to the technical PC discussions with great dedication. We would like to thank them for their valuable work, feedback to authors and the inspiring discussions! We would also like to thank the ECOOP 2024 program committee chairs Guido Salvaneschi and Jonathan Aldrich for the pleasant and productive interactions over the coordination of the paper and artifact review processes, and the Dagstuhl Publishing team for their proactive and highly responsive assistance during the preparation of this DARTS volume.

■ Foreword by the President of AITO

After last year's event in Seattle, ECOOP 2024 returns to the heart of Europe, hosted by the prestigious Vienna University of Technology (TU Wien). Before this year, the conference had been held in Austria only once, 28 years ago in Linz. Therefore, I am especially pleased to welcome the ECOOP community to Vienna.

Although I have been involved in many ECOOP conferences, ECOOP 2024 holds special significance for me, as this is my first time attending the conference as President of AITO. Recently, the AITO Executive Board has undergone significant renewal. I am glad to welcome Christian Hammer and Ben Hermann as the new Secretary and Treasurer of the Board, respectively.

I owe deep gratitude to Eric Jul and Walter Olthoff, our previous President and Treasurer, for supporting us during this transition and for their long-standing contributions to the AITO community and the success of ECOOP.

As in previous years, ECOOP 2024 is co-located with ISSTA and, for the first time, with MPLR. The ECOOP 2024 team, along with the ISSTA and MPLR teams, has done a great job in putting together an excellent and rich program for the conferences, including ten workshops, a doctoral symposium, tool demos, and tutorials. A huge thanks to them and to all others who have contributed.

I am looking forward to excellent conferences and workshops, great presentations fostering personal interaction, and excellent keynotes, including talks by the two 2024 Dahl-Nygaard Prize Winners. Enjoy the conference and Vienna.

Davide Ancona
AITO President

Abstract

In this paper we focus on TINY SOL, a minimal calculus for Solidity smart contracts, introduced by Bartoletti et al. We start by rephrasing its syntax (to emphasise its object-oriented flavour) and give a new big-step operational semantics. We then use it to define two security properties, namely call integrity and noninterference. These two properties have some similarities in their definition, in that they both require that some part of a program is not influenced by the other part. However, we show that the two properties are actually incomparable. Nevertheless, we provide a type system for noninterference and show that well-typed programs satisfy call integrity as well; hence, programs that are accepted by our type system satisfy both properties. We finally discuss the practical usability of the type system and its limitations by means of some simple examples.

2012 ACM Subject Classification Theory of computation → Program analysis; Theory of computation → Type structures

Keywords and phrases smart contracts, call integrity, noninterference, type system

Acknowledgements We thank the anonymous reviewers for their constructive attitude and for the fruitful comments that helped us improve our paper. Luca Aceto and Stian Lybech thank Mohammad Hamdaqa for sharing his expertise with them during extensive discussions on safety properties for smart contracts, which helped shape the research agenda for the work reported in this paper.

1 Introduction

The classic notion of noninterference [12] is a well-known concept that has been applied in a variety of settings to characterise both integrity and secrecy in programming. In particular, this property has been defined by Volpano et al. [28] in terms of a lattice model of security levels (e.g. “High” and “Low”, or “Trusted” and “Untrusted”); the key point being that information must not flow from a higher to a lower level. Thus, the lower levels are unaffected by the higher ones, and, conversely, the higher levels are “noninterfering” with the lower ones.

Ensuring noninterference seems particularly relevant in a setting where not only information, but also *currency*, flows between programs. This is a core feature of *smart contracts*, which are programs that run atop a blockchain and are used to manage financial assets of users, codify transactions, and implement custom tokens; see e.g. [24] for an overview of the architecture. The code of a smart contract resides on the blockchain itself, and is therefore both immutable and publicly visible. This is one of the important ways in which the “smart-contract programming paradigm” differs from conventional programming languages.

1:2 A Sound Type System for Secure Currency Flow

```

1  contract X {
2    ...
3    field called := F;
4    transfer(z) {
5      if  $\neg$ called  $\wedge$  this.balance  $\geq$  1
6        then z.deposit(this):1;
7          this.called := T;
8        else skip
9    }
10 }
```

```

contract Y {
  ...
  deposit(x) {
    x.transfer(this):0
  }
}
```

Figure 1 Illustration of reentrancy written in the language TINY SOL.

Public visibility means that *vulnerabilities* in the code can be found and exploited by a malicious user. Moreover, if a vulnerability is discovered, immutability prevents the contract creator from correcting the error. Thus, it is obviously desirable to ensure that a smart contract is safe and correct *before* it is deployed onto the blockchain.

The combination of immutability and visibility has led to huge financial losses in the past (see, e.g., [2, 8, 19, 20, 26]). A particularly spectacular example was the infamous DAO-attack on the Ethereum platform in 2016, which led to a loss of 60 million dollars [8]. This was made possible because a certain contract (the DAO contract, storing assets of users) was *reentrant*, that is, it allowed itself to be called back by the recipient of a transfer *before* recording that the transfer had been completed.

Reentrancy is a pattern based on mutual recursion, where one method f calls another method g whilst also transferring an amount of currency along with the call. If g then immediately calls f back, it may yield a recursion where f will keep transferring funds to g . We can illustrate the problem as in Figure 1, using a simple, imperative and class-based model language called TINY SOL [3]. This model language, which we shall formally describe in Section 2, captures some of the core features of the smart-contract language Solidity [10], which is the standard high-level language used to write smart contracts for the Ethereum platform. A key feature of this language is that contracts have an associated **balance**, representing the amount of currency stored in each contract, which cannot be modified *except* through method calls to other contracts. Each method call has an extra parameter, representing the amount of currency to be transferred along with the call, and a method call thus represents a (potential) outgoing currency flow.

In Figure 1, **X.transfer(z)** first does a sanity check to ensure that it has not already been called and that the contract contains sufficient funds, which are stored in the **balance** field. Then it calls **z.deposit(this)** and transfers 1 unit of currency along with the call, where **z** is the address received as parameter. However, suppose the address received is **Y**. Then **Y.deposit(x)** immediately calls **X.transfer(z)** back, with **this** as actual parameter; this yields a mutual recursion, because the field **called** will never be set to **T**. A transaction that invokes **X.transfer(Y)** with any number of currency units will trigger the recursion.

The problem is that currency cannot be transferred without also transferring control to the recipient, and the execution of **X.transfer(z)** comes to depend on unknown and untrusted code in the contract residing at the address received as the actual parameter. Simply switching the order of lines 6 and 7 in **X** solves the problem in this particular case, but it might not always be possible to move external calls to the last position in a sequence of statements. Furthermore, the execution of a function f can also depend on external fields, and not only on external calls. Thus, reentrancy is not just a purely syntactic property.

The property of reentrancy in Ethereum smart contracts has been formally characterised by Grishchenko et al. in [13]. Specifically, they define another property, named *call integrity*, which implies the absence of reentrancy (see [13, Theorem 1]) and has been identified in the literature as one of the safety properties that smart contracts should have. Informally, this property requires any call to a method in a “trusted” contract (say, X) to yield the exact same sequence of currency flows (i.e. method calls) even if some of the other “untrusted” contracts (or their stored values) are changed. In a sense, the code and values of the other contracts, which could be controlled by an attacker, must not be able to affect the currency flow from X .

A disadvantage of the definition of call integrity given in [13] is that it relies on a universal quantification over all possible execution contexts, which makes it hard to be checked in practice. However, call integrity seems intuitively to be related to noninterference, in the sense that both stipulate that changes in one part of a program should not have an effect upon another part. Even though we discover that the two properties are incomparable, one might hope to be able to apply techniques for ensuring noninterference to also capture call integrity. Specifically, Volpano et al. [28] show that noninterference can be soundly approximated using a type system. In the present paper, we shall therefore create an adaptation of this type system for secure-flow analysis to the setting of smart contracts and show that the resulting type system *also* captures call integrity.

To recap, our main contributions in this paper are: (1) a thorough study of the connections between call integrity and noninterference for smart contracts written in the language TINY SOL, and (2) a sound type system guaranteeing (noninterference and) call integrity for programs written in that language. We choose TINY SOL because it provides a minimal calculus for Solidity contracts and thus allows us to focus on the gist of our main contributions in a simple setting. In doing this, we also provide a simpler operational semantics for this language; this can be considered a third contribution of our work.

The paper is organised as follows: In Section 2, we describe a revised version of the smart-contract language TINY SOL [3]. In Section 3, we adapt the definition of call integrity from [13] and of noninterference from [25] to this language; we then show that these two desirable properties are actually incomparable. Nevertheless, there *is* an overlap between them. In Section 4, we create a type system for ensuring noninterference in TINY SOL, along the lines of Volpano et al. [28], and prove a type soundness result (Theorems 12–15). Our main result is Theorem 19, which shows that well-typedness provides a sound approximation to *both* noninterference *and* call integrity. This is used on a few examples in Section 5, where we also discuss the limitations of the type system. We survey some related work in Section 6 and conclude the paper with some directions for future research in Section 7. All proofs and some technical details are omitted from this paper for space reasons; they can be found in [1].

2 The TinySol language

In [3], Bartoletti et al. present the TINY SOL language, a standard imperative language (similar to Dijkstra’s `While` language [18]), extended with classes (contracts) and two constructs: (1) a `throw` command, representing a fatal error, and (2) a procedure call, with an extra parameter n , denoting an amount of some digital asset, which is transferred along with the call from the caller to the callee. TINY SOL captures (some of) the core features of Solidity, and, in particular, it is sufficient to represent reentrancy phenomena. In this section, we present a version of TINY SOL which has been adapted to facilitate our later developments of the type system. Compared to the presentation in [3], we have, in particular, added explicit declarations of variables (local to the scope of a method) and fields (corresponding to the *keys* in the original presentation) to have a place for type annotations in the syntax.

$$\begin{aligned}
DF \in \text{Dec}_F &::= \epsilon \mid \text{field } p := v; DF \\

v \in \text{Val} &::= \mathbb{N} \cup \mathbb{B} \cup \text{ANames}
\end{aligned}$$

where $x, y \in \text{VNames}$ (variable names), $p, q \in \text{FNames}$ (field names),
 $X, Y \in \text{ANames}$ (address names), $f, g \in \text{MNames}$ (method names)

■ **Figure 2** The syntax of TINY SOL.

2.1 Syntax

The syntax of TINY SOL is given in Figure 2, where we use the notation $\tilde{\cdot}$ to denote (possibly empty) sequences of items. The set of *values*, ranged over by v , is formed by the sets of integers \mathbb{N} , ranged over by n , booleans $\mathbb{B} = \{\text{T}, \text{F}\}$, ranged over by b , and address names ANames , ranged over by X, Y .

We introduce explicit declarations for fields DF , methods DM , and contracts DC . The latter also encompasses declarations of accounts: an *account* is a contract that contains only the declarations of a special field **balance** and of a single special method **send()**, which does nothing and is used only for transferring funds to the account. By contrast, a contract usually contains other declarations of fields and methods. For the sake of simplicity, we make no syntactic distinction between an account and a contract but, for the purpose of distinguishing, we can assume that the set ANames is split into contract addresses and account addresses.

We have four “magic” keywords in our syntax:

- **balance** (type **int**), a special field recording the current balance of the contract (or account). It can be read from, but not directly assigned to, except through method calls. This ensures that the total amount of currency “on-chain” remains constant during execution.
- **value** (type **int**), a special variable that is bound to the currency amount transferred with a method call.
- **sender** (type **address**), a special variable that is always bound to the address of the caller of a method.
- **this** (type **address**), a special variable that is always bound to the address of the contract containing the currently executing method.

The last three of these are local variables, and we collectively refer to them as “magic variables” $m \in \text{MVar}$. The declaration of variables and fields are very alike: the main difference is that variable bindings will be created at runtime (and with scoped visibility), hence we can let the initial assignment be an *expression* e ; whilst the initial assignment to fields must be *values* v .

The core part of the language is the declaration of expressions e and statements S , that are almost the same as in [3]. The main differences are: (1) we introduce fields p in expressions, instead of keys; (2) we explicitly distinguish between (global) fields and (local) variables, where the latter are declared with a scope limited to a statement S ; and (3) we introduce explicit *lvalues* L , to restrict what can appear on the left-hand side of an assignment (in particular, this ensures that the special field `balance` can never be assigned to directly).

As in the original presentation of TINY SOL, we can also use our new formulation of the language to describe transactions and blockchains. A *transaction* is simply a call, where the caller is an account A , rather than a contract. We denote this by writing $A \rightarrow X.f(\tilde{v}):n$, which expresses that the account A calls the method f on the contract (residing at address) X , with actual parameters \tilde{v} , and transferring n amount of currency with the call. We can then model blockchains as follows:

► **Definition 1** (Syntax of blockchains). *A blockchain $B \in \mathcal{B}$ is a list of initial contract declarations DC , followed by a sequence of transactions $T \in Tr$:*

$$B ::= DC \ T \quad T ::= \epsilon \mid A \rightarrow X.f(\tilde{v}):n, T$$

Notationally, a blockchain with an empty DC will be simply written as the sequence of transactions.

2.2 Big-step semantics

To define the semantics, we need some environments to record the bindings of variables (including the three magic variable names `this`, `sender` and `value`), fields, methods, and contracts. We define them as sets of partial functions as follows:

► **Definition 2** (Binding model). *We define the following sets of partial functions:*

$$\begin{array}{ll} \text{env}_V \in \text{Env}_V : \text{VNames} \cup \text{MVar} \rightarrow \text{Val} & \text{env}_S \in \text{Env}_S : \text{ANames} \rightarrow \text{Env}_F \\ \text{env}_F \in \text{Env}_F : \text{FNames} \cup \{\text{balance}\} \rightarrow \text{Val} & \text{env}_T \in \text{Env}_T : \text{ANames} \rightarrow \text{Env}_M \\ \text{env}_M \in \text{Env}_M : \text{MNames} \rightarrow \text{VNames}^* \times \text{Stm} & \end{array}$$

We regard each environment env_X , for any $X \in \{V, F, M, S, T\}$, as a list of pairs (d, c) where $d \in \text{dom}(\text{env}_X)$ and $c \in \text{codom}(\text{env}_X)$. The notation $\text{env}_X[d \mapsto c]$ denotes the update of env_X mapping d to c . We write env_X^\emptyset for the empty environment. To simplify the notation, when two or more environments appear together, we shall use the convention of writing the subscripts together (e.g. env_{MF} instead of $\text{env}_M, \text{env}_F$).

Our binding model consists of two environments: a *method table* env_T , which maps addresses to method environments, and a *state* env_S , which maps addresses to lists of fields and their values. Thus, for each contract, we have the list of methods it declares and its current state; of course, the method table is constant, once all declarations are performed, whereas the state will change during the evaluation of a program.

2.2.1 Declarations

The semantics of declarations builds the field and method environments, env_F and env_M , and the state and method table env_S and env_T . We give the semantics in a classic big-step style; thus, transitions are of the form $\langle DX, \text{env}_X \rangle \rightarrow_{DX} \text{env}'_X$ for $X \in \{F, M, C, S, T\}$, and their defining rules are given in Figure 3. Notationally, here and in what follows, we denote

$$\begin{array}{c}
[\text{DEC-F}_1] \frac{}{\langle \epsilon, \text{env}_F \rangle \rightarrow_{DF} \text{env}_F} \quad [\text{DEC-F}_2] \frac{\langle DF, \text{env}_F \rangle \rightarrow_{DF} \text{env}'_F}{\langle \text{field } p := v; DF, \text{env}_F \rangle \rightarrow_{DF} (p, v) : \text{env}'_F} \\
[\text{DEC-M}_1] \frac{}{\langle \epsilon, \text{env}_M \rangle \rightarrow_{DM} \text{env}_M} \quad [\text{DEC-M}_2] \frac{\langle DM, \text{env}_M \rangle \rightarrow_{DM} \text{env}'_M}{\langle f(\tilde{x}) \in S \models DM, \text{env}_M \rangle \rightarrow_{DM} (f, (\tilde{x}, S)) : \text{env}'_M} \\
[\text{DEC-C}_1] \frac{}{\langle \epsilon, \text{env}_{ST} \rangle \rightarrow_{DC} \text{env}_{ST}} \\
[\text{DEC-C}_2] \frac{\langle DF, \text{env}_F^\emptyset \rangle \rightarrow_{DF} \text{env}_F \quad \langle DM, \text{env}_M^\emptyset \rangle \rightarrow_{DM} \text{env}_M \quad \langle DC, \text{env}_{ST} \rangle \rightarrow_{DC} \text{env}'_{ST}}{\langle \text{contract } X \{ DF \ DM \} DC, \text{env}_{ST} \rangle \rightarrow_{DC} (X, \text{env}_F) : \text{env}'_S, (X, \text{env}_M) : \text{env}'_T}
\end{array}$$

■ **Figure 3** Semantics of declarations.

$$\begin{array}{c}
[\text{EXP-VAR}] \frac{k \in \text{dom}(\text{env}_V) \quad \text{env}_V(k) = v}{\text{env}_{SV} \vdash k \rightarrow_e v} \quad [\text{EXP-OP}] \frac{\text{env}_{SV} \vdash \tilde{e} \rightarrow_e \tilde{v} \quad \text{op}(\tilde{v}) \rightarrow_{\text{op}} v}{\text{env}_{SV} \vdash \text{op}(\tilde{e}) \rightarrow_e v} \\
[\text{EXP-VAL}] \frac{}{\text{env}_{SV} \vdash v \rightarrow_e v} \quad [\text{EXP-FIELD}] \frac{\text{env}_{SV} \vdash e \rightarrow_e X \quad q \in \text{dom}(\text{env}_S(X)) \quad \text{env}_S(X)(q) = v}{\text{env}_{SV} \vdash e.q \rightarrow_e v}
\end{array}$$

■ **Figure 4** Semantics of expressions.

with $e : l$ the list that results from prepending an element e to the list l . We assume that field and method names are distinct within each contract; therefore, the rules in Figure 3 define partial, finite functions.

2.2.2 Expressions

Figure 4 gives the semantics of expressions e . Expressions have no side effects, so they cannot contain method calls, but they can access both local variables and fields of any contract. Thus expression evaluations are of the form $\text{env}_{SV} \vdash e \rightarrow_e v$, i.e. they are relative to the state and variable environments. We use k to range over `this`, `sender`, `value` and variables x (i.e. $k \in \text{dom}(\text{env}_V)$), and q to range over `balance` and fields p (i.e. $q \in \text{dom}(\text{env}_F)$).

We do not give explicit rules for the boolean and integer operators subsumed under op , but simply assume that they can be evaluated to a unique value by some semantics $\text{op}(\tilde{v}) \rightarrow_{\text{op}} v$.¹ It follows that each expression evaluates to a unique value relative to some given state and variable environments. Note that we assume that no operation is defined for addresses X , so we disallow any form of pointer arithmetic.

2.2.3 Statements

The semantics of statements describes the actual execution steps of a program. In Figure 5 we give the semantics in big-step style, where a step describes the execution of a statement in its entirety. Statements can read from the method table and they can modify the state (i.e., the variable and field bindings). The result of executing a statement is a new state, so transitions must here be of the form $\text{env}_T \vdash \langle S, \text{env}_{SV} \rangle \rightarrow_S \text{env}'_{SV}$ (recall that env'_{SV} stands for $\text{env}'_S, \text{env}'_V$), since both the field values in env_S and the values of the local variables in env_V may have been modified by the execution of S .

¹ To simplify the definitions, we assume that all operations are total. If this was not the case, we would have needed some exception handling for partial operations (e.g., division by zero).

$$\begin{array}{c}

Figure 5 Big-step semantics of statements in TINY SOL.

Most of the rules are straightforward. The rule [BS-DECV] is used when we declare a new variable x , with scope limited to the statement S ; we implicitly assume alpha-conversion to handle shadowing of an existing name. In the premise, we evaluate the expression e to a value v , and then execute the statement S with a variable environment $(x, v) : \text{env}_V$, where we have added the pair (x, v) . During the execution of S , this variable environment may of course be updated (by applications of the rule [BS-AssV]), which may alter any value in the environment, including v . However, outside of the scope of the declaration, x is not visible and so the pair (x, v') is removed from the environment once S finishes. By contrast, any other change made to env'_V (as well as any change made to the global state env_S) is retained.

The [BS-CALL] rule is the most complicated, because we need to perform a number of actions. Some of them are obvious (e.g., evaluate the address and the parameters e_1 , \tilde{e} and e_2 , relatively to the current execution environment env_{SV} ; use the obtained address Y of the callee to retrieve the field environment env_F^Y for this contract and, through the method table, to extract the list of formal parameters \tilde{x} and the body of the method S ; and check that the number of actual parameters is the same as the number of formal parameters). Then, we also have to check that the `balance` of the caller is at least n , and, in that case,

$$\begin{array}{c}
 [\text{GENESIS}] \frac{\langle DC, \text{env}_{ST}^\emptyset \rangle \rightarrow_{DC} \text{env}_{ST}}{\langle DC, T, \text{env}_{ST}^\emptyset \rangle \rightarrow_B \langle T, \text{env}_{ST} \rangle} \qquad [\text{REVELATION}] \frac{}{\langle \epsilon, \text{env}_{ST} \rangle \rightarrow_B \text{env}_{ST}} \\
 \\
 [\text{TRANS}] \frac{\text{env}_T \vdash \langle X.f(\tilde{v}):n, \text{env}_S, (\text{this}, A) : \text{env}_V^\emptyset \rangle \rightarrow_S \text{env}'_S, \text{env}_V}{\langle A \rightarrow X.f(\tilde{v}):n, T, \text{env}_{ST} \rangle \rightarrow_B \langle T, \text{env}'_S, \text{env}_T \rangle}
 \end{array}$$

 **Figure 6** Semantics of blockchains.

update the state environment by subtracting n from the balance of X and adding n to the balance of Y , in their respective field environments; this yields a new state env'_S , where we write $\text{env}_F[\text{balance} == n]$ and $\text{env}'_F[\text{balance} += n]$ for these two operations. Finally, we create the new execution environment by creating new bindings for the special variables `this`, `sender` and `value`, and by binding the formal parameters \tilde{x} to the values of the actual parameters \tilde{v} in env'_V . Then we execute the statement S in this new environment. This yields the new state env'_S , and also an updated variable environment env'_V , since S may have modified the bindings in env'_V . However, these bindings are local to the method, and therefore we throw them away once the call finishes. So, the result of this transition is the updated state env'_S and the original variable environment of the caller env_V .

It should be noted that a *local* method call, i.e. a call to a method within the same (calling) contract, is merely a special case of the rule [BS-CALL]. Such a call would have the form `this.f(̄e):0`, since transferring any amount of currency will not alter the balance of the contract. Thus, we could introduce some syntactic sugar, omitting both the address and the value, and instead simply write $f(\tilde{e})$.

2.2.4 Transactions and blockchains

The semantics for blockchains is given as a transition system defined by the rules given in Figure 6. Here, the rule [GENESIS] describes the “genesis event” where contracts are declared, whilst [TRANS] describes a single transaction. This is thus a *small-step* semantics, invoking the big-step semantics for declarations and statements for its premises. We remark that the rules of the operational semantics for blockchains (as well as those for statements presented above) define a deterministic transition relation.

Note that, unlike in the original formulation of TINY SOL, we do not include a rule like [Tx2] in [3] for rolling back a transaction in case it is non-terminating or it aborts via a `throw` command. Such a rule would require a premise that cannot be checked effectively for a Turing-complete language like TINY SOL and therefore we omit it, since it is immaterial for the main contributions we give in this paper.² In practice, termination of Ethereum smart contracts is ensured via a “gas mechanism” and is assumed by techniques for the formal analysis of smart contracts. However, as observed in, for instance, [11], proof of termination for smart contracts is non-trivial even in the presence of a “gas mechanism.” In the aforementioned paper, the authors present the first mechanised proof of termination of contracts written in EVM bytecode using minimal assumptions on the gas cost of operations (see the study [29] for an empirical analysis of the effectiveness of the “gas mechanism” in estimating the computational cost of executing real-life transactions). We leave for future work the addition of a “gas mechanism” to TINY SOL and the adaption of the results we present in this paper to that setting.

² For instance, rule [Tx2] in [3] has an undecidable premise that checks whether the execution of the body of a contract does *not* yield a final state. It is debatable whether such rules should appear in an operational semantics.

3 Call integrity and noninterference in TinySol

Grishchenko et al. [13] formulate the property of *call integrity* for smart contracts written in the language EVM, which is the “low-level” bytecode of the Ethereum platform, and the target language to which e.g. Solidity compiles. They then prove [13, Theorem 1] that this property suffices for ruling out reentrancy phenomena, as those described in the example in Figure 1. We first formulate a similar property for TINY SOL; this requires a few preliminary definitions.

► **Definition 3** (Trace semantics). A trace of method invocations is given by

$$\pi ::= \epsilon \mid X \rightarrow Y . f(\tilde{v}) : n, \pi$$

where X is the address of the calling contract, Y is the address of the called contract, f is the method name, and \tilde{v} and n are the actual parameters.

We annotate the big-step semantics with a trace containing information on the invoked methods to yield labeled transitions of the form $\xrightarrow{\pi}_S$. To do this, we modify the rules in Table 5 as follows:

- in rules [BS-SKIP], [BS-LOOP_F], [BS-AssV] and [BS-AssF], every occurrence of \rightarrow_S becomes $\xrightarrow{\epsilon}_S$;
- in rules [BS-IF] and [BS-DECV], every occurrence of \rightarrow_S becomes $\xrightarrow{\pi}_S$;
- rules [BS-SEQ], [BS-LOOPT] and [BS-CALL] respectively become:

$$\frac{\begin{array}{c} \text{env}_T \vdash \langle S_1, \text{env}_{SV} \rangle \xrightarrow{\pi_1}_S \text{env}_{SV}'' \\ \text{env}_T \vdash \langle S_2, \text{env}_{SV}'' \rangle \xrightarrow{\pi_2}_S \text{env}'_{SV} \end{array}}{\text{env}_T \vdash \langle S_1 ; S_2, \text{env}_{SV} \rangle \xrightarrow{\pi_1, \pi_2}_S \text{env}'_{SV}} \quad \frac{\begin{array}{c} \text{env}_{SV} \vdash e \rightarrow_e T \\ \text{env}_T \vdash \langle S, \text{env}_{SV} \rangle \xrightarrow{\pi_1}_S \text{env}_{SV}'' \\ \text{env}_T \vdash \langle \text{while } e \text{ do } S, \text{env}_{SV}'' \rangle \xrightarrow{\pi_2}_S \text{env}'_{SV} \end{array}}{\text{env}_T \vdash \langle \text{while } e \text{ do } S, \text{env}_{SV} \rangle \xrightarrow{\pi_1, \pi_2}_S \text{env}'_{SV}}$$

$$\frac{\dots \quad \text{env}_T \vdash \langle S, \text{env}_{SV}'' \rangle \xrightarrow{\pi}_S \text{env}'_{SV}}{\text{env}_T \vdash \langle e_1 . f(\tilde{e}) : e_2, \text{env}_{SV} \rangle \xrightarrow{X \rightarrow Y . f(\tilde{v}) : n, \pi} \text{env}'_S, \text{env}_V}$$

The full definition is given in [1]. We extend this annotation to the semantics for blockchains and write $\xrightarrow{\pi}_B$ for this annotated relation.

► **Definition 4** (Projection). The projection of a trace to a specific contract X , written $\pi \downarrow_X$, is the trace of calls with X as the calling address. Formally:

$$\epsilon \downarrow_X = \epsilon \quad (Z \rightarrow Y . f(\tilde{v}) : n, \pi) \downarrow_X = \begin{cases} X \rightarrow Y . f(\tilde{v}) : n, (\pi \downarrow_X) & \text{if } Z = X \\ \pi \downarrow_X & \text{otherwise} \end{cases}$$

Notationally, given a (partial) function f , we write $f|_X$ for denoting the restriction of f to the subset X of its domain.

► **Definition 5** (Call integrity). Let \mathcal{A} denote the set of all contracts (addresses), $\mathcal{X} \subseteq \mathcal{A}$ denote a set of trusted contracts, $\mathcal{Y} \triangleq \mathcal{A} \setminus \mathcal{X}$ denote all other contracts, and $\text{env}_{ST}^{\mathcal{X}}$ have domain \mathcal{X} . A contract $C \in \mathcal{X}$ has call integrity for \mathcal{Y} if, for every transaction T and environments env_{ST}^1 and env_{ST}^2 such that $\text{env}_{ST}^1(X)|_{\mathcal{X}} = \text{env}_{ST}^2(X)|_{\mathcal{X}} = \text{env}_{ST}^{\mathcal{X}}$, it holds that

$$\langle T, \text{env}_{ST}^1 \rangle \xrightarrow{\pi_1}_B \text{env}_{ST}^{1'} \wedge \langle T, \text{env}_{ST}^2 \rangle \xrightarrow{\pi_2}_B \text{env}_{ST}^{2'} \implies \pi_1 \downarrow_C = \pi_2 \downarrow_C$$

The definition is quite complicated and contains a number of elements:

- C is the contract of interest.

- \mathcal{X} is a set of *trusted* contracts, which we assume are allowed to influence the behaviour of C . This set must obviously contain C , since C at least must be assumed to be trusted. Thus, a contract C can have call integrity for all contracts, if $\mathcal{X} = \{C\}$.
- Conversely, the set $\mathcal{Y} = \mathcal{A} \setminus \mathcal{X}$ is the set of addresses of all contracts that are *untrusted*.³
- env_{ST}^1 and env_{ST}^2 are any two pairs of method/field environments that coincide (both in the code and in the values) for all the trusted contracts.⁴ The point is that the contracts in \mathcal{X} are assumed to be known, and hence invariant, whereas any contract in \mathcal{Y} is assumed to be unknown and may be controlled by an attacker. Thus, we are actually quantifying over all possible contexts where the contracts in \mathcal{X} can be run.
- T is any transaction; it may be issued from any account and to any contract. Thus we also quantify over all possible transactions, since an attacker may request an arbitrary transaction, that is thus part of the execution context as well.

Then, the call integrity property intuitively requires that, if we run the trusted part of the code in any execution context, the behavior of C remains the same, i.e. C must make exactly the same method calls (and in exactly the same order). Thus, to *disprove* that C has call integrity, it suffices to find two environments and a transaction that will induce a difference in the call trace of C .

The idea in the property of call integrity is that the behaviour of C should not depend on any untrusted code (i.e. contracts in \mathcal{Y}), even if control is transferred to a contract in \mathcal{Y} . The latter could for example happen if C calls a method on $B \in \mathcal{X}$, and B then calls a method on a contract in \mathcal{Y} . This also means that C cannot directly call any contract in \mathcal{Y} , since that can only happen if C calls a method on a contract, where the address is received as a parameter, or if it calls a method on a “hard-coded” contract address. In both cases, we can easily pick up two environments able to induce different behaviors, for example by choosing a non-existing address for one context (in the first case), or by ensuring that no contract exists on the hard-coded address in one context (in the second case). The latter possibility can seem somewhat contrived, especially if we assume that all contracts are created at the genesis event, and it might therefore be reasonable to require also that $\text{dom}(\text{env}_{ST}^1) = \text{dom}(\text{env}_{ST}^2)$, such that we at least assume that contracts exist on the same addresses. However, on an actual blockchain, new contracts can be deployed (and in some cases also deleted) at any time, and if such a degree of realism is desired, this extra constraint should not be imposed.

The main problem with the definition of call integrity is that it relies on a universal quantification over all possible executions contexts. This makes it hard to be checked in practice. However, our previous discussion indicates that call integrity may intuitively be viewed as a form of *noninterference* between the trusted and the untrusted contracts. We now see to what extent this intuition is true and formally compare the two notions.

First of all, we consider a basic lattice of security levels, made up by just two levels, namely H (for *high*) and L (for *low*), with $L < H$. We tag every contract to be high or low through a contracts-to-levels mapping $\lambda : \mathcal{A} \rightarrow \{L, H\}$; this induces a bipartition of the contract names \mathcal{A} into the following sets:

$$\mathcal{L} = \{X \in \mathcal{A} \mid \lambda(X) = L\} \quad \mathcal{H} = \{X \in \mathcal{A} \mid \lambda(X) = H\}$$

³ Note that this is formulated inversely by Grishchenko et al., who instead formulate the property for a set of *untrusted* contracts \mathcal{A}_C , corresponding to \mathcal{Y} in the present formulation. However, using the set of *trusted* addresses \mathcal{X} seems more straightforward.

⁴ This too is inversely formulated by Grishchenko et al.

In this way, we create a bipartition of the state into low and high, corresponding to the fields of the low and of the high contracts, respectively. Then, we define *low-equivalence* $=_L$ to be the equivalence on states such that $\text{env}_S^1 =_L \text{env}_S^2$ if and only if $\text{env}_S^1(X) = \text{env}_S^2(X)$, for every $X \in \mathcal{L}$.

We can now adapt the notion of noninterference for multi-threaded programs by Smith and Volpano [25] to the setting of TINY SOL.

► **Definition 6** (Noninterference). *Given a contracts-to-levels mapping $\lambda : \mathcal{A} \rightarrow \{L, H\}$ and a contract environment env_T , the contracts satisfy noninterference if, for every env_S^1 and env_S^2 and for every transaction T such that*

$$\text{env}_S^1 =_L \text{env}_S^2 \quad \langle T, \text{env}_S^1, \text{env}_T \rangle \rightarrow_B \text{env}_S^{1'}, \text{env}_T \quad \langle T, \text{env}_S^2, \text{env}_T \rangle \rightarrow_B \text{env}_S^{2'}, \text{env}_T$$

it holds that $\text{env}_S^{1'} =_L \text{env}_S^{2'}$.

► **Remark 7** (Incomparability). Call integrity and noninterference seem strongly related, in the sense that the first requires that the behaviour of a contract is not influenced by the (bad) execution context, whereas the second one requires that a part of the computation (the “low” one) is not influenced by the remainder context (the “high” one). So, one may try to prove a statement like: “ $C \in \mathcal{X}$ has call integrity for $\mathcal{Y} \triangleq \mathcal{A} \setminus \mathcal{X}$ if and only if it satisfies noninterference w.r.t. λ such that $\mathcal{L} = \mathcal{X}$ and $\mathcal{H} = \mathcal{Y}$.” However, both directions are false.

For the direction from right to left, consider:

```

1 contract X {
2   field balance = 0
3   go() { }
4 }
```

```

contract Y {
  field balance = v
  go() { X.go():this.balance }
```

where **X** is trusted and **Y** untrusted. Since **X** cannot invoke any method, this example satisfies call integrity. However, it does not satisfy noninterference. To see this, consider two environments, one assigning 1 to **Y**’s balance and the other one assigning 0, and the transaction **Y->Y.go():0**.

For the direction from left to right, consider the following:

```

1 contract X {
2   go() {
3     if Y.balance = 0
4       then Z.a():0
5       else Z.b():0
6   }
7 }
```

```

contract Y {
  field balance = v;
}
contract Z {
  a() { }
  b() { }
}
```

Assuming that both **X** and **Z** are low, the example satisfies noninterference: there is no way for **Y** to influence the low memory. By contrast, the code does not satisfy call integrity. Indeed, let **v** be 0 in one environment and 1 in the other, and consider **T** to be **X->X.go():0**: in the first environment, it generates **X->Z.a():0**, whereas in the second one it generates **X->Z.b():0**.

4 A type system for noninterference and call integrity

As demonstrated in Remark 7, call integrity and noninterference are incomparable properties. This is so because noninterference is a 2-property on the pair of *stores* $(\text{env}_S^{1'}, \text{env}_S^{2'})$ resulting from two different executions, whereas call integrity is a 2-property on the pair of *call traces*

(π_1, π_2) generated during two executions. However, the two properties have an interesting overlap, because an outgoing currency flow (i.e. a method call) may also result, at least potentially, in a change of the stored values of the `balance` fields of the sender and recipient. Every method call is therefore *also* an information flow between the two, even when no amount of currency is transferred. In [28], Volpano et al. devise a type system for checking information flows, which, as they show, yields a sound approximation to noninterference. In the following, we create an adaptation of this type system to TINY SOL and show that it may *also* be used to soundly approximate call integrity.

4.1 Type syntax

We begin by assuming a finite lattice $(\mathcal{S}, \sqsubseteq)$ consisting of a set of *security levels* \mathcal{S} , ranged over by s , and equipped with a partial order \sqsubseteq . We write s_{\perp} , and s_{\top} for the least and largest elements in \mathcal{S} .

In the simplest setting, we can let $\mathcal{S} \stackrel{\Delta}{=} \{L, H\}$ (for “low” and “high”) and define $L \sqsubseteq L$, $L \sqsubseteq H$, and $H \sqsubseteq H$. This is sufficient for ensuring bi-partite noninterference, but the type system can also handle more fine-grained security control. With this, we can define the types:

► **Definition 8.** *We use the following language of types, where $I \in \text{TNames}$ is a type name (or “interface name”):*

$$\begin{array}{ll} B \in \mathcal{B} ::= s \mid I_s & T \in \mathcal{T} ::= B \mid \text{var}(B) \mid \text{cmd}(s) \mid \text{proc}(B) : s \\ \Gamma \in \mathcal{G} ::= \mathcal{N} \multimap \mathcal{T} \cup \mathcal{G} & \mathcal{N} ::= \text{ANames} \cup \text{FNames} \cup \text{VNames} \cup \text{MNames} \cup \text{TNames} \end{array}$$

We write \tilde{T} for a tuple of types (T_1, \dots, T_n) .

Note that for the purpose of the type system, unless otherwise noted, we shall assume that the four “magic names” `MVar` are contained in the respective sets of field and variable names; i.e. `balance` \in `FNames` and `this`, `sender`, `value` \in `VNames`.

The meaning of the types is as follows:

- \mathcal{B} is a set of *base types*, which can either be a security level s , or an interface name I , annotated with a security level, I_s . Security levels are assigned to plain data, i.e. *values* of type `int` or `bool`, as well as *expressions* yielding values of these types. The annotated interface type is assigned to *addresses*, as well as expressions yielding addresses. In either case, the meaning of the type s (resp. I_s), when given to an expression e , is that all variables *read from* within e , are of level s or lower.

Note that for the purpose of the present type system, we do not distinguish between values of type `int` and `bool`, in the sense that we do not check whether these type constraints are preserved. Instead, we shall just assume that all programs are well-typed w.r.t. these simple type constraints, such that e.g. expressions in the guards of `if` and `while` constructs indeed yield boolean values. The present type system can easily be extended to incorporate such a simple type check by extending the set of base types with annotated value types `ints` and `bools`, similar to the annotated interface types.

- $\text{var}(B)$ is a box type given to value *containers*, i.e. variables and fields. It denotes that the container can store data of type B . In the case of $\text{var}(s)$, it denotes that the box can store data of level s or lower, whereas in the case of $\text{var}(I_s)$ it additionally denotes that the address stored in the variable must be of type I .
- $\text{cmd}(s)$ is a *phrase type* given to *code*, i.e. commands S . It denotes that all *assignments* in the code are made to variables whose security level is s or higher.

- $\text{proc}(\tilde{B}):s$ is a procedure type given to methods $f(\tilde{x}) \{ S \}$. It denotes that the body S can be typed as $\text{cmd}(s)$, under the assumption that the formal parameters \tilde{x} have types $\text{var}(\tilde{B})$. We shall discuss the types assigned to the “magic variables” `this`, `sender` and `value` below.

Note that every method declaration contains an implicit write to the `balance` field of the containing contract: hence, given the meaning of $\text{cmd}(s)$, this also means that the security level of `balance` must always be s or higher than the level of any method declared in an interface.

Finally, Γ is a type environment, which is a partial function from names to types *or type environments*. The latter possibility is included because we shall represent each contract declaration as its own type environment, containing box types and procedure types for the fields and methods of the contract, and pointed to by the corresponding interface name. Thus, if a contract has address X , then $\Gamma(X) = I_s$ for some interface name I and security level s , and $\Gamma(I) = \Gamma_I$, where Γ_I is a type environment containing the signatures of the methods and fields of the contract. We shall use the following simple interface declaration language for the interfaces of contracts:

```
 $IC ::= \epsilon \mid \text{interface } I \{ IF \; IM \} \; IC$ 
 $IF ::= \epsilon \mid \text{field } p : \text{var}(B); \; IF$ 
 $IM ::= \epsilon \mid \text{method } f : \text{proc}(B):s; \; IM$ 
```

mirroring the syntax of contract declarations.

We require that all interface declarations be *well-formed* in the sense that they must at least contain a declaration for the mandatory members, i.e. the `balance` field and the `send()` method. This ensures that we can define a minimal interface declaration called I^\top , such that every well-formed interface declaration is a specialisation of I^\top . This minimal interface contains just the signatures of the mandatory `balance` field and of the `send()` method; i.e.

```
 $1 \; \text{interface } I^\top \{$ 
 $2 \; \; \text{field } \text{balance} : \text{var}(s_\top);$ 
 $3 \; \; \text{method } \text{send} : \text{proc}():s_\perp;$ 
 $4 \; \}$ 
```

in the aforementioned interface declaration syntax.

Intuitively, this definition ensures that, for any valid interface definition I (containing at least `balance` and `send`) and any security level annotation s , it must hold that I_s is a subtype of $I_{s_\top}^\top$, thus always allowing us to type I_s up to $I_{s_\top}^\top$. In the following section, we shall give a definition of a subtyping relation that will ensure that this indeed is the case.

The inclusion of a contract “supertype” $I_{s_\top}^\top$ is similar to what is done in the type system developed for Featherweight Solidity by Crafa et al. in [7]. This is necessary to enable us to give a type to the “magic variable” `sender`, which is available within the body of every method, since this variable can be bound to the address of any contract or account. We shall assume that $I^\top \in \text{dom}(\Gamma)$ for any Γ we shall consider.

We shall also use a *typed* syntax of TINY SOL, where local variables are now declared as

$\text{var}(B) \; x := e$

where B is the type of the value of the expression e . Likewise, we add annotated type names I_s to contract declarations thus:

$\text{contract } X : I_s \{ DF; DM \}$

where I is a declared type name. Note that the security level is given on the *contract*, rather than on the interface. This is intentional, since multiple contracts may implement the

$$\begin{array}{c}
[\text{SUBS-NAME}] \frac{\Gamma \vdash \Gamma(I^1) <: \Gamma(I^2)}{\Gamma \vdash I_{s^1}^1 <: I_{s^2}^2} (s_1 \sqsubseteq s_2) \quad [\text{SUBS-ENV}] \frac{\forall n \in \text{dom}(\Gamma_2). \Gamma_1(n) <: \Gamma_2(n)}{\Gamma \vdash \Gamma_1 <: \Gamma_2} (\text{dom}(\Gamma_2) \subseteq \text{dom}(\Gamma_1)) \\
[\text{SUBS-SEC}] \frac{}{\Gamma \vdash s_1 <: s_2} (s_1 \sqsubseteq s_2) \quad [\text{SUBS-CMD}] \frac{}{\Gamma \vdash cmd(s_1) <: cmd(s_2)} (s_2 \sqsubseteq s_1) \\
[\text{SUBS-VAR}] \frac{\Gamma \vdash B_1 <: B_2}{\Gamma \vdash var(B_1) <: var(B_2)} \quad [\text{SUBS-PROC}] \frac{\Gamma \vdash \tilde{B}_1 <: \tilde{B}_2}{\Gamma \vdash proc(\tilde{B}_1):s_1 <: proc(\tilde{B}_2):s_2} (s_2 \sqsubseteq s_1)
\end{array}$$

Figure 7 Subtyping rules.

same interface but nevertheless be categorised into different security levels. For the sake of simplicity, we shall omit the explicit definition of interfaces in the code and merely assume that an interface declaration Γ_I with an associated name I is provided for each contract.

4.2 Subtyping

We shall introduce a parametrised subtyping relation $\Gamma \vdash \cdot <: \cdot$ on types. For each choice of Γ , we define it as the least preorder satisfying the rules given in Figure 7. The parameter Γ is needed to handle subtyping for interface names I in rule [SUBS-NAME]. Note that by this rule we have, for each well-formed interface I_s (with security level s and interface name I) declared in Γ , that $\Gamma \vdash I_s <: I_{s^\top}^\top$ as expected. Also note that we write $\Gamma \vdash \tilde{B}_1 <: \tilde{B}_2$ to mean $\Gamma \vdash B_1^i <: B_2^i$ for each i ($1 \leq i \leq n$, where $|\tilde{B}_1| = n = |\tilde{B}_2|$).

By rule [SUBS-SEC], subtyping is covariant in the types of *data*, i.e. the security level s , and likewise, the box type constructor $var(B)$ is covariant by rule [SUBS-VAR]. On the other hand, the type constructor for commands, $cmd(s)$, is *contravariant* by rule [SUBS-CMD]. Lastly, the type constructor for methods, $proc(\tilde{B}):s$, is covariant in the input parameters \tilde{B} by rule [SUBS-PROC], but contravariant in the “return” type s , which indicates the level of the underlying command type. These variances are consistent with the intended meaning of the types:

- A box of type $var(B)$ can store something of B or lower (where B is either s or I_s). Hence, if $\Gamma \vdash B_1 <: B_2$, then a box type $var(B_2)$ can safely be used wherever a box type $var(B_1)$ is needed.
- A command of type $cmd(s)$ will assign to variables whose level is s or higher. Hence, if $s_1 \sqsubseteq s_2$, then a command type $cmd(s_1)$ can safely be used wherever a command type $cmd(s_2)$ is needed.
- A method of type $proc(\tilde{B}):s$ expects parameters of types \tilde{B} and promises that the method body will only assign to variables that are level s or higher. Hence, if $\Gamma \vdash \tilde{B}_1 <: \tilde{B}_2$ and $s_2 \sqsubseteq s_1$, a command type $proc(\tilde{B}_2):s_2$ can safely be used wherever a command type $proc(\tilde{B}_1):s_1$ is needed. This is consistent with the type for the body S since, if S can be typed to level $cmd(s_1)$, then it can also safely be typed to level $cmd(s_2)$.

4.3 Type judgments

We can now give the rules for concluding type judgments, starting with the type rules for declarations given in Figure 8.

Type judgments for contract declarations are of the form $\Gamma \vdash DC$, stating that the declarations DC are *well-typed* w.r.t. the environment Γ . This holds if the declarations are consistent with the type information recorded in Γ , i.e. every field and method must have a

$$\begin{array}{c}
 [T\text{-DEC-C}] \frac{\Gamma(X) = I_s \quad \Gamma_1 = \Gamma, \mathbf{this} : var(I_s) \quad \Gamma \vdash DC \quad \Gamma_1 \vdash DF \quad \Gamma_1 \vdash DM}{\Gamma \vdash \mathbf{contract} \ X : I_s \not\models DF \ DM \models DC} \\
 [T\text{-DEC-F}] \frac{\Gamma(\mathbf{this}) = var(I_s) \quad p \in \text{dom } (\Gamma(I)) \quad \Gamma \vdash DF}{\Gamma \vdash \mathbf{field} \ p := v; \ DF} \\

■ **Figure 9** Type rules for environment agreement.

type, and the body of each method must be typable according to the assumptions of the type. Note that the check here only ensures that every declared contract member has a type; the converse check (i.e. that every declared type in an interface also has an implementation) should also be performed. However, we shall omit this in the present treatment.

After the initial reduction step, all declarations are stored in the two environments \mathbf{env}_{ST} , and further reductions also use the variable environment \mathbf{env}_V for local variable declarations. Hence, we also need to be able to conclude *agreement* between these environments and Γ . These rules are given in Figure 9, closely mirroring those of Figure 8. We omit the type rules for empty environments (since an empty environment is always well-typed). As with declarations above, we also omit the rules for ensuring that all declared types in an interface also have an implementation in any contract claiming to implement that interface.

Next, we consider the type rules for statements appearing in the body of method declarations; they are given in Figure 10. Here, judgments are of the form $\Gamma \vdash S : cmd(s)$, indicating that s is the *lowest* level of any variable written to within S . This is derived from the types of the variables occurring in S , i.e. the types $var(B)$. However, as B can be either s or I_s , we need a way to extract just the security level and drop the interface name. For this, we write $B \rightsquigarrow s$, defined in the obvious way:

$$s \rightsquigarrow s \qquad I_s \rightsquigarrow s$$

\end{array}$$

Figure 11 Type rules for expressions.

This is used in the rules for assignments (rules [T-ASS-V] and [T-ASS-F]). Note that in the rules [T-IF] and [T-LOOP], we know (by our assumption that all contracts are well-typed w.r.t. simple type preservation) that e will evaluate to a boolean value, which therefore necessarily will have a type s . Thus, we do not need the extra step of $B \rightsquigarrow s$ here.

All rules are straightforward, except for [T-CALL]. According to the semantics for call (cf. rule [BS-CALL]), every call includes an implicit read and write of the `balance` field of the calling contract, since the call will only be performed if the value of e_2 is less than, or equal to, the value of `balance` (to ensure that the subtraction will not yield a negative number). There is thus an implicit flow from `this.balance` to the body S of the method call, similar to the case for the guard expression e in an if-statement. Furthermore, there is an implicit write to the `balance` field of the callee, and thus a flow of information from one field to the other. This might initially seem like it would require both caller and callee to have the same security level for their `balance` field. However, the levels *can* differ, since by subtyping we can coerce one up to match the level of the other. For this reason, we have $\Gamma \vdash \text{this.balance}$ in the premise, to be explicitly *concluded*, rather than as a simple lookup. This enables calls from a lower security level into a higher security level, but not the other way around.

Next, we consider the type rules for expressions e , given in Figure 11. Here, judgments are of the form $\Gamma \vdash e : B$. There are a few things to note:

- In rule [T-VAL], the type of a value v can be chosen freely, if v is a value type, i.e. of type `int` or `bool`. This rule is a consequence of the fact that there is no simple relationship between the datatype of a value and its security level. The actual security level will then be determined by the type of the variable (resp. field) to which it is assigned.

$$\begin{array}{c}
 [\text{T-BOX-X}] \frac{}{\Gamma \vdash x : \text{var}(B)} (\Gamma(x) = \text{var}(B)) \quad [\text{T-BOX-F}] \frac{\Gamma \vdash e : I_s}{\Gamma \vdash e.p : \text{var}(B)} \left(\begin{array}{l} \Gamma(I)(p) = \text{var}(B) \\ B \rightsquigarrow s \end{array} \right) \\
 [\text{T-M-SUB}] \frac{\begin{array}{c} \Gamma \vdash e.f : \text{proc}(\tilde{B}_1) : s_1 \\ \Gamma \vdash \text{proc}(\tilde{B}_1) : s_1 <: \text{proc}(\tilde{B}_2) : s_2 \end{array}}{\Gamma \vdash e.f : \text{proc}(\tilde{B}_2) : s_2} \quad [\text{T-METH}] \frac{\Gamma \vdash e : I_s}{\Gamma \vdash e.f : \text{proc}(\tilde{B}) : s} \left(\Gamma(I)(f) = \text{proc}(\tilde{B}) : s \right)
 \end{array}$$

■ **Figure 12** Type rules for method, variable and field lookup.

- The rules [T-VAR] and [T-FIELD] simply unwrap the type of the contained value from the box type of the container. Note that here we assume that x also covers the “magic variable” names `this`, `sender` and `value`, and that p also covers the field name `balance`.
- Finally, in rule [T-OP], we require that all arguments and the return value must be typable to the same security level s . Note in particular that we assume that *no* operation is defined with an address *return* type; i.e. we do not allow any form of pointer arithmetic. Operations may be defined on addresses for their *arguments*, e.g. equality testing, but the return type must be one of the other value types, which can be given a security level. Thus, in the rule [T-OP], we also need to extract the security level s from the types of the argument expressions.

Finally, we have the look-up rules for methods, variables and fields, given in Figure 12.

- In rule [T-BOX-X] we assume that x also covers the magic variable names `this`, `sender` and `value`.
- In rule [T-BOX-F] we assume that p also covers the special field name `balance`. Furthermore, we require e in $e.p$ to resolve to an *interface name* rather than variable; i.e. the expression must yield an address. This is again warranted by our assumption that expressions are well-typed w.r.t. simple type preservation.
- The same is the case in rule [T-METH] for method lookup $e.f$, which is used in the premise of the rule [T-CALL].

In the lookup rules, the expression e is an *object path*, which must resolve to an address. As we disallow operations op to return addresses, the object paths form a proper subset of the set of expressions, since they can only consist of variable lookups, field reads or addresses given as pure values. Note that, in the rules [T-BOX-F] and [T-METH], we require that the object path e must be typable as an interface with the *same* security level s as the value (resp. method) that is being looked up. This is necessary to ensure that values residing in a higher-level part of the memory cannot affect values at lower levels, in this case by altering the *path* to the object being resolved.

4.4 Safety and soundness

As is the case for the type system proposed in [28], our type system does not have a now-safety predicate in the usual sense, since (invariant) safety in simple type systems is a 1-property, whereas noninterference is a hyper-property (specifically, a 2-property). Instead, the meaning of “safety” is expressed directly in the meaning of the types. Specifically:

- If an expression e has type B such that $B \rightsquigarrow s$, then it denotes that all variables *read from* in the evaluation of e are of level s or *lower*, i.e. no read-up.
- If a statement S has type $\text{cmd}(s)$, then it denotes that all variables *written to* in the execution of S are of level s or *higher*, i.e. no write-down.

$$\begin{aligned}

 & [\text{EQ-ENV}_{SV}] \frac{\Gamma \vdash \mathsf{env}_S^1 =_s \mathsf{env}_S^2 \quad \Gamma \vdash \mathsf{env}_V^1 =_s \mathsf{env}_V^2}{\Gamma \vdash \mathsf{env}_{SV}^1 =_s \mathsf{env}_{SV}^2} \\
 & [\text{EQ-ENV}_{ST}] \frac{\Gamma \vdash \mathsf{env}_S^1 =_s \mathsf{env}_S^2 \quad \Gamma \vdash \mathsf{env}_T^1 =_s \mathsf{env}_T^2}{\Gamma \vdash \mathsf{env}_{ST}^1 =_s \mathsf{env}_{ST}^2}
 \end{aligned}$$

 **Figure 13** Rules for the s -parameterised equivalence relation.

Intuitively, the meaning of these two types together imply that information from higher-level variables cannot flow into lower-level variables. For a statement such as $x := e$ to be well-typed, it must therefore be the case that, if $\Gamma \vdash x : \mathit{var}(s_1)$ and $\Gamma \vdash e : s_2$, then $s_2 \sqsubseteq s_1$. Since s_2 can be coerced up to s_1 through subtyping to match the level of the variable, the statement itself can then be typed as $\mathit{cmd}(s_1)$. We shall prove that our type system indeed ensures these properties in Theorems 12-14 below.

Before proceeding, we need to define a way to express that two *states*, i.e. two collections of variable and field environments env_{SV} , are *equal* up to a certain security level s . This relation, written $\Gamma \vdash \mathsf{env}_{SV}^1 =_s \mathsf{env}_{SV}^2$, is given by the rules in Figure 13. Note in particular that the definition implies that env_{SV}^1 and env_{SV}^2 must have the same domain, and this carries over to the inner environments env_F inside env_S . The above definition gives us the following obvious result, which can be shown by induction on the rules of $=_s$:

► **Lemma 9 (Restriction).** *If $\Gamma \vdash \mathsf{env}_{SV}^1 =_s \mathsf{env}_{SV}^2$ and $s' \sqsubseteq s$, then $\Gamma \vdash \mathsf{env}_{SV}^{1'} =_{s'} \mathsf{env}_{SV}^{2'}$.*

Given our annotation of security levels on interfaces as well, we also extend the $=_s$ relation to method tables env_T , and finally to the combined representation of state and code, i.e. env_{ST} .

Next, we need the standard lemmas for strengthening and weakening of the variable environment:

► **Lemma 10 (Strengthening).** *If $\Gamma, x : \mathit{var}(B) \vdash (x, v_1) : \mathsf{env}_V^1 =_s (x, v_2) : \mathsf{env}_V^2$ then also $\Gamma \vdash \mathsf{env}_V^1 =_s \mathsf{env}_V^2$.*

► **Lemma 11 (Weakening).** *If $\Gamma \vdash \mathsf{env}_V^1 =_s \mathsf{env}_V^2$ and $x \notin \mathit{dom}(\mathsf{env}_V^1)$ and $x \notin \mathit{dom}(\mathsf{env}_V^2)$, then also $\Gamma, x : \mathit{var}(B) \vdash (x, v_1) : \mathsf{env}_V^1 =_s (x, v_2) : \mathsf{env}_V^2$ for any B, v, x .*

Both results can be shown by induction on the rules of $=_s$. Furthermore, both of the lemmas can then be directly extended to $\Gamma \vdash \mathsf{env}_{SV}^1 =_s \mathsf{env}_{SV}^2$. With this, we can now state the first of our main theorems:

► **Theorem 12** (Preservation). Assume that $\Gamma \vdash S : cmd(s)$, $\Gamma \vdash env_T$, $\Gamma \vdash env_{SV}$, and $env_T \vdash \langle S, env_{SV} \rangle \rightarrow env'_{SV}$. Then, $\Gamma \vdash env_{SV} =_{s'} env'_{SV}$ for any s' such that $s \not\sqsubseteq s'$.

The Preservation theorem assures us that the promise made by the type $cmd(s)$ is actually fulfilled. If $\Gamma \vdash S : cmd(s)$, then every variable or field written to in S will be of level s or higher; hence every variable or field of a level that is strictly lower than, or incomparable to, s will be unaffected. Thus, the pre- and post-transition states will be equal on all values stored in variables or fields of level s' or lower, since they cannot have been changed during the execution of S . In other words, what is shown to be “preserved” in this theorem is the values at levels lower than, or incomparable to, s .

Note that the theorem does not show preservation of *well-typedness* for the environments (as is otherwise usually required in preservation proofs for type systems). Indeed, a result saying that also $\Gamma \vdash env'_{SV}$ would be pointless. As can be seen in Figure 9, the type judgment $\Gamma \vdash env_{SV}$ only ensures that every field and variable in env_{SV} has *any* type in Γ . The number of declared fields and variables cannot change between the pre- and post-states of a transition (this is ensured by the rule [BS-DECV]); only the stored values can change, but there is no inherent relationship between a value and its assigned security level.

Our next theorem assures us that the type of an expression is also in accordance with the intended meaning, namely: if $\Gamma \vdash e : s$, then every variable (or field) read from in e will be of level s or lower (i.e. no read-down of values from a higher level). We express this by considering two different states, env_{SV}^1 and env_{SV}^2 , which must agree on all values of level s and lower. Evaluating e w.r.t. either of these states should then yield the same result.

► **Theorem 13** (Safety for expressions). Assume that $\Gamma \vdash e : B$ where $B \rightsquigarrow s$, $\Gamma \vdash env_{SV}^1$, $\Gamma \vdash env_{SV}^2$, and $\Gamma \vdash env_{SV}^1 =_s env_{SV}^2$. Then, $env_{SV}^1 \vdash e \rightarrow v$ and $env_{SV}^2 \vdash e \rightarrow v$.

Finally, we can use the preceding two theorems to show soundness for the type system. The soundness theorem expresses that, if a statement S is well-typed to any level s_1 and we execute S with any two states env_{SV}^1 and env_{SV}^2 that agree up to any level s_2 , then the resulting states $env_{SV}^{1'}$ and $env_{SV}^{2'}$ will still agree on all values up to level s_2 . This ensures noninterference, since any difference in values of a higher level than s_2 cannot induce a difference in the computation of values at any lower levels.

► **Theorem 14** (Soundness). Assume that $\Gamma \vdash S : cmd(s_1)$, $\Gamma \vdash env_T$, $\Gamma \vdash env_{SV}^1$, $\Gamma \vdash env_{SV}^2$, $\Gamma \vdash env_{SV}^1 =_{s_2} env_{SV}^2$, $env_T \vdash \langle S, env_{SV}^1 \rangle \rightarrow env_{SV}^{1'}$, and $env_T \vdash \langle S, env_{SV}^2 \rangle \rightarrow env_{SV}^{2'}$. Then, $\Gamma \vdash env_{SV}^{1'} =_{s_2} env_{SV}^{2'}$.

Theorem 14 corresponds to the soundness theorem proved by Volpano, Smith and Irvine [28] for their While-like language. However, given the object-oriented nature of TINY SOL, we can actually take this one step further and allow even parts of the code to vary. Specifically, given two “method table” environments, env_T^1 and env_T^2 , we just require that these two environments agree up to the same level s_2 to ensure agreement of the resulting two states $env_{SV}^{1'}$ and $env_{SV}^{2'}$. We state this in the following theorem:

► **Theorem 15** (Extended soundness). Assume that $\Gamma \vdash S : cmd(s_1)$, $\Gamma \vdash env_T^1$, $\Gamma \vdash env_T^2$, $\Gamma \vdash env_T^1 =_{s_2} env_T^2$, $\Gamma \vdash env_{SV}^1$, $\Gamma \vdash env_{SV}^2$, $\Gamma \vdash env_{SV}^1 =_{s_2} env_{SV}^2$, $env_T^1 \vdash \langle S, env_{SV}^1 \rangle \rightarrow env_{SV}^{1'}$, and $env_T^2 \vdash \langle S, env_{SV}^2 \rangle \rightarrow env_{SV}^{2'}$. Then, $\Gamma \vdash env_{SV}^{1'} =_{s_2} env_{SV}^{2'}$.

4.5 Extending the type system to transactions

A transaction is nothing but a method call with real-valued parameters and `sender` set to an *account* address, which corresponds to a minimal implementation of I^\top . Thus, the theorems from the preceding section can easily be extended to transactions and blockchains.

A blockchain consists of a set of contract declarations DC , followed by a list of transactions \tilde{T} . Hence, we can conclude $\Gamma \vdash DC \tilde{T} : cmd(s)$, if it holds that $\Gamma \vdash DC$ and $\Gamma \vdash \tilde{T} : cmd(s)$. The latter can be simply concluded by the following rules:

$$\begin{array}{c} [\text{T-EMPTY}] \frac{}{\Gamma \vdash \epsilon : cmd(s)} \\ [\text{T-TRANS}] \frac{\Gamma \vdash X.f(\tilde{v}) : n : cmd(s) \quad \Gamma \vdash \tilde{T} : cmd(s)}{\Gamma \vdash A \rightarrow X.f(\tilde{v}) : n, \tilde{T} : cmd(s)} \end{array}$$

This gives us the following two results:

► **Lemma 16.** *If $\Gamma \vdash DC$ and $\langle DC, \text{env}_{ST}^\emptyset \rangle \rightarrow \text{env}_{ST}$, then $\Gamma \vdash \text{env}_{ST}$.*

► **Lemma 17.** *If $\Gamma \vdash A \rightarrow X.f(\tilde{v}) : n, \tilde{T} : cmd(s)$ and $\Gamma \vdash \text{env}_{ST}$ and*

$$\langle A \rightarrow X.f(\tilde{v}) : n, \tilde{T}, \text{env}_{ST} \rangle \rightarrow \langle \tilde{T}, \text{env}_S, \text{env}_T \rangle$$

then also $\Gamma \vdash \text{env}_S, \text{env}_T$ and $\Gamma \vdash \tilde{T}$.

As the initial step (the “genesis event”) does nothing except transforming the declaration DC into the environment representation env_{ST} , the first result is obvious, and as the rule [TRANS] just unwraps a transaction step into a call to the corresponding method, the second result follows directly from the Preservation theorem. This can then be generalised in an obvious way to the whole transaction list. Likewise, the Safety and Soundness theorems can be extended to transactions in the same manner.

4.6 Noninterference and call integrity

As immediately evident from Definition 6 and Theorem 14, well-typedness ensures noninterference:

► **Corollary 18 (Noninterference).** *Assume a set of security levels $\mathcal{S} \stackrel{\Delta}{=} \{L, H\}$, with $L \sqsubseteq L$, $L \sqsubseteq H$ and $H \sqsubseteq H$, and furthermore that $\Gamma \vdash \tilde{T} : cmd(s)$, $\Gamma \vdash \text{env}_{ST}^1$, $\Gamma \vdash \text{env}_{ST}^2$, $\Gamma \vdash \text{env}_{ST}^1 =_L \text{env}_{ST}^2$, $\langle \tilde{T}, \text{env}_{ST}^1 \rangle \rightarrow^* \text{env}_{ST}^{1'}$, and $\langle \tilde{T}, \text{env}_{ST}^2 \rangle \rightarrow^* \text{env}_{ST}^{2'}$. Then, $\Gamma \vdash \text{env}_{ST}^{1'} =_L \text{env}_{ST}^{2'}$,*

From Corollary 18, we then obviously also have that $\Gamma \vdash \text{env}_S^{1'} =_L \text{env}_S^{2'}$, regardless of whether s is L or H . In particular, we can assign security levels to entire contracts, as well as all their members. Thus, our type system can be used to ensure noninterference according to Definition 6.

As we previously argued in Remark 7, noninterference and call integrity are incomparable properties. However, as our next theorem shows, *well-typedness* actually *also* ensures call integrity. This is surprising, so before stating the theorem, we should give some hints as to why this is the case.

The definition of call integrity (Definition 5) requires the execution of any code in a contract C to be unaffected by all contracts in an “untrusted set” \mathcal{Y} , regardless of whether parts of the code in \mathcal{Y} execute before, meanwhile or after the code in C . This is expressed by a quantification over all possible traces resulting from a change in \mathcal{Y} , i.e. either in the code or in the values of the fields. Regardless of any such change, it must hold that the sequence of method calls originating from C be the same.

Noninterference, on the other hand, says nothing about execution traces, but only speaks of the correspondence between values residing in the memory before and after the execution step. The two counter-examples used in Remark 7 made use of this fact:

- The first counter-example had C be unable to perform any method calls at all, thus obviously satisfying call integrity, but allowed different `balance` values to be transferred into it from a “high” context by means of a method call, thereby violating noninterference. However, this situation is ruled out by well-typedness, because well-typedness disallows *any* method calls from a “high” to a “low” context, precisely because every method call may transfer the `value` parameter along with each call.
- The second counter-example had an `if` statement in C (the “low” context) depend on a field value in a “high” context. The two branches then perform two different method calls, thus enabling a change of the “high” context to induce two different execution traces for C . Thus, the example satisfies noninterference, because no value stored in memory is changed, but it obviously does not satisfy call integrity. However, this situation is also ruled out by well-typedness, because the rule [T-IF] does not allow the boolean guard expression e in a “low” context to depend on a value from a “high” context.

Thus, both of the two counter-examples would be rejected by the type system. With a setting of L for the “trusted” segment and H for the “untrusted”,⁵ no values or computations performed in the untrusted segment can affect the values in the trusted segment, *nor* the value of any expression in this segment, nor can it even perform a call into the trusted segment. On the other hand, the trusted segment *can* call out into the untrusted part, but such a call cannot then reenter the trusted segment: it must return before any further calls from the trusted segment can happen.

► **Theorem 19** (Well-typedness implies call integrity). *Let $\mathcal{S} \triangleq \{ L, H \}$ with $L \sqsubseteq L$, $L \sqsubseteq H$ and $H \sqsubseteq H$. Fix the two sets of addresses \mathcal{X} and \mathcal{Y} as in Definition 5, such that $\mathcal{A} = \mathcal{X} \cup \mathcal{Y}$ and $\mathcal{A} = \text{dom}(\text{env}_T)$. Fix a type assignment Γ such that*

- $\forall X \in \mathcal{X} . \Gamma(X) = I_L$ for some I where
 - $\forall p \in \Gamma(I) . \Gamma(I)(p) = \text{var}(B)$ where $B \rightsquigarrow L$, and
 - $\forall f \in \Gamma(I) . \Gamma(I)(f) = \text{proc}(\tilde{B}) : L$ for any \tilde{B}
- and with the level H given to all other interfaces, fields and methods.

Also assume that $\Gamma \vdash T : \text{cmd}(s)$, $\Gamma \vdash \text{env}_{ST}^1$, $\Gamma \vdash \text{env}_{ST}^2$, $\Gamma \vdash \text{env}_{ST}^1 =_L \text{env}_{ST}^2$, $\langle T, \text{env}_{ST}^1 \rangle \xrightarrow{\pi_1} \text{env}_{ST}^{1'}$, and $\langle T, \text{env}_{ST}^2 \rangle \xrightarrow{\pi_2} \text{env}_{ST}^{2'}$. Then, $\pi_1 \downarrow_X = \pi_2 \downarrow_X$, for any $X \in \mathcal{X}$.

Theorem 19 tells us that *every* contract X in the trusted segment \mathcal{X} has call integrity w.r.t. the untrusted segment \mathcal{Y} . This is thus a stronger condition than that of Definition 5, which only defines call integrity for a *single* contract $C \in \mathcal{X}$, rather than for the whole set. This means that our type system will reject cases where e.g. C calls another contract $Z \in \mathcal{X}$ and Z calls `send()` methods of different contracts, depending on a “high” value. As `send()` is always ensured to do nothing, such calls could never lead to C being reentered, so this would actually still be safe, even though Z itself would not satisfy call integrity. Thus, this is an example of what resides in the “slack” of our type system.

However, this situation seems rather contrived, since it depends specifically on the `send()` method, which is always ensured to do nothing except returning. For practical purposes, it would be strange to imagine a contract $C \in \mathcal{X}$ having call integrity w.r.t. \mathcal{Y} , but *without* the other contracts in \mathcal{X} also satisfying call integrity w.r.t. \mathcal{Y} . Thus, our type system seems to yield a reasonable approximation to the property of call integrity.

⁵ This counter-intuitive naming can perhaps best be thought of as indicating our level of *distrust* in a contract.

5 Examples and limitations

Let us see a few examples of the application of the type system. To begin with, consider the first counter-example in Remark 7, which should be ill-typed by the type system. In the counter-example we say that X is Low and Y is High, so we let them both implement the interface $I<S>$ defined as follows:

<pre> 1 interface I<s> { 2 field balance : var(s) 3 method go : proc():s 4 }</pre>	<pre> contract X : I<L> { ... } contract Y : I<H> { ... }</pre>
---	---

where $I<L>$ (resp. $I<H>$) is a shorthand for I_L (resp. I_H) with all occurrences of s within the interface definition replaced by L (resp. H). A part of the failing typing derivation for the body of the method $Y.go()$ in the declaration of contract Y is:

$$\frac{\begin{array}{c} \Gamma(\text{this}) = I<H> \\ \Gamma \vdash \text{this} : I<H> \end{array} \quad \begin{array}{c} \Gamma(I<H>)(\text{balance}) = var(H) \\ \hline \Gamma \vdash \text{this.balance} : var(H) \end{array} \quad \begin{array}{c} \Gamma(X) = I<L> \\ \Gamma \not\vdash X : I<H> \end{array} \quad \begin{array}{c} \Gamma(I<L>)(go) \neq proc() : H \\ \hline \Gamma \not\vdash X.go : proc() : H \end{array}}{\Gamma \not\vdash X.go() : this.balance : cmd(H)} \quad (1)$$

We have that $\Gamma \vdash \text{this.balance} : var(H)$ in contract Y , so in order for the method declaration $go() \{ X.go() : this.balance \}$ in Y to be well-typed, the body of the method must be typable as $proc() : H$ by rule [T-DEC-M]. However, as the derivation in (1) illustrates, this constraint cannot be satisfied, because the lookup $\Gamma(I<L>)(go)$ yields $proc() : L$, but $proc() : H$ is needed, and this cannot be obtained through subtyping, because the $proc(\tilde{B}) : s$ type constructor is contravariant in s .

The above example is simple, since the name X is “hard-coded” directly in the body of $Y.go()$, and therefore the type check fails already while checking the contract definition. However, suppose X were instead received as a parameter. Then the signature of the method $Y.go$ would have to be $\text{method go} : proc(I<H>) : H$ instead, and the type check would then fail at the call-site, if a Low address were passed. The following shows a part of the failing typing derivation for the call $Y.go(X) : this.balance$, where the parameter X is assumed to implement the interface $I<L>$ as before:

$$\frac{\begin{array}{c} \Gamma(X) = I<L> \quad L \sqsubseteq H \quad \frac{\Gamma \vdash L <: H}{\Gamma \vdash var(L) <: var(H)} \quad H \not\sqsubseteq L \\ \Gamma \vdash X : I<L> \end{array} \quad \frac{}{\Gamma \not\vdash I<L> <: I<H>}}{\Gamma \not\vdash Y.go(X) : this.balance : cmd(H)} \quad (2)$$

Here $\Gamma \vdash Y.go : proc(I<H>) : H$ (not shown). The method call expects a parameter of type $I<H>$, but $I<L>$ cannot be coerced up to $I<H>$ through subtyping, because its definition of the method $go()$ has type $proc() : L$, as given in the code listing above, and $\Gamma \not\vdash proc() : L <: proc() : H$ due again to contravariance of the type constructor. Thus we see that the type system indeed prevents calls from High to Low, regardless of whether the Low address is “hard-coded” or passed as a parameter to a High method. However, the aforementioned examples also illustrate a limitation of our type system approach to ensuring call integrity: the entire blockchain must be checked, i.e. both the contracts *and* the transactions. This is necessary since the type check can fail at the call-site of a method, as in the example shown in (2), and the call-site of any method can be a transaction.

```

1 contract X : IBankL {
2   field owner = A;
3   transfer(recipient, amount) {
4     if this.sender = this.owner then
5       recipient
6         .deposit(this.sender):amount
7     else skip
8   }
9   ...
10 }
```

```

contract Y : IBankH {
  field credit = 0;
  deposit(owner) {
    this.credit = this.value;
    this.owner = owner
  }
  ...
}
```

■ **Figure 14** A two-bank setup.

Next, we shall briefly consider two examples, reported by Grishchenko et al. in [13], of Solidity contracts that are misclassified w.r.t. reentrancy by the static analyser Oyente [16]; a false positive and a false negative example.

The false negative example relies on a misplaced update of a field value, just as in the example in Figure 1 (page 2).⁶ In this example, suppose X were assigned the level L and Y the level H. With a transaction $A \rightarrow X.transfer(Y):n$ (for any address A and any amount of currency n), the type system would then correctly reject this blockchain because of the inherent flow from High to Low that is implicit in the call $X.transfer(this)$ issued by Y. The typing derivation would fail in a similar manner as the situation depicted in (2).

The false positive example of Grishchenko et al. from [13] is also similar to the example in Figure 1, but this time just with the assignment to the guard variable correctly placed *before* the method call (i.e. with lines 6 and 7 switched in Figure 1). This too would be rejected by our type system, since it does not take the ordering of statements in sequential composition into account (i.e. rule [T-SEQ]). Thus, this example constitutes a false positive for our type system as well, which is hardly surprising.

Finally, let us consider a true positive example. Figure 14 illustrates a part of the code for two banks, which would allow users to store some of their assets and also to transfer assets between them.⁷ We assume both banks implement the same interface `IBank`, but with different security settings: X is L and Y is H, meaning the latter is untrusted. There is no callback from Y, so in this setup a blockchain with a transaction $A \rightarrow X.transfer(Y, 1):0$ would actually be accepted by the type system, because the Low values from X can safely be coerced up (via subtyping) to match the setting of High on Y.

6 Related work

In light of the visibility and immutability of smart contracts, which makes it hard to correct errors once they are deployed in the wild, it is not surprising that there has been a substantial research effort within the formal methods community on developing formal techniques to

⁶ It also involves the presence of a “default function”, which is a special feature of Solidity. It is a parameterless function that is implicitly invoked by `send()`, thus allowing the recipient to execute code upon reception of a currency transfer. This feature is not present in TINY SOL, yet we can achieve a similar effect by simply allowing the mandatory `send()` method to have an arbitrary method body, rather than just `skip`. This has no effect on the type system and associated proofs, since the `send()` method is treated as any other method therein. Hence, this situation is in principle the same as if the sender had invoked some other method than `send()`, similarly to the example in Figure 1.

⁷ TINY SOL does not have a “mapping” type such as in Solidity, so the setup here is limited to a single user.

prove safety properties of those programs – see, for instance, [26] for a survey. The literature on this topic is already huge and the whole gamut of techniques from the field of verification and validation has been adapted to the smart-contract setting. For example, this includes contributions employing frameworks based on finite-state machines to design and synthesise Ethereum smart contracts [17], a variety of static analysis techniques and accompanying tools, such as those presented in [9, 15, 23, 27], and deductive verification [5, 6, 21], amongst others. The Dafny-based approach reported in [6] is able to model arbitrary reentrancy in a setting with the “gas mechanism”, whereas [4] presents a way to analyse safety properties of smart contracts exhibiting reentrancy in a gas-free setting.

The study in [14] is close in spirit to ours in that it uses a sound type system to guarantee the absence of information flows that violate integrity policies in Solidity smart contracts. That work also presents a type verifier and its prototype implementation within the K-framework [22], which is then applied to analyse more than one hundred smart contracts. However, their technique has not been related to call integrity, which, by contrast, is the focus of our work. Thus, our contribution in the present paper complements this work and serves to further highlight the utility and applicability of secure-flow types in the smart-contract setting. However, there are also clear differences between this aforementioned work and the present one. Most notably, our type system uses a more refined subtyping relation, which also handles subtyping of method and address types, whereas subtyping is not defined for the former in [14], and the latter is not given a type altogether. This gives us a more fine-grained control over the information flow, since it allows us to assign different security levels to a contract and its members. For example, a High contract might have certain Low methods, which hence would not be callable from another High contract, whereas High methods would. This is in line with standard object-oriented principles, e.g. Java-style visibility modifiers.

Another approach to using a type system to ensure smart-contract safety in a Solidity-like language is presented by Crafa et al. in [7]. This work is indeed related to ours in that both are based on well-known typing principles from object-oriented languages, especially subtyping for contract/address types and the inclusion of a “default” supertype for all contracts, similar to our I^\top . However, the aim of [7] is rather different from ours, in that the type system offered in that paper seeks to prevent *runtime errors* that do not stem from a negative account balance, e.g. those resulting from attempts to access nonexistent members of a contract. Incidentally, such runtime errors would *also* be prevented by our type system (rules [T-CALL] and [T-FIELD] in particular), due to our use of “interfaces” as address types, if the converse check (ensuring every declared type in an interface has an implementation) were also performed. However, our focus has been on checking the currency flow, rather than preventing runtime errors of this kind.

The aforementioned paper [7] introduced Featherweight Solidity (FS). Like TINY SOL, FS is a calculus that formalises the core features of Solidity and, as mentioned above, it supports the static analysis of safety properties of smart contracts via type systems. Therefore, the developments in the present paper might conceivably have been carried out in FS instead of TINY SOL. Our rationale for using TINY SOL is that it provided a very simple language that was sufficient to express the property of call integrity, thus allowing us to focus on the core of this property. Of course, “simplicity” is a subjective criterion and the choice of one language instead of another is often a matter of preference and convenience. To our mind, TINY SOL is slightly simpler than FS, which includes functionalities such as callback functions and revert labels. Moreover, the big-step semantics of TINY SOL provided was more convenient for the development of our type system than the small-step semantics given for FS. Furthermore, unlike FS, TINY SOL also formalises the semantics of blockchains. Having said so, TINY SOL and FS are quite similar and it would be interesting to study their similarities

in more detail. To this end, in future work, we intend to carry out a formal comparison of these two core languages and to see which adaptations to our type system are needed when formulated for FS. In particular, we note that FS handles the possibility of an explicit type conversion (type cast) of `address` to `address payable` by augmenting the `address` type with type information about the contract to which it refers. This distinction is not present in our version of TINY SOL, as we require all contracts and accounts to have a default `send()` function, so all addresses are in this sense “payable”. However, our type system does not depend on the presence of a `send()` function, so this difference is not important here.

7 Conclusion and future work

In this paper we studied two security properties, namely call integrity and noninterference, in the setting of TINY SOL, a minimal calculus for Solidity smart contracts. To this end, we rephrased the syntax of TINY SOL to emphasise its object-oriented flavour, gave a new big-step operational semantics for that language and used it to define call integrity and noninterference. Those two properties have some similarities in their definition, in that they both require that some part of a program is not influenced by the other part. However, we showed that the two properties are actually incomparable. Nevertheless, we provided a type system for noninterference and showed that well-typed programs *also* satisfy call integrity. Hence, programs that are accepted by our type systems lie at the intersection between call integrity and noninterference.

A challenging development of our work would be to prove whether the type system exactly characterises the intersection of these two properties, or to find another characterisation of this set of programs. Orthogonally, it would be important to devise type inference algorithms for the present type system, to be used in practical situations where the typing environment is hard to guess. It would also be interesting to compare our typing-based proof method with those proposed, e.g., in [13, 16, 23]. Finally, we also aim at applying our static analysis methodology to many concrete case studies, to better understand the benefits of using a completely static proof technique for call integrity. To do so, it would be useful to extend TINY SOL with a “gas mechanism” allowing one to prove the termination of transactions and to compute their computational cost.

A potential limitation of the approach presented in this paper is that the entire blockchain must be checked to show call integrity of a contract. Indeed, since a typing derivation can fail at the call-site and the call-site of a method can be a transaction, transactions must be well-typed too. In passing, we note that this kind of problem is also present in [25, 28] (and, in general, in many works on type systems for security), where the whole code needs to be typed in order to obtain the desired guarantees. We think that an important avenue for future work, and one we intend to pursue, is to explore whether, and to what extent, other typing disciplines can be employed to mitigate this problem. As mentioned earlier, we also plan to extend the language (and the type system) to enable checking of real-life Solidity contracts; this will also allow us to better assess how (un)feasible it would be to check the whole blockchain.

Abstract

Reactive software calls for instrumentation methods that uphold the reactive attributes of systems. Runtime verification imposes another demand on the instrumentation, namely that the trace event sequences it reports to monitors are *sound* – that is, they reflect actual executions of the system under scrutiny. This paper presents RIARC, a novel decentralised instrumentation algorithm for outline monitors meeting these two demands. Asynchrony in reactive software complicates the instrumentation due to potential trace event loss or reordering. RIARC overcomes these challenges using a next-hop IP routing approach to rearrange and report events soundly to monitors.

RIARC is validated in two ways. We subject its corresponding implementation to rigorous systematic testing to confirm its correctness. In addition, we assess this implementation via extensive empirical experiments, subjecting it to large realistic workloads to ascertain its reactivity. Our results show that RIARC optimises its memory and scheduler usage to maintain latency feasible for soft real-time applications. We also compare RIARC to inline and centralised monitoring, revealing that it induces comparable latency to inline monitoring in moderate concurrency settings where software performs long-running, computationally-intensive tasks, such as in Big Data stream processing.

1 Introduction

Modern software is generally built in terms of concurrent components that execute without relying on a global clock or shared state [87]. Instead, components interact via non-blocking messaging, creating a loosely-coupled architecture known as a *reactive system* [9, 94], which

- responds in a timely manner (is *responsive*),
- remains available in the face of failure (is *resilient*),

- reacts to inputs from users or their environment (is *message-driven*), and
- grows and shrinks to accommodate varying computational loads (is *elastic*).

The real-world behaviour of reactive systems is hard to understand statically, and *monitoring* is used to inspect their operation at *runtime*, e.g. for debugging [111], security checking [62], profiling [76], resource usage analysis [36], etc. This paper considers runtime verification (RV), an application of monitoring used to detect whether the *current* execution of a system under scrutiny (SuS) deviates from its correct behaviour [17, 71, 22]. A RV monitor is a *sequence recogniser* [123, 101]: a state machine that incrementally analyses a *finite* fragment of the runtime information exhibited by a SuS to reach an *irrevocable* verdict (see [6, 5] for details).

Instrumentation lies at the core of runtime monitoring [70, 22, 64]. It is the mechanism by which runtime information from a SuS is extracted and reported to monitors as a stream of system events called a *trace*. Software is typically instrumented in one of two ways. Inline instrumentation, or *inlining*, modifies the SuS by injecting tracing instructions at specific joinpoints, e.g. using AspectJ [90] or BCEL [54]. Outline instrumentation, or *outlining*, uses an external tracing infrastructure to gather events, e.g. LTTng [56] or OpenJ9 [58], thereby treating the SuS as a *black box*. A key requirement setting RV apart from monitoring, e.g., telemetry [85] or profiling [121, 26], is that the instrumentation must report *sound traces*.

- **Definition 1 (Sound traces).** A finite trace T is sound w.r.t. a system component P iff it is
1. Complete. T contains all the events exhibited by P so far, and
 2. Consistent. The event sequence in T reflects the order the events occur locally at P . \square

Traces violating this soundness invariant are unfit for RV, as omitted, spurious, or out-of-sequence events incorrectly characterise the system behaviour, *nullifying* the verdicts that monitors flag [22, 52]. Reactive software imposes another requirement: that the instrumentation *safeguards* the responsive, resilient, message-driven, and elastic attributes of the SuS. This necessitates an instrumentation method which is itself *reactive*, in order to

1. not hamper the SuS by inducing unfeasible runtime overhead (is responsive),
2. permit monitors to fail independently of SuS components (is resilient),
3. react to trace events without blocking the SuS (is message-driven), and
4. grow and shrink in proportion to the size of the SuS (is elastic).

Limitations of current RV instrumentation methods. State-of-the-art RV tools use instrumentation methods that do not satisfy *all* of the conditions 1–4 above. This renders them inapplicable to reactive software; see [64, tables 3 and 4] for details. Many approaches, including [24, 31, 49, 75, 110, 122, 127, 19], assume systems with a *fixed* architecture where the number of components remains constant at runtime, failing to meet condition 4. Works foregoing the assumption of a fixed system size, such as [45, 91, 60, 59, 25, 31, 68, 3], inline the SuS with monitors *statically*. Inlining monitors pre-deployment inherently accommodates systems that grow and shrink (condition 4) as a by-product of the embedded monitor code that executes on the same thread of system components; see fig. 1a. This scheme, however, has shortcomings that make it less suited to reactive software. Recent studies [22, 52] observe that the lock-step execution of the SuS and monitors can impair the operation of the instrumented system, e.g. slow runtime analyses manifest as high latencies [37], and faulty monitors may break the system [69], which do not meet conditions 1 and 2 (e.g. M_Q in fig. 1a). Other works [46, 16] argue that errors, such as deadlocks or component crashes, are hard to detect since the monitoring logic shares the runtime thread of the affected component. Entwining the execution of the SuS and monitors may also diminish the scalability, performance, and resource usage efficiency of the monitored system because inlined monitor code cannot be run on separate threads [12]. Lastly, inlining is *incompatible* with unmodifiable software, such as closed-source components (e.g. R in figs. 1a–1c), making outlining the only alternative.

Outline instrumentation *can* address the limitations of inlining by isolating the SuS and its monitors (works [45, 37, 38] that view externalised monitors as “outline” embed tracing code to extract events from the SuS, subjecting them to the cons of inlining). The latest survey on decentralised RV [71, tables 1 and 2] establishes that outlining-based tools, e.g. [50, 18, 19, 72, 37, 38, 125, 65], are variations on *centralised* instrumentation. In this set-up, events exhibited by SuS components are funnelled through a *global* trace buffer (e.g. $\kappa_{\{P,Q,R\}}$ in fig. 1b) that a singleton monitor can analyse asynchronously, meeting condition 3. Yet, the central buffer introduces contention and sacrifices the scalability of the SuS [11], violating condition 4. Centralised architectures are prone to single point of failures (SPOFs) [94, 93] (violating condition 2), which is not ideal for monitoring medium-scale reactive systems.

Contribution. We propose RIARC, a *decentralised* instrumentation algorithm for outline monitors that overcomes the above shortcomings, fulfilling conditions 1–4. Outline monitors minimise latency effects due to slow trace event analyses associated with inlining (meeting condition 1). While RIARC does not handle monitor failure explicitly, it intrinsically enjoys a degree of fault tolerance by isolating the SuS and its decentralised monitor components (meeting condition 2); e.g. monitors $M_{\{P\}}$ and $M_{\{Q,R\}}$ in fig. 1c. RIARC uses a tracing infrastructure to obtain system events passively without modifying the SuS (meeting condition 3). The algorithm equips each isolated monitor with a *local* trace buffer, using it to report events based on the SuS components a monitor is tasked to analyse (e.g. buffers $\kappa_{\{P\}}$ and $\kappa_{\{Q,R\}}$ in fig. 1c). RIARC reorganises its instrumentation set-up to reflect dynamic changes in the SuS. It reacts to specific events in traces to instrument monitors for new SuS components and to remove redundant monitors when it detects graceful or abnormal component terminations. This enables RIARC to grow and shrink the verification set-up on demand (meeting condition 4). Given the challenges of fulfilling the conditions 1–4, we scope our work to settings where communication is reliable (i.e., no message corruption, duplication, and loss) [57] and Byzantine failures do not arise [96].

To the best of our knowledge, the approach RIARC advocates is novel. One reason why outlining has never been adopted for decentralising monitors are the onerous conditions 1–4 imposed by reactive software. Utilising non-invasive tracing makes our set-up necessarily *asynchronous*. At the same time, this complicates the instrumentation, which must ensure trace soundness (def. 1), notwithstanding the inherent phenomena arising from the concurrent execution of the SuS and monitors, e.g. trace event reordering and process crashes. Consequently, the second reason is that the overhead incurred to uphold this invariant – in addition to scaling the verification set-up as the SuS executes – is perceived as prohibitive when compared to inlining. This opinion is often reinforced when the viability of outline instrumentation is predicated on empirical criteria tied to monolithic, batch-style programs, that *may not* apply to reactive software (e.g. percentage slowdown); e.g. see [97, 114, 113, 47, 46, 119, 30, 98].

This paper shows how instrumenting outline monitors under conditions 1–4 can be achieved using a decentralised approach that guarantees def. 1, while *also* exhibiting overheads considered feasible for typical soft real-time reactive systems. Concretely, we

- (i) recall the benefits of the actor model [82, 10] for building reactive systems and argue how our model of processes and tracers readily maps to that setting, sec. 2;
- (ii) give a decentralised instrumentation algorithm for outline monitors, detailing how the reactive characteristics of the SuS can be preserved whilst ensuring def. 1, sec. 3;
- (iii) show the implementability of our algorithm in an actor language and systematically validate the correctness of its corresponding implementation w.r.t. def. 1 by exhaustively inducing interleaved executions for a selection of instrumented systems, sec. 4;

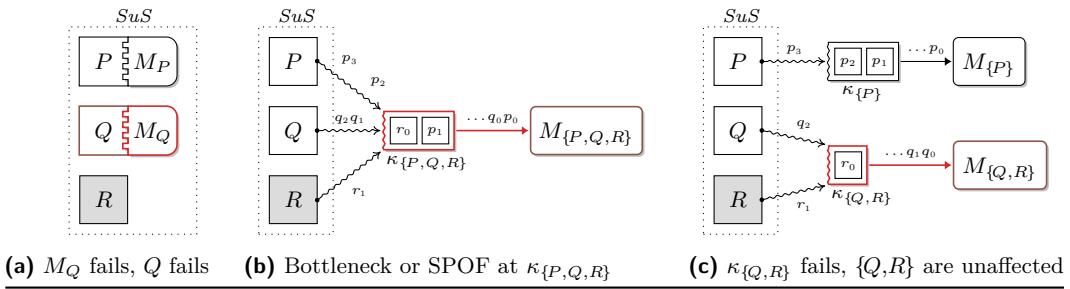

Figure 1 P, Q, R instrumented in inline (*left*), centralised (*middle*) and decentralised (*right*) modes.

- (iv) back up the feasibility of the implemented algorithm via a comprehensive empirical study that uses various workload configurations surpassing the state of the art, showing that the induced overhead minimally impacts the reactive attributes of the SuS, sec. 5.

The extended version [8] contains the full details about RIARC and further discussion of our experiments and results. That material is ancillary to the one presented in this paper.

2 A computational model for reactive systems

The actor model [82, 10] emerged as *the* paradigm to design and build reactive systems [33]. *Actors* – the units of decomposition in this model – are abstractions of concurrent entities that share no mutable memory with other actors. Instead, actors interact through asynchronous message passing and alter their internal state based on the messages they consume. Asynchronous communication decouples actors spatially and temporally, which fully isolates system components and establishes the foundation for resiliency and elasticity [32, 94]. Each actor is equipped with an incoming message buffer called the *mailbox*, from which messages deposited by other actors can be selectively read. Besides sending and receiving messages, actors can *spawn* other actors. Actors in a system are addressable by their unique process identifier (PID), which they use to engage in directed, *point-to-point* communication. This idea of addressability is central to the actor model: it enables reasoning about decentralised computation, as the identity of components or messages can be propagated through a system and used in handling complex tasks, such as process registration and failure recovery [33]. As is often the case in decentralised computations, we assume that messages exchanged between pairs of processes are always received in the order in which they have been sent [43].

Frameworks, notably Erlang [12], Elixir [88], Akka [1] for Scala [117], along with others [118, 130], instantiate the actor model. We adopt Erlang since its ecosystem is specifically engineered for highly-concurrent, soft real-time reactive systems [131, 13, 44]. The Erlang virtual machine (EVM) implements actors as lightweight processes. It employs *per process* garbage collection that, unlike the JVM, does not subject the virtual machine to global unpredictable pauses [86, 116]. This factor minimises the impact on the soft real-time properties of a system *and* is also crucial to the empirical evaluation of sec. 5 since it stabilises the variance in our experiments. The EVM exposes a flexible *process tracing* API aimed at reactive software [42]. Erlang provides other components, e.g. supervision trees, message queues, etc., for building fault-tolerant distributed applications. While we scope our work to fault-free settings (see sec. 1), adopting Erlang gives us the foundation upon which our work can be naturally extended to address these aspects. Henceforth, we follow the established convention in Erlang literature and use the terms *actor*, *process*, and *component* synonymously.

2.1 Process tracing and trace partitioning

Processes in a concurrent system form a *tree*, starting at the *root* process that spawns *child* processes, and so forth¹. Concurrency induces inherent *partitions* to the execution of the SuS in the form of isolated traces that reflect the *local* behaviour at each process [19]. RIARC exploits this aspect to attain several benefits. First, one can *selectively* specify the SuS processes to be instrumented. The upshot is that fewer trace events need to be gathered, improving *efficiency*. Another benefit of partitioned traces is that each process can be dynamically instrumented, free from assumptions about the number of processes the SuS is expected to have. This makes the RV set-up *elastic*. Lastly, the instrumentation set-up can *partially fail*, as faulty SuS or monitor processes do not imperil the execution of one another.

► **Example 2** (Trace partitions). Trace partitions enable RIARC to instrument a system in various arrangements. Fig. 2a depicts an interaction sequence for the execution of the SuS from sec. 1. In this interaction, the root process, P , spawns Q and communicates with it, at which point Q spawns process R ; P and Q eventually terminate. We denote the process *spawning* and *termination* trace events by \diamond and \star , and use $!$ and $?$ for *send* and *receive* events respectively. The *sound* trace partitions for the processes in fig. 2a are “ $\neg \diamond_P . !_P . \star_P$ ” for P , “ $?_Q . \neg \diamond_Q . \star_Q$ ” for Q , and the empty trace for R . □

A centralised set-up such as that of fig. 1b can be obtained by instrumenting $\{P, Q, R\}$ with one monitor, $M_{\{P, Q, R\}}$, whereas instrumenting the components $\{P\}$ and $\{Q, R\}$ with monitors $M_{\{P\}}$ and $M_{\{Q, R\}}$ gives the decentralised arrangement of fig. 1c. Each of these instrumentation arrangements generates different executions.

► **Example 3** (Sound traces). For the case of fig. 1b, RIARC can report to $M_{\{P, Q, R\}}$ one of four possible traces “ $\neg \diamond_P . !_P . \star_P . ?_Q . \neg \diamond_Q . \star_Q$ ”, “ $\neg \diamond_P . !_P . ?_Q . \star_P . \neg \diamond_Q . \star_Q$ ”, “ $\neg \diamond_P . !_P . ?_Q . \neg \diamond_Q . \star_P . \star_Q$ ”, or “ $\neg \diamond_P . !_P . ?_Q . \neg \diamond_Q . \star_Q . \star_P$ ”. These *sound* traces result from the interleaved execution of processes P , Q . Any other trace, e.g. “ $\neg \diamond_P . \star_P . ?_Q . \neg \diamond_Q . \star_Q$ ” or “ $\neg \diamond_P . !_P . \star_P . ?_Q . \star_Q . \neg \diamond_Q$ ”, is *unsound* since it contradicts the local behaviour at processes P and Q of fig. 2a. The former trace omits the request $!_P$ that P makes to Q (it is *incomplete* w.r.t. P), and the latter trace inverts $\neg \diamond_Q$ and \star_Q , suggesting that Q spawns R after Q terminates (it is *inconsistent* w.r.t. Q). □

► **Example 4** (Separate instrumentation). Fig. 2b shows another decentralised set-up, where P , Q , and R are instrumented separately. In this case, the instrumentation should report to $M_{\{P\}}$, $M_{\{Q\}}$ and $M_{\{R\}}$ the events observed *locally* at each process, as stated in ex. 2. □

RIARC makes two assumptions about process tracing in order to support the instrumentation arrangements shown in figs. 1b, 1c, and 2b:

A₁ *Tracing processes sets*. Tracing can gather events for *sets* of SuS processes, e.g. $\kappa_{\{P, Q, R\}}$ in fig. 1b gathers the events of $\{P, Q, R\}$, and $\kappa_{\{Q, R\}}$ in fig. 1c gathers the events of $\{Q, R\}$.

A₂ *Tracing inheritance*. Tracing gathers the events of a SuS process *and* the children it spawns by default to eliminate the risk that trace events from child processes are missed.

We opt for tracing inheritance since it follows established centralised RV monitoring tools, including [18, 41, 50, 110]. In fact, tracing assumptions A₁ and A₂ mean that centralised set-ups like that of fig. 1b can be obtained just by tracing the root process P . Tracing inheritance requires the instrumentation to *intervene* if it needs to channel the events of a child process into a *new* trace partition that is *independent* from that of its parent, e.g. as in

¹ For example, using `spawn()` in Erlang [42] and Elixir [88], `ActorContext.spawn()` in Akka [1], `Actor.createActor()` in Thespian [118], `CreateProcess()` in Windows [108], etc.

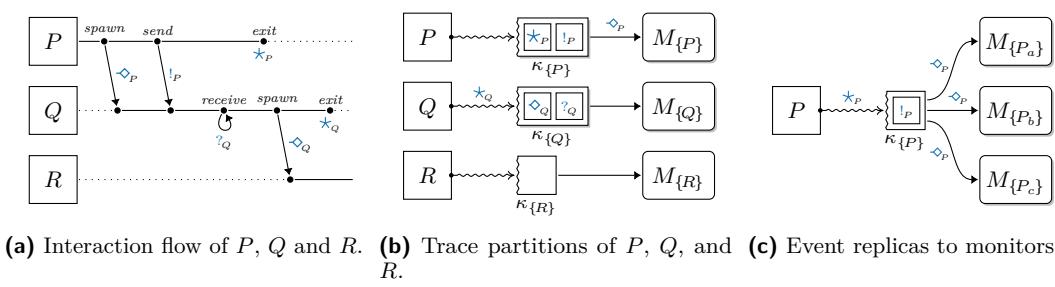

Figure 2 SuS with processes P , Q , and R instrumented with independent monitors.

fig. 1c. In such cases, the instrumentation must first stop tracing the child process, allocate a fresh trace buffer, and resume tracing the child process. The out-of-sync execution of the SuS and instrumentation complicates the creation of these new trace partitions because it can lead to reordered or missed events. This, in turn, would violate trace soundness, def. 1.

We supplement A₁ and A₂ with the following to keep our exposition in sec. 3 manageable:

- A₃** *Single-process tracing.* Any SuS process can be traced *at most* once at any point in time.
- A₄** *Causally-ordered spawn events.* Tracing gathers the spawn trace event of a parent process before *all* the events of the child process spawned by that parent, e.g. if P spawns Q , and Q receives, as in fig. 2a, the reported sequence is “ $\diamond_P \cdot ?_Q$ ” rather than “ $?_Q \cdot \diamond_P$ ”.

The constraint of tracing assumption A₃ is easily overcome by replicating trace events for a process and reporting them to different monitors (e.g. the events in the trace partition of process P are replicated to monitors $M_{\{P_a\}}$, $M_{\{P_b\}}$, $M_{\{P_c\}}$ in fig. 2c). Tracing assumption A₄ requires trace buffers to reorder \diamond events using the spawner and spawned process information carried by each event before reporting them to monitors. Sec. 3.3 gives more details.

► **Example 5 (Unsound traces).** Fig. 3a shows one possible configuration that can be reached by our three-process system introduced in fig. 2a, where the trace buffer $\kappa_{\{P\}}$ contains the events for both P and Q . The trace in buffer $\kappa_{\{Q\}}$ is unsound, as it inaccurately characterises the local behaviour of process Q (the sound trace for Q should be “ $?_Q \cdot \diamond_Q \cdot \star_Q$ ”, not “ \star_Q ”). □

RIARC programs trace buffers to coordinate with one another to ensure that sound traces are invariably reported to monitors. We refer to a trace buffer and the coordination logic it encapsulates as a *tracer*. RIARC employs an approach based on *next-hop routing* in IP networks [80, 104] to counteract the effects of trace event reordering and loss by rearranging and forwarding events to different tracers. Fig. 3b conveys our organisation of tracers (refer to [8, fig. 10 in app. A] for legend). Sec. 3 details how RIARC dynamically reorganises the tracer choreography and performs next-hop routing.

2.2 Modelling decentralised instrumentation

Since RV monitors are passive verdict-flagging machines (refer to sec. 1), they are orthogonal to our instrumentation. We, thus, focus our narrative on tracers and omit monitors, except when relevant in the surrounding context. The model assumes a set of SuS process, $P, Q, R \in \text{PRC}$, and tracer names, $T \in \text{TRC}$, together with a countable set of PID values to reference processes. We distinguish between SuS and tracer PIDs, which we denote respectively by the sets, $p_s, q_s \in \text{PID}_S$ and $p_T, q_T \in \text{PID}_T$. The variables i_s and j_s , and i_T and j_T range over PIDs from the corresponding sets PID_S and PID_T . We also assume the function signature sets, $f_S \in \text{SIG}_S$, $f_T \in \text{SIG}_T$, and, $f_M \in \text{SIG}_M$, to denote SuS, tracer, and RV monitor functions, together with

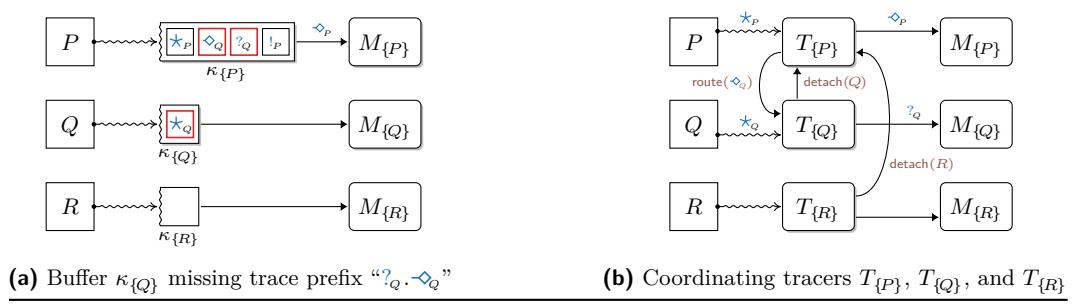

Figure 3 Choreographed tracers coordinating to ensure sound traces.

the variables ς_S , ς_T , and ς_M that range over each signature set. New SuS processes are created via the function $\text{spwn}(\varsigma_S)$ that accepts the function signature ς_S to be spawned, and returns a fresh PID, ι_S . We overload spwn to spawn tracer signatures ς_T equivalently, returning corresponding PIDs, ι_T . The function self obtains the PID of the process invoking it. We write P as shorthand for a singleton process set $\{P\}$ to simplify notation.

RIARC uses three message types, $\tau \in \{\text{evt}, \text{dtc}, \text{rtd}\}$. These determine when to *create* or *terminate* tracer processes, and what trace events to *route* between tracers:

- **evt** are *trace events* gathered via process tracing,
- **dtc** are *detach requests* that tracers exchange to reorganise the tracer choreography, and
- **rtd** are *routing packets* that transport **evt** or **dtc** messages forwarded between tracers.

We encode messages m as tuples. Trace event messages, $\langle \text{evt}, \ell, \iota_S, j_S, \varsigma_S \rangle$, comprise the event label ℓ that ranges over the SuS events \diamond (*spawn*), \star (*exit*), $!$ (*send*), and $?$ (*receive*). The PID value ι_S identifies the SuS process exhibiting the trace event, and is defined for *all* events. The SuS PID j_S and function signature ς_S depend on the type of the event. Tbl. 1a catalogues the values defined for each event. We write trace events in their shorthand form, omitting undefined values (denoted by \perp), e.g. $\langle \text{evt}, \star, \iota_S \rangle$ instead of $\langle \text{evt}, \star, \iota_S, \perp, \perp \rangle$.

Table 1 Trace event (**evt**), detach request (**dtc**), and routing packet (**rtd**) message index names.

(a) Messages encoding *spawn*, *exit*, *send*, and *receive* events.

Label ℓ	Index	Description (ι_S and j_S are SuS PIDs)
\diamond	$e.\iota_S$	Parent PID spawning new child PID j_S
\diamond	$e.j_S$	Child PID spawned by parent PID ι_S
\diamond	$e.\varsigma_S$	Signature ς_S spawned by parent PID ι_S
\star	$e.\iota_S$	Terminated PID
\star	$e.j_S, e.\varsigma_S$	Undefined for exit events
$!$	$e.\iota_S$	Sending PID
$!$	$e.j_S$	Recipient PID
$!$	$e.\varsigma_S$	Undefined for send events
$?$	$e.\iota_S$	Recipient PID
$?$	$e.j_S, e.\varsigma_S$	Undefined for receive events

(b) Detach and routing messages.

Index	Description
$m.\tau$	Message type: event (evt) detach (dtc), routing (rtd)
$d.\iota_T$	PID of tracer requesting detach of SuS PID ι_S
$d.\iota_S$	PID of SuS process to stop tracing
$r.\iota_T$	PID of tracer that starts routing message m
$r.m$	Embedded evt or dtc message being routed

■ **Table 2** RIARC approach to ensure trace soundness (def. 1) and reactive instrumentation (sec. 1).

Requirement	Approach
R ₁ Growing the set-up	Instrument tracers on-demand to create new trace partitions
R ₂ Ensuring complete traces	Route trace events to deliver them to the correct tracer
R ₃ Ensuring consistent traces	Prioritise routed trace events before others
R ₄ Isolating tracers	Detach tracers from others once all trace events are routed
R ₅ Minimising overhead	Target specific processes to instrument
R ₆ Shrinking the set-up	Garbage collect redundant tracers and monitors

Detach request messages have the form $\langle \text{dtc}, \iota_T, \iota_S \rangle$. A tracer with the PID ι_T uses **dtc** to request that another tracer *stop* tracing the SuS PID ι_S . Routing packet messages, $\langle \text{rtd}, \iota_T, m \rangle$, move **evt** and **dtc** messages between tracers. The PID ι_T identifies the tracer that embeds the message m into the routing packet and dispatches it to other tracers. Tbl. 1b summarises detach request and routing packet messages.

► **Note 6 (Notation).** We reserve the variables e , d , and r for the messages types **evt**, **dtc**, and **rtd** respectively. Our model uses the suggestive dot notation $(.)$ to index message fields, e.g. $m.\tau$ reads the message type, $e.\ell$ reads the trace event label, etc. (see tbl. 1). For simplicity, we occasionally write the label ℓ in lieu of the full trace event form, e.g. we write \star instead of $\langle \text{evt}, \star, \iota_S \rangle$, etc. □

3 Decentralised instrumentation

Our reason for encapsulating trace buffers and their coordination logic as tracers stems from the actor model. Trace buffers align with actor mailboxes, which localise the tracer state and enable tracers to run *independently*. The main logic replicated at each tracer is given in algs. 1–3. Tracers operate in two modes, *direct* (\circ) and *priority* (\bullet), to counteract the effects of trace event reordering. We organise our tracer logic in algs. 1 and 3 to reflect these modes, respectively. Algs. 1 and 3 use the function **ANALYSE.EVT**, which analyses events; see [8, app. C.5.2] for details. Auxiliary tracer logic referenced in this section is given in [8, app. A].

Every tracer maintains an internal state σ consisting of the following three maps:

- the *routing* map, Π , governing how events are routed to other tracers,
 - the *instrumentation* map, Λ , that determines which SuS processes to instrument, and
 - the *traced-processes* map, Γ , tracking the SuS process set that the tracer currently traces.
- Tbl. 2 summarises the challenges that RIARC needs to overcome to attain the reactive characteristics stated in sec. 1. Requirements R₁ and R₆ in tbl. 2 oblige the instrumentation to reorganise dynamically while the SuS executes to preserve its *elasticity*. Requirement R₄ offers a modicum of *resiliency* between the SuS and tracer processes, whereas R₅ minimises the instrumentation overhead by gathering only the events monitors require. This keeps the overall set-up *responsive*. Since RIARC builds on the actor model, it fulfils the *message-driven* requirement intrinsically. *Trace soundness* is safeguarded by requirements R₂ and R₃.

The operations **TRACE**, **CLEAR** and **PREEMPT** give access to the tracing infrastructure. **TRACE**(ι_S, ι_T) enables a tracer with PID ι_T to register its interest in receiving trace events of a SuS process with PID ι_S . This operation can be undone using **CLEAR**(ι_S, ι_T), which *blocks* the calling tracer ι_T and returns once all the trace event messages for the SuS process ι_S that are in transit to the tracer ι_T have been delivered to ι_T . It is worth remarking that this behaviour conforms to our proviso in sec. 1, i.e., no communication faults. **PREEMPT**(ι_S, ι_T) combines

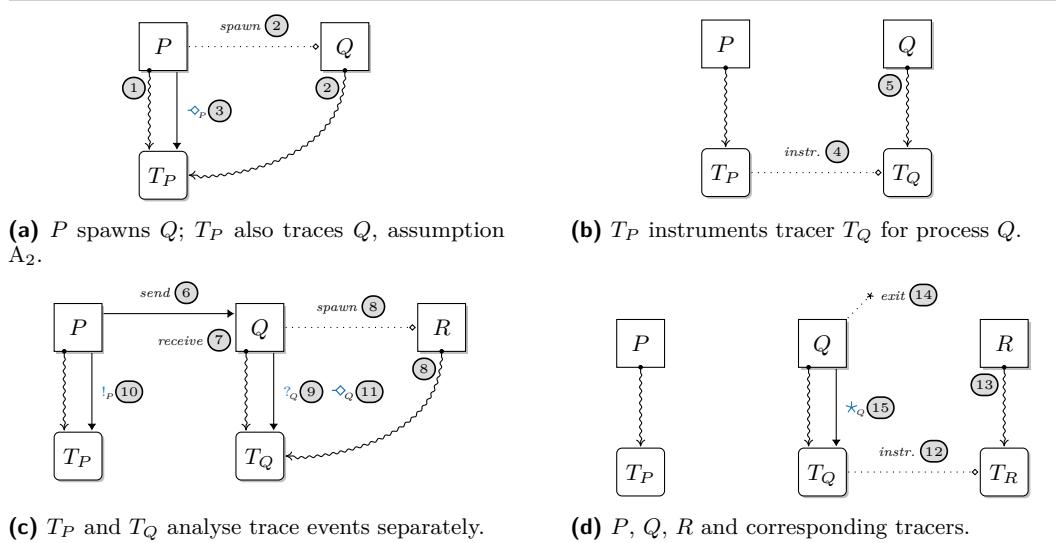

CLEAR and TRACE. It enables the tracer pre-empting ι_T to take control of tracing the SuS process ι_s from another tracer ι'_T that is currently tracing ι_s . Tracers use CLEAR or PREEMPT to modify the default process-tracing inheritance behaviour that tracing assumption A₂ describes. We refer readers to [8, alg. 5 in app. A] for the specifics of these operations.

We focus our presentation in secs. 3.1–3.6 of how RIARC addresses the challenges listed in tbl. 2 on the set-up of fig. 2b, where the processes P , Q and R , are instrumented separately. This specific case highlights two aspects. First, it *emphasises* the complications that RIARC overcomes to establish the desired set-up while ensuring trace soundness, def. 1. Second, fig. 2b *covers all* other possible instrumentation set-ups. Disjoint sets of SuS processes, including the one shown in fig. 1c, can be obtained when tracers do not act on certain \diamond (*spawn*) events, as sec. 3.1 explains. Notably, *any* centralised set-up, e.g. the one in fig. 1b, emerges naturally when the root tracer disregards all \diamond events exhibited by the SuS.

► **Note 7 (Naming conventions).** For clarity, we adopt the convention that a SuS process P is spawned from the signature f_{s_P} and is assigned the PID p_s . A tracer for P is named T_P (short for $T_{\{P\}}$) and has the PID p_T . Other processes are treated likewise, e.g. the SuS process Q has signature f_{s_Q} , PID q_s , while the tracer T_Q for Q has PID q_T , etc. □

3.1 Growing the set-up

Fig. 4 illustrates how the hierarchical creation sequence of SuS processes described in sec. 2.1 is exploited to instrument separate tracers. RIARC programs tracers to react to \diamond (*spawn*) events in the trace. In fig. 4a, the root tracer T_P traces process P , step ①. When P spawns process Q , Q automatically inherits T_P (tracing assumption A₂ from sec. 2.1). Steps ② in fig. 4a emphasise that tracing inheritance is instantaneous. The event $e = \langle \text{evt}, \diamond, p_s, q_s, f_{s_Q} \rangle$ is generated by P when it spawns its child Q , step ③ in fig. 4a. The PID values of the parent and child processes carried by e , namely p_s and q_s , are accessed via the indexes $e.\iota_s$ and $e.\jmath_s$ respectively (see tbl. 1a). Tracer T_P uses this PID information to instrument a new tracer T_Q for process Q in step ④ of fig. 4b. By invoking PREEMPT(q_s, q_T), T_Q takes over tracing process Q from the former tracer T_P going forward. T_Q creates a new trace partition for

■ **Figure 4** Growing the tracer instrumentation set-up for processes P , Q and R (monitors omitted).

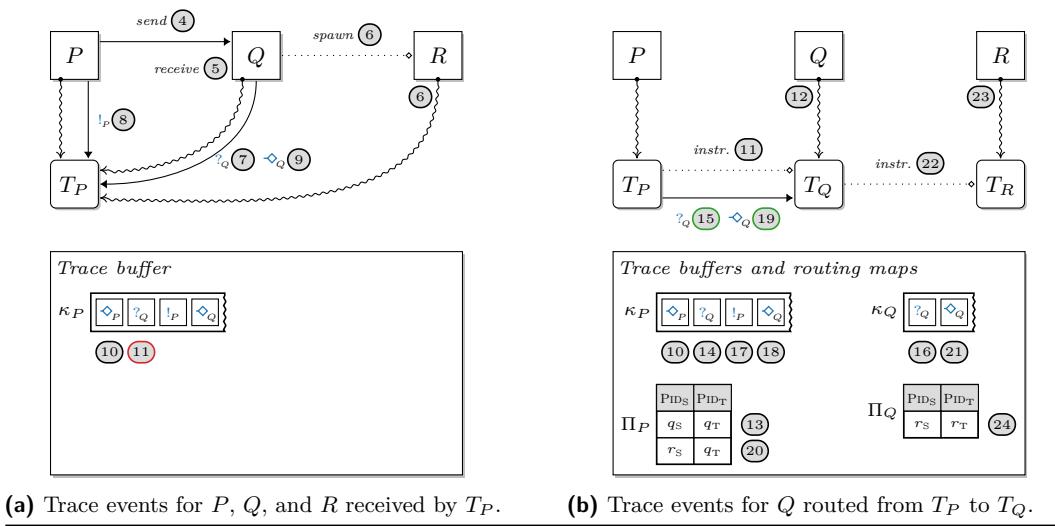

Figure 5 Next-hop trace event routing using tracer routing maps Π (monitors omitted).

process Q that is independent of the partition of P , step ⑤. Meanwhile, T_P receives the send event $\langle \text{evt}, !, p_s, q_s \rangle$ in step ⑩ after P messages Q in step ⑥ of fig. 4c. Subsequent \diamond events that T_P or T_Q may gather are handled as described in steps ③–⑤. Figs. 4c and 4d show how the final tracer T_R is instrumented in step ⑫ after Q spawns R in step ⑧. As before, T_Q traces R automatically in step ⑧. T_Q receives the event $\langle \text{evt}, \diamond, q_s, r_s, f_{s_R} \rangle$ generated by Q in step ⑪. T_R invokes $\text{PREEMPT}(r_s, r_T)$ to create the trace partition for R in step ⑬.

3.2 Ensuring complete traces

The asynchrony between the SuS and tracer processes can induce the interleaved execution shown in fig. 5, as an alternative execution to that shown in figs. 4b–4d. In fig. 5a, T_P is slow to handle \diamond_P it receives in ③ of fig. 4a and fails to instrument T_Q promptly. Consequently, the events $?_Q$ and \diamond_Q that Q exhibits are sent to T_P in steps ⑦ and ⑨ of fig. 5a. Step ⑪ shows the case where $\langle \text{evt}, ?, q_T \rangle$ is processed by T_P , rather than by the *intended* tracer T_Q that would have been instrumented by T_P . This error breaches the *completeness* property of trace soundness w.r.t. Q , as the events $?_Q$ and \diamond_Q meant for Q reach the wrong tracer T_P .

To address this issue, RIARC uses a next-hop routing approach, where tracers *retain* the events they should handle and *forward* the rest to neighbouring tracers. We use the term *dispatcher tracer* (*dispatcher* for short) to describe a tracer that receives trace events meant to be handled by another tracer. For instance, T_P in fig. 5a becomes the dispatcher tracer for Q when it receives the events $?_Q$ and \diamond_Q exhibited by Q , steps ⑦ and ⑨. We expect these events to be handled by T_Q once it is instrumented. Dispatchers are tasked with embedding trace event (evt) or detach requests (dtc) into routing packet messages (rtd) and transmitting them to the next *known* hop. In fig. 5b, T_P dispatches the events $?_Q$ and \diamond_Q as follows. It first instruments T_Q with Q in step ⑪. Next, T_P prepares $\langle \text{evt}, ?, r_s \rangle$ and $\langle \text{evt}, \diamond, q_s, r_s, f_{s_R} \rangle$ for transmission by embedding each in rtd messages (steps ⑭ and ⑯). T_P forwards the resulting routing packets, $\langle \text{rtd}, p_T, \langle \text{evt}, ?, r_s \rangle \rangle$ and $\langle \text{rtd}, p_T, \langle \text{evt}, \diamond, q_s, r_s, f_{s_R} \rangle \rangle$, to its next-hop neighbour T_Q in steps ⑮ and ⑯. The trace event $\langle \text{evt}, !, p_s, q_s \rangle$, however, is not forwarded but handled by T_P , as step ⑰ shows. Concurrently, T_Q acts on the forwarded events $?_Q$ and \diamond_Q in steps ⑯ and ⑰ and instruments T_R as a result, step ⑲.

Algorithm 1 Logic handling of trace events, detach request dispatching, and forwarding.

```

Tracers determine the events to retain or forward using the routing map, $\Pi: \text{PID}_S \rightarrow \text{PID}_T$. Every tracer queries its private routing map for each message it receives on SuS PID $m.\iota_S$. A tracer forwards a message to its neighbouring tracer with PID ι_T if a next-hop for that message exists, i.e., $\Pi(m.\iota_S) = \iota_T$. When the next-hop is undefined, i.e., $\Pi(m.\iota_S) = \perp$, m is handled by the tracer. HANDLEVT, HANDLEEXIT and HANDLCOMM in alg. 1 implement this forwarding logic on lines 14, 23 and 31.

Dynamically populating the routing map is key to transmitting messages between tracers. A tracer adds the new mapping $e.\jmath_S \mapsto \jmath_T$ to its routing map Π in case 1 or 2 below whenever it processes spawn trace events $e = \langle \text{evt}, \diamond, \iota_S, \jmath_S, \xi_S \rangle$. One of two cases is considered for $e.\iota_S$:

Algorithm 2 Tracer instrumentation operations for direct (\circ) and priority (\bullet) modes.

Expect: $e = \langle \text{evt}, \diamond, \iota_s, j_s, \varsigma_s \rangle$ <pre> 1 def INSTRUMENT$_{\circ}$(σ, e, ι_T) 2 if (($\varsigma_M \leftarrow \sigma.\Lambda(e.\varsigma_S)$) $\neq \perp$) # New tracer j_T for new SuS process $e.j_s$ 3 $j_T \leftarrow \text{spwn}(\text{TRACER}(\sigma, \varsigma_M, e.j_s, \iota_T))$ 4 $\sigma.\Pi \leftarrow \sigma.\Pi \cup \{e.j_s, j_T\}$ 5 else # In \circ mode, this tracer has detached # all processes from its dispatcher ι_T # This tracer traces new SuS process $e.j_s$ # by tracing inheritance assumption A₂ 6 $\sigma.\Gamma \leftarrow \sigma.\Gamma \cup \{e.j_s, \circ\}$ 7 return σ</pre>	Expect: $e = \langle \text{evt}, \diamond, \iota_s, j_s, \varsigma_s \rangle$ <pre> 8 def INSTRUMENT$_{\bullet}$(σ, e, ι_T) 9 if (($\varsigma_M \leftarrow \sigma.\Lambda(e.\varsigma_S)$) $\neq \perp$) # New tracer j_T for new SuS process $e.j_s$ 10 $j_T \leftarrow \text{spwn}(\text{TRACER}(\sigma, \varsigma_M, e.j_s, \iota_T))$ 11 $\sigma.\Pi \leftarrow \sigma.\Pi \cup \{e.j_s, j_T\}$ 12 else # In \bullet mode, this tracer must detach # SuS process $e.j_s$ from its dispatcher ι_T 13 DETACH($e.j_s, \iota_T$) # This tracer traces new SuS process $e.j_s$ 14 $\sigma.\Gamma \leftarrow \sigma.\Gamma \cup \{e.j_s, \bullet\}$ 15 return σ</pre>
---	---

- $\Pi(\iota_s) = \perp$. The next-hop for e is undefined, which cues the tracer to instrument the SuS process with PID j_s . When applicable, the tracer processes the event *and* instruments a separate tracer with PID j_T . It then adds the mapping $e.j_s \mapsto j_T$ to Π . The tracer leaves Π *unmodified* and handles the event itself if a separate tracer is not required. Opting for a separate tracer is determined by the instrumentation map Λ , as discussed in sec. 3.5.
- $\Pi(\iota_s) = j_T$. The next-hop for e is defined, and the tracer forwards the event to the neighbouring tracer j_T . The tracer also records a new next-hop by adding $e.j_s \mapsto j_T$ to Π . The addition of $e.j_s \mapsto j_T$ in cases 1 and 2 ensures that future events originating from j_s can always be forwarded via a next-hop to a neighbouring tracer j_T (see invariants on lines 37, 51, and 60). Fig. 5b shows the routing maps of the tracers T_P and T_Q . T_P adds $q_s \mapsto q_T$ in step ⑯ after processing $\langle \text{evt}, \diamond, p_s, q_s, f_{s_Q} \rangle$ from its trace buffer in ⑮. T_P then instruments Q with the tracer T_Q in step ⑰; an instance of case 1. The function INSTRUMENT in alg. 2 details this on line 4, where the mapping $e.j_s \mapsto j_T$ is added to Π following the creation of tracer j_T , line 3. Step ⑳ of fig. 5b is an instance of case 2. Here, T_P adds $r_s \mapsto q_T$ to Π_P after processing $\langle \text{evt}, \diamond, q_s, r_s, f_{s_R} \rangle$ for R in step ⑱ since $\Pi_P(q_s) = q_T$. Crucially, T_P *does not* instrument a new tracer, but delegates the task to T_Q by forwarding \diamond_Q . Lines 20 and 64 in alg. 1 (and later line 24 in alg. 3) are manifestations of this, where the mapping $e.j_s \mapsto j_T$ is added after the \diamond event e is forwarded to the next-hop j_T . T_Q instruments the SuS process R in step ㉑ with T_R , which has the PID r_T . It then adds the mapping $r_s \mapsto r_T$ to Π_Q in step ㉒, as no next-hop is defined for q_s , i.e., $\Pi_Q(q_s) = \perp$. Henceforth, any events exhibited by R and received at T_P can be dispatched by the latter tracer through T_Q to T_R .

Note that every tracer is *only* aware of its neighbouring tracers. This means messages may pass through multiple tracers before reaching their intended destination. Next-hop routing keeps the logic inside RIARC straightforward since tracers forward messages based on local information in their routing map. This approach makes the instrumentation set-up adaptable to dynamic changes in the SuS and has been shown to induce lower latency when compared to general routing strategies [80, 104]. The DAG of interconnected tracers induced by next-hop routing ensures that every message is eventually delivered to the correct tracer if a path exists or handled by the tracer otherwise. Fig. 5b illustrates this concept, where the next-hop mappings inside Π_P point to T_Q , and the mappings in Π_Q point to T_R . Consequently, any events that R exhibits and that T_P receives are forwarded *twice* to reach the target tracer T_R : from tracer T_P to T_Q , and from T_Q to T_R . RIARC relies on the operations DISPATCH and FORWD to achieve next-hop routing (see [8, alg. 4 in app. A]). DISPATCH creates a routing packet, $\langle \text{rtd}, \iota_T, m \rangle$, and embeds the trace event or detach message m to be routed. Alg. 1 shows how tracers handle routing packets. For instance, FORWDEVT extracts the embedded

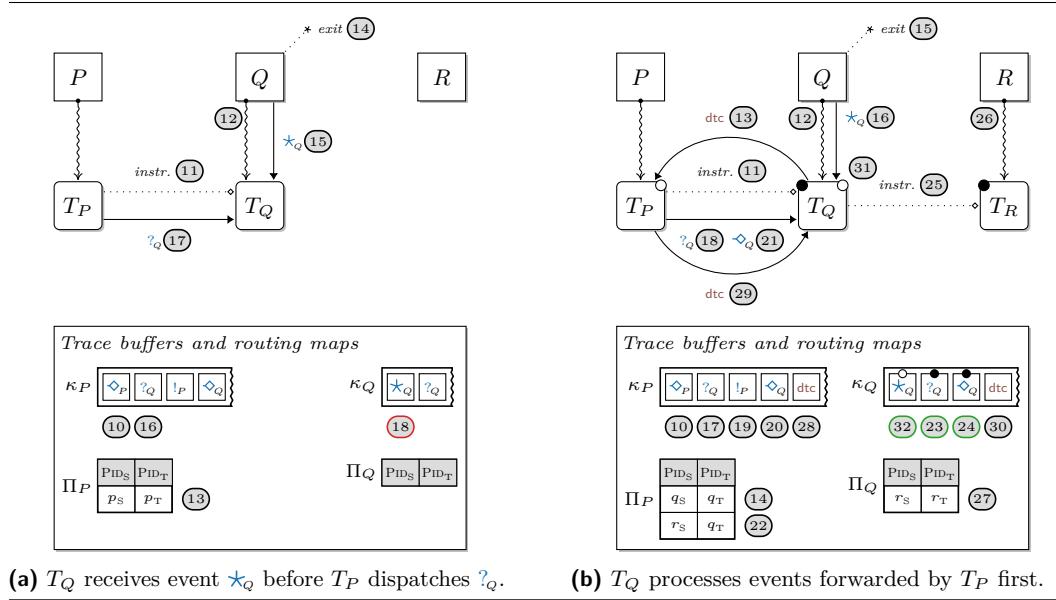

message from the routing packet on line 58 and queries the routing map to determine the next-hop, line 59. If found, the packet is forwarded, as $\text{FORWD}(r, j_T)$ on line 62 indicates. Crucially, the **fail** invariant on line 60 asserts that the next-hop for a routing packet is *always* defined. The cases for DISPATCHDTC and FORWDDTC in alg. 1 are analogous.

3.3 Ensuring consistent traces

Next-hop routing alone does not guarantee trace consistency, i.e., that the order of events in the trace reflects the one in which these occur locally at SuS processes, def. 1. Trace event reordering arises when a tracer gathers events of a SuS process (we call these *direct events*) and simultaneously receives *route events* concerning said process from other tracers. Fig. 6a gives another interleaving to the one of fig. 5b to underscore the deleterious effect such a race condition provokes when events are reordered at T_Q . In step ⑫ T_Q takes over T_P to continue tracing process Q . T_Q collects the event \star_Q in step ⑯, which happens before T_Q receives the routed event $?_Q$ concerning Q in step ⑰ of fig. 6a. If T_Q processes events from its trace buffer κ_Q in sequence, as in step ⑱, it violates trace consistency w.r.t. Q (the correct trace ordering should be “ $?_Q \cdot \star_Q \cdot \star_Q$ ”). Naïvely handling \star before $?$ erroneously reflects that Q receives messages after it terminates.

RIARC tracers resolve this issue by prioritising the processing of route events using selective message reception [42]. In doing so, tracers encode the invariant that “*route events* temporally precede all others that are gathered *directly* by the tracer”. RIARC tracers operate in one of two modes, priority (\bullet) and direct (\circ), which adequately distinguishes past (i.e., route) and current (i.e., direct) events from the perspective of the tracer receiving them.

Fig. 6b illustrates this concept. It shows that when in priority mode, T_Q dequeues the route events $?_Q$ and \star_Q labelled by \bullet first. The event $?_Q$ is handled in step ⑬, whereas \star_Q results in the instrumentation of tracer T_R in step ⑮ of fig. 6b. Meanwhile, T_Q can still receive events directly from Q while priority events are being handled. Yet, direct trace events from Q are considered only *after* T_Q transitions to direct mode. Newly-instrumented tracers default to \bullet mode to implement the described logic; see [8, line 14 in alg. 4 of app. A].

■ **Figure 6** Trace event reordering using priority (\bullet) and direct (\circ) tracer modes (monitors omitted).

Algorithm 3 Logic handling • trace events, detach request acknowledgements, and forwarding.

```

LOOP_• in alg. 3 shows the logic prioritising routed events, which are dequeued on line 3 and handled on line 6. HANDLSPWN, HANDLEXIT, and HANDLCOMM in LOOP_○ and LOOP_• handle events *differently*. A tracer in direct mode performs *one* of three actions (see alg. 1):

1. it *analyses* events for RV purposes via the function ANALYSE.EVT(ς_M, e), e.g. line 32,
2. it *dispatches* events that it directly gathers using DISPATCH(e, \jmath_T), when events ought to be handled by other tracers, e.g. line 33, or
3. it *forwards* routed events to the next-hop through FORWD(r, \jmath_T), e.g. line 62.

Tracers in priority mode exclusively handle routed messages as points 1 and 3 describe, e.g. lines 38 and 39 in alg. 3. However, no event dispatching is performed.

3.4 Isolating tracers

A tracer in priority mode coordinates with the dispatch tracer of a particular SuS process it traces. This enables the tracer to determine when *all* of the events of that process have been routed to it by the dispatch tracer. The negotiation is effected using dtc, which the tracer sends to the relevant dispatch tracer. Each tracer records the set of processes it traces in the *traced-processes map*, $\Gamma : \text{PID}_S \rightarrow \{\circ, \bullet\}$. A SuS process mapping is added to Γ when a tracer starts gathering trace events for that process and removed once the process terminates. Lines 6 and 14 in alg. 2 add fresh mappings to Γ ; lines 26 in alg. 1 and 31 in alg. 3 purge mappings from Γ . A tracer in priority mode must issue a dtc request *for each* process it

tracks in Γ before it can transition to direct mode and start operating on the trace events it gathers directly. The detach request, $d = \langle \text{dtc}, \iota_T, \iota_S \rangle$, contains the PIDs of the issuing tracer and the SuS process to be detached from the dispatch tracer. Once the tracer receives an acknowledgement to the **dtc** request for the SuS PID $d.\iota_S$ from the dispatch tracer, it updates the corresponding entry $d.\iota_S \mapsto \bullet$ in Γ , marking it as detached, $d.\iota_S \mapsto \circ$. Alg. 3 shows this logic on line 46. A tracer transitions from priority to direct mode once *all* the processes in its Γ map are marked detached; line 47 in alg. 3 performs this check. Once in direct mode, tracers are isolated from others in the choreography.

Fig. 6b depicts the tracer T_Q in priority mode sending the detach request $\langle \text{dtc}, q_T, q_S \rangle$ for SuS PID q_S to the dispatch tracer. This happens in step ⑯, after T_Q starts tracing Q directly in step ⑮. Alg. 2 effects this transaction with the dispatch tracer by the operation DETACH on line 13; see [8, app. A] for definition of DETACH. The **dtc** request issued by T_Q is deposited in the trace buffer of the dispatch tracer T_P after the events ?_Q and ?_Q . T_P processes the messages in its buffer sequentially in ⑩, ⑯, ⑰, ⑱ and ⑲, and forwards ?_Q and ?_Q to T_Q , steps ⑯ and ⑰. Crucially, T_P acknowledges the **dtc** request issued by T_Q : T_P dispatches **dtc** back to tracer T_Q , as step ⑳ indicates. T_Q first handles the events ?_Q and ?_Q (tagged with \bullet in fig. 6b) in steps ㉑ and ㉒. Lastly, T_Q handles **dtc** in ㉓ and marks process Q as detached from its dispatch tracer T_P . The update on the traced-process map Γ is performed by HANDLDTC on line 46 in alg. 3. Tracer T_Q in fig. 6b transitions to direct mode in step ㉔, when the only process Q that it traces is detached. T_Q resumes handling ?_Q in step ㉕, which is consistent w.r.t. the events exhibited locally at Q , i.e., “ $\text{?}_Q . \text{?}_Q . \star_Q$ ”.

An acknowledgement to a detach request sent from a dispatch tracer, $\langle \text{dtc}, \iota_T, \iota_S \rangle$, is generally propagated through multiple next-hops before it reaches the tracer with PID ι_T issuing the request. Since a **dtc** request informs the dispatch tracer that ι_T is gathering trace events for the SuS PID ι_S *directly*, the next-hop entries in the routing maps of tracers on the DAG path from the dispatch tracer to ι_T are *stale*. Each tracer on this DAG path purges the next-hop entry for the SuS PID ι_S in Γ once it forwards **dtc** to the neighbouring tracer. DISPATCHDTC and FORWDDTC in alg. 1 perform this clean-up. Fig. 6b does not illustrate the latter clean-up flow, which we summarise next. After receiving **dtc**, the dispatch tracer T_P removes from Π_P the next-hop mapping $q_S \mapsto q_T$ and calls DISPATCHDTC to acknowledge the detach request $\langle \text{dtc}, q_T, q_S \rangle$ it receives from T_Q . Similarly, T_P removes $r_S \mapsto q_T$ once it acknowledges the detach request $\langle \text{dtc}, r_T, r_S \rangle$ sent from T_R . Once T_Q receives the routing packet $\langle \text{rtd}, p_T, \langle \text{dtc}, r_T, r_S \rangle \rangle$ that embeds the detach acknowledgement T_P sends, it removes the next-hop mapping $r_S \mapsto r_T$ from Π_Q . T_Q then forwards this **dtc** acknowledgement to T_R .

RIARC ensures that all routing packets carrying **dtc** acknowledgements terminate at the tracers that issued these **dtc** requests. This requires *one* of two tracer conditions to hold:

1. either the tracer cannot forward the **dtc** acknowledgement to a next-hop, meaning that the tracer sent the **dtc** request, or
2. the tracer can forward the **dtc** acknowledgement via a next-hop, in which case the tracer did not issue the **dtc** request.

Alg. 3 enforces this invariant on lines 44 and 45 for case 1, and on lines 49 and 50 for case 2.

3.5 Minimising overhead

Instrumenting specific processes – in contrast to fully instrumenting the SuS – reduces the volume of gathered trace events and helps lower the runtime overhead induced. RIARC uses the instrumentation map, $\Lambda : \text{SIG}_S \rightarrow \text{SIG}_M$, to this end. Λ specifies the SuS function signatures to instrument and the corresponding RV monitor signatures tasked with the analysis via ANALYSEEVT. RIARC utilises the signature $e.\varsigma_S$ carried by spawn events $e = \langle \text{evt}, \text{?}, \iota_S, \jmath_S, \varsigma_S \rangle$ to

determine whether the SuS process spawning $e.\varsigma_s$ requires a separate tracer. The INSTRUMENT operations in alg. 2 perform this check against Λ (lines 2 and 9). If a separate tracer is not required, $e.\jmath_s$ is instrumented using the tracer of its parent process, $e.\iota_s$; see tracing assumptions A₁ and A₂. This logic caters for all the set-ups shown in figs. 1b, 1c, and 2b.

3.6 Shrinking the set-up

RIARC remains elastic by discarding unneeded tracers. Tracers in direct and priority mode purge SuS PID references from the traced-process map when handling \star trace events. HANDLEEXIT_o and HANDLEEXIT_• implement this logic in algs. 1 and 3 on lines 26 and 31. Tracer termination does *not* occur when the tracer has no processes left to trace, i.e., when $\Gamma = \emptyset$, since the tracer may be required to forward trace events to neighbouring tracers. Instead, tracers perform a garbage collection check each time a mapping from Γ or Π is removed. A tracer terminates when $\Gamma = \Pi = \emptyset$, indicating that it has no SuS processes left to trace or any next-hop forwarding to perform. TRYGC used on lines 27, 41, and 55 in alg. 1, as well as on line 32 in alg. 3 encapsulates this check. Note that garbage collection never prematurely disrupts the RV analysis that tracers conduct, as invocations to ANALYSE.EVT always precede TRYGC checks in our logic of algs. 1 and 3.

4 Correctness validation

We assess the validity of RIARC in two stages. First, we confirm its implementability by instantiating the core logic of algs. 1–3 to Erlang. Our implementation targets two RV scenarios: online and offline monitoring [64, 22]. Second, we subject the implementation to a series of systematic tests using a selection of instrumentation set-ups. These tests exhaustively emulate the interleaved execution of the SuS and tracer processes by generating all the *valid* permutations of events in a set of traces. This exercises the tracer choreography invariants mentioned in sec. 3, confirming the integrity of the tracer DAG topology under each interleaving. We also use specialised RV monitor signatures in ANALYSE.EVT to assert the soundness (def. 1) of trace event sequences analysed by tracers; see algs. 1 and 3 in sec. 3.

4.1 Implementability

Our implementation of RIARC maps the tracer processes from sec. 3 to Erlang actors. The routing (Π), instrumentation (Λ), and traced-processes (Γ) maps constituting the tracer state σ are realised as Erlang maps for efficient access. Trace event buffers κ coincide with actor mailboxes, while the remaining logic in algs. 1–3 translates directly to Erlang code. This one-to-one mapping gives us confidence that our implementation reflects the algorithm logic.

In *online* RV, monitors analyse trace events while the SuS executes, whereas the *offline* setting defers this analysis until the system terminates; [8, fig. 11 in app. B.1] captures the distinction in process tracing between online and offline instrumentation in our setting (showing trace buffers only). The online instrumentation set-up employs the tracing infrastructure offered by the EVM, which deposits SuS trace event messages in tracer mailboxes. Erlang tracing complies with tracing assumption A₁, enabling RIARC to instrument disjoint SuS processes sets. We configure the EVM with the `set_on_spawn` flag so that spawned processes automatically inherit the same tracer as their parent [42]. This tracer assignment is atomic, meeting tracing assumption A₂. We also use the `procs`, `send`, and `receive` tracing flags, which constrain the events emitted by the EVM to \diamond , \star , $!$, and $\#$. The EVM enforces single-process tracing, i.e., tracing assumption A₃, and guarantees that \diamond events of descendant processes are causally-ordered [128], i.e., tracing assumption A₄.

The offline counterpart differs only in its tracing layer, where events are read as *recorded* runs of the SuS. Recorded runs can be acquired externally, e.g. using DTrace [36] or LTTng [56], making it possible to monitor systems that execute outside of the EVM. Our bespoke offline tracing engine of [8, fig. 11b in app. B.1] fulfils tracing assumptions A₁–A₄. This is crucial since it permits the *same* implementation of RIARC to be used in online and offline settings. Sec. 4.2 leverages this aspect to validate RIARC exhaustively using trace permutations.

We develop two versions of the TRACE, CLEAR, and PREEMPT functions of [8, alg. 5 in app. A] to standardise tracing for online and offline use. The overloads for online use access the EVM tracing via the Erlang built-in primitive `trace` [42]. The second set of overloads wraps around our offline tracing engine to replay files containing specifically-formatted trace events. Offline tracing relaxes tracing assumption A₄, as recorded runs do not generally guarantee that the \diamond events of descendant SuS processes are causally ordered. Our offline tracing logic relies on the PID information carried by \diamond events to rearrange them and recover the causal ordering per tracing assumption A₄. $\text{TRACE}(\iota_S, \iota_T)$ registers a tracer ι_T with the offline tracing engine, which maintains an event buffer for ι_T , together with a set of SuS PIDs that ι_T traces. A tracer can use TRACE with multiple SuS PIDs to register to obtain events for a process set, i.e., tracing assumption A₁. The tracing engine accumulates the events it reads from file in each tracer buffer and delivers events to the corresponding tracer mailbox once the causal ordering between \diamond events of descendant SuS processes is established. Our offline tracing engine implements tracing inheritance (tracing assumption A₂) and enforces single-process tracing (tracing assumption A₃); [8, ex. 7 in app. B.1] sketches how the tracing engine uses its internal tracer buffers to deliver events to tracers.

4.2 Correctness

Conventional testing does not guarantee the absence of concurrency errors due to the different interleaved executions that may be possible [105]. While subjecting the system under test to high loads raises the likelihood of obtaining more coverage, this still depends on external factors, such as scheduling, which dictate the executions induced in practice. Controlling the conditions for concurrency testing requires a *systematic exploration* of all the interleaved executions [74]. In fact, it is *not the size* of the testing load that matters, but the choice of interleaved executions that exhaust the space of possible system states [14]. Concuerror [48] is a tool for systematic Erlang code testing. Unfortunately, we could not use Concuerror to test our RIARC implementation, as we were unable to integrate it with Erlang tracing.

We, nevertheless, adopt the systematic scheme advocated by Concuerror. Our approach uses the offline tracing tool described in sec. 4.1 to induce specific interleaved sequences for instrumentation set-ups, such as those of figs. 1b, 1c, and 2a. We obtain these sequences by taking all the sound (def. 1) event permutations of traces produced by the SuS. These sequences are then replayed by the offline tracing engine to systematically induce interleaved SuS executions. Our final RIARC implementation embeds further invariants besides those mentioned in sec. 3, e.g. the `assert` and `fail` statements in algs. 1 and 3. Readers are referred to [8, app. B.2] for the full list. We ascertain *trace soundness* for each SuS interleaving that is emulated. This is accomplished via the function ANALYSE_EVT, which we preload with monitors that assert the event sequence expected at each tracer. We also use identical tests in our empirical evaluation of sec. 5 under high loads. It is worth mentioning that while we systematically drive the execution of the SuS, we do not control the execution of tracers. Yet, we indirectly induce various dynamic tracer arrangements in the monitor DAG topology under the different groupings of SuS process sets that tracers instrument. For example, we fully instrument system depicted in fig. 2a in all its configurations, e.g. $\mathcal{C}_1 = [T_{\{P\}} \rightsquigarrow$

$\{P\}, T_{\{Q\}} \rightsquigarrow \{Q\}, T_{\{R\}} \rightsquigarrow \{R\}$, $C_2 = [T_{\{P,Q\}} \rightsquigarrow \{P,Q\}, T_{\{R\}} \rightsquigarrow \{R\}]$, \dots , $C_5 = [T_{\{P,Q,R\}} \rightsquigarrow \{P,Q,R\}]$, as well as instrument it partially, e.g. $C_6 = [T_{\{P\}} \rightsquigarrow \{P\}]$, $C_7 = [T_{\{P,Q\}} \rightsquigarrow \{P,Q\}]$, etc. Each of these configurations, when individually paired with every fabricated interleaved execution of the SuS, indicate that our RIARC implementation and corresponding logic of sec. 3 is correct.

5 Empirical evaluation

We assess the feasibility of our RIARC implementation, confirming it safeguards the *responsive*, *resilient*, *message-driven*, and *elastic* attributes of the SuS. Sec. 4 targets a small selection of instrumentation set-ups to induce interleaved execution sequences and validate correctness exhaustively. We now employ *stress testing* [109] to investigate how RIARC performs in terms of the *runtime overhead* it exhibits. Our study focusses on *online* monitoring, as its overhead requirement is far more stringent than offline monitoring [63, 64, 22, 71]. We evaluate RIARC against inline instrumentation since the latter is regarded as the most efficient instrumentation technique [62, 61, 22]. This comparison establishes a solid basis for our results to be generalised reliably. We also compare RIARC to centralised instrumentation to confirm that the latter approach does not scale under typical loads.

Our experiments are extensive. We use two hardware platforms to model edge-case scenarios based on limited hardware and general-case scenarios using commodity hardware. The evaluation subjects inline, centralised, and RIARC instrumentation to high loads that go beyond the state of the art and use realistic workload profiles. We gauge overhead under three performance metrics, the *response time*, *memory consumption*, and *scheduler utilisation*, which are crucial for reactive systems [7, 109]. Our results confirm that the overhead RIARC induces is adequate for applications such as soft real-time systems [42, 94], where the latency requirement is typically in the order of seconds [92]. We also show that RIARC yields overhead comparable to inlining in settings exhibiting moderate concurrency.

5.1 Benchmarking tool

Benchmarking is standard practice for gauging runtime overhead in software [100, 77, 35]. Frameworks, including DaCapo [28] and Savina [84], offer limited concurrency, making them inapplicable to our case; see [8, app. C.1] for detailed reasons. Industry-proven *synthetic* load testing benchmarking tools cater to reactive systems, e.g. Apache JMeter [67], Tsung [115], and Basho Bench [23]. Their general-purpose design, however, necessarily treats systems as a black box by gathering metrics externally, which may impact measurement *precision* [7]. Moreover, these load testers generate standard workloads, e.g. Poisson processes [79, 102, 89], but lack others, e.g. load bursts, that replicate typical operation or induce edge-case stress.

We adopt BenchCRV [7], another synthetic load testing tool specific to RV benchmarking for reactive systems. BenchCRV sets itself apart from the tools mentioned above because it does not require external software (e.g., a web server) to drive tests. Instead, BenchCRV produces different SuS models that *closely emulate* real-world software behaviour. These models are based on the master-worker paradigm [120]: a pervasive architecture in distributed (e.g. Big Data stream processing frameworks, render farms) and concurrent systems [129, 73, 55, 132]. Like Tsung and Basho Bench, BenchCRV exploits the lightweight EVM process model to generate highly-concurrent synthetic workloads.

BenchCRV creates master-worker models and induces workloads derived from configurable parameters. In these models, the master process spawns a series of workers and allocates tasks. The volume of workers per benchmark run is set via the parameter n . Each worker task consists of a *batch* of requests that the worker receives, processes, and echoes back to

the master process. The amount of requests batched in one task is given by the parameter w . Workers terminate when all of their allotted tasks are processed and acknowledged by the master. BenchCRV creates workers based on *workload profiles*. A profile dictates how the master spreads its creation of workers along the loading timeline, t , given in seconds. BenchCRV supports three workload profiles based on ones typical in practice:

Steady models the SuS under stable workload (Poisson process).

Pulse models the SuS under gradually rising and falling workload (Normal distribution).

Burst models the SuS under stress due to workload spikes (Log-normal distribution).

BenchCRV records three performance metrics to give a multi-faceted view of system overhead:

Mean response time in milliseconds (ms), gauging monitoring latency effects on the SuS.

Mean memory consumption in GB, gauging monitoring memory pressure on the SuS.

Mean scheduler utilisation as a percentage of the total processing capacity, showing how monitors maximise the scheduler use.

The prevalent use of the master-worker paradigm, the veracity with which BenchCRV models systems, the range of realistic workload profiles, and the choice of runtime metrics it gathers make this tool ideal for our experiments. We refer readers to [8, app. C.2] and [7] for details.

5.2 Benchmark configuration

The BenchCRV master-worker models we generate take the role of the SuS in our experiments. We consider *edge-case* and *general-case* hardware platform set-ups for the following reasons:

P_E **Edge-case** captures platforms with *limited* hardware. It uses an Intel Core i7 M620 64-bit CPU with 8GB of memory, running Ubuntu 18.04 LTS and Erlang/OTP 22.2.1.

P_G **General-case** captures platforms with *commodity* hardware. It uses an Intel Core i9 9880H 64-bit CPU with 16GB of memory, running macOS 12.3.1 and Erlang/OTP 25.0.3.

The EVMs on platforms P_E and P_G are set with 4 and 16 scheduling threads, respectively. These scheduler settings coincide with the processors available on each SMP [12] platform. We also use the P_E and P_G platforms with two concurrency scenarios for reactive systems:

C_H **High concurrency scenarios** perform short-lived tasks, e.g. web apps that fulfil thousands of HTTP client requests by fetching static content or executing back-end commands.

C_M **Moderate concurrency scenarios** engage in long-running, computationally-intensive tasks, e.g. Big Data stream processing frameworks.

Our benchmark workloads match the hardware capacity afforded by P_E and P_G:

High concurrency benchmarks on P_E set $n = 100k$ workers and $w = 100$ work requests per worker. These generate $\approx (n \times w \text{ requests} \times w \text{ responses}) = 20M$ message exchanges between the master and worker processes, totalling $\approx (20M \times ! \text{ events} \times ? \text{ events}) = 40M$ analysable trace events. Platform P_G sets $n = 500k$ workers batched with $w = 100$ requests to produce $\approx 100M$ messages and $\approx 200M$ trace events. The high concurrency model C_H is studied in sec. 5.4.

Moderate concurrency benchmarks on P_G set $n = 5k$ workers and $w = 10k$ work requests per worker. These settings yield roughly the same number of trace events as on P_G with concurrency scenario C_H. The moderate concurrency model C_M is studied in sec. 5.5.

All experiments in secs. 5.4 and 5.5 use a total loading time of $t = 100s$. Each experiment consists of *ten* benchmarks that apply Steady, Pulse, and Burst workloads. We repeat every experiment *thrice* to obtain *negligible variability* and ensure the accuracy of our results; see [8, app. C.4] for a summary of these workloads and [8, app. C.5] for the precautions we take.

The hardware, OS, and Erlang versions of platforms P_E and P_G, combined with the workloads of concurrency scenarios C_H and C_M provide generality to our conclusions.

5.3 Instrumentation configuration

One challenge in conducting our experiments is the lack of RV monitoring tools targeting the EVM. To the best of our knowledge [64, tables 3 and 4], detectEr [72, 18, 19, 17, 70, 40] is the only RV tool for Erlang that implements centralised outline instrumentation². We are unaware of inline RV tools besides [38] and [3, 4]. Since the former tool is *unavailable*, we use the latter, more recent work³. In our experiments, we instrument the master *and each* worker process in the SuS models generated from sec. 5.2 to exert the highest possible load and capture *worst-case* scenarios. BenchCRV annotates work requests and responses with a unique sequence number to account for each message in benchmark runs. We leverage this numbering to write specialised monitor replicas that ascertain the *soundness* of trace event sequences reported to every RV monitor linked with the master and workers; see [8, app. C.5] for details. Equally crucial, this runtime checking introduces a degree of *realistic* RV analysis slowdown that is *uniform* across all monitors in the inline, centralised, and RIARC monitoring set-ups. We empirically estimate this slowdown at $\approx 5\mu\text{s}$ per analysed event.

5.4 High concurrency benchmarks

We study runtime overhead in the high concurrency scenario C_H with two aims. First, we show the effect overhead has on the SuS as it executes. Specifically, we consider how the memory consumption and scheduler utilisation impact the *latency* a client of the SuS experiences, e.g. end-user or application. We use the edge-case platform P_E for these experiments; analogous results obtained on P_G are detailed in [8, app. C]. Our second goal targets the general-case platform P_G to assess the *scalability* of the instrumentation methods through their optimal use of the *additional* memory and scheduler capacity afforded by P_G .

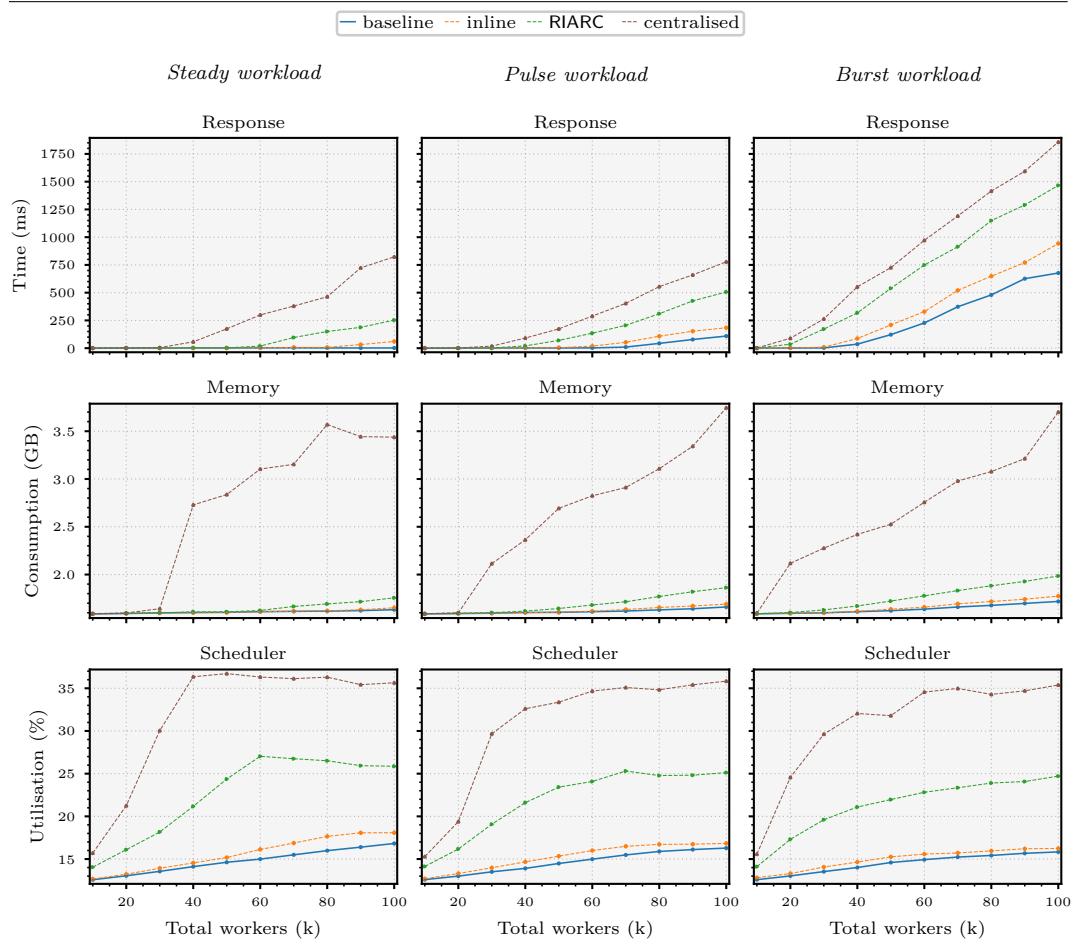

The charts in secs. 5.4.1–5.4.3 plot performance metrics, e.g. memory consumption (y -axis) against the number of concurrent worker processes or the execution duration (x -axis). Since inline instrumentation prevents us from delineating the SuS and monitoring-induced runtime overhead, we follow the standard RV literature practice and include the *baseline* plots, e.g. [19, 72, 46, 38, 99, 114, 112]. Baseline plots show the *unmonitored* SuS to compare the relative overhead between each evaluated instrumentation method.

5.4.1 Instrumentation overhead

The first set of experiments isolates the instrumentation overhead induced on the SuS: this is the aggregated cost of tracing *and* reporting the traces soundly per def. 1 to RV monitors. Crucially, these experiments *omit monitors*, as we want to quantify the instrumentation overhead and understand its impact on the SuS. This enables us to focus on the differences between inlining – regarded as the most efficient instrumentation method [62, 61, 22] – and outlining. As far as we know [64, 71], outlining has *never* been used for decentralised RV in a *dynamic* setting such as ours. While we confirm that inline instrumentation uses less memory and scheduler capacity, RIARC dynamically scales and economises their use *without* adverse impact on the latency. In fact, the latency induced by RIARC is a mere 519ms higher than that of inline instrumentation at the peak stress-inducing loading point of 3.7k workers/s under Burst workloads. Our experiments indicate that centralised instrumentation manages resources poorly due to its inability to scale, increasing the chances of failure; see sec. 5.4.2.

³ <https://github.com/ScienceofComputerProgramming/SCICO-D-22-00294>

■ **Figure 7** Isolated instrumentation overhead (*high workload, 100k workers*).

Fig. 7 plots our results. Centralised instrumentation carries the largest overhead penalty. Regardless of the workload applied, it uses the most memory, $\approx 3.8\text{GB}$, highlighting its ineptitude to scale. This stems from the backlog of trace event messages that accumulate in the mailbox of the central tracer and is a manifestation of two aspects. First, the central tracer does not consume events at the same rate worker processes produce them. Evidence of this *bottleneck* is visible as high scheduler utilisation in fig. 7 (bottom). This values settles at $\approx 36\%$ for the benchmarks with $\approx 40\text{k}$ workers under the Steady workload and $\approx 60\text{k}$ workers under Pulse and Burst workloads. Interpreting these $< 36\%$ scheduler usage values in isolation may suggest that centralised instrumentation has the potential to scale. However, its memory consumption plots in fig. 7 (middle) contradict this erroneous hypothesis.

By contrast, RIARC uses fewer resources to yield lower response times across the three workloads. The scheduler utilisation for RIARC slightly plateaus in the Steady ($\approx 60\text{k}$ workers) and Pulse ($\approx 70\text{k}$ workers) workload charts. This is not owed to scalability limitations of RIARC but to the intrinsic throttling instigated by the master process [120]. In fact, the plots for the baseline system and inline instrumentation in fig. 7 (middle) exhibit analogous signs of throttling. Even at a peak Burst workload of 3.7k workers/s, inline and RIARC instrumentation consume fairly similar amounts of memory, 1.7GB vs. 1.9GB , respectively.

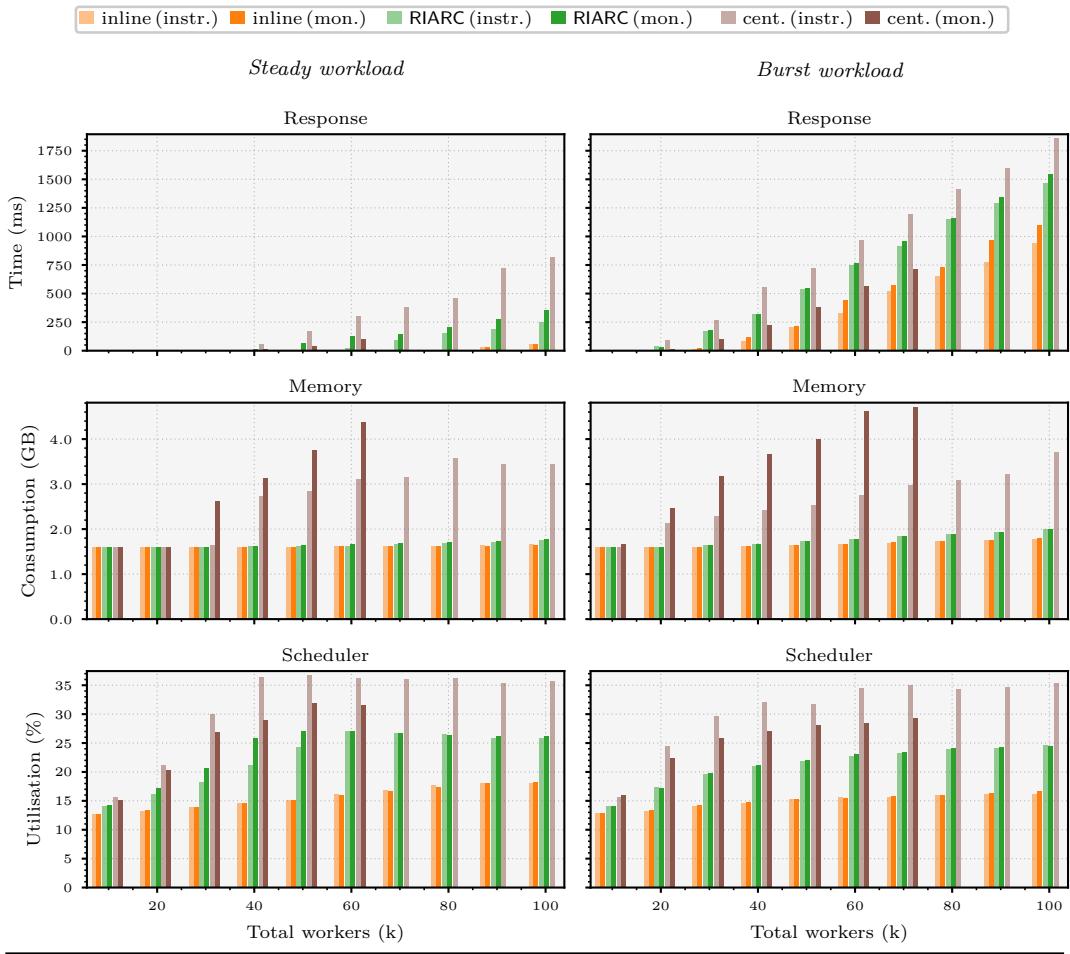

Figure 8 Instrumentation and RV monitoring overhead gap (*high* workload, 100k workers).

5.4.2 Monitoring overhead

Our second set of experiments extends the results of sec. 5.4.1 and quantifies the cost of RV monitoring. The *runtime monitoring* overhead combines the instrumentation and slowdown due to the RV analysis, established at $\approx 5\mu\text{s}$ per event in sec. 5.3 for our experiments. Fig. 8 plots the instrumentation (*instr.*) overhead from sec. 5.4.1 next to the runtime monitoring overhead (*mon.*). It shows that the RV analysis slowdown aggravates centralised monitoring to the point of crashing. Inline and RIARC monitoring are minimally affected. Our results also reveal that the instrumentation incurs the *major* overhead portion, not the RV analysis. Sec. 5.6 comments on this finding in the context of existing RV tools.

Fig. 8 plots our results under the Steady and Burst workloads; [8, fig. 14 in app. C.6.1] includes all three workloads. The charts for centralised monitoring exhibit a significant disparity between the instrumentation and runtime monitoring bar plots as the workload increases. This trend is consistent across both workloads in fig. 8. The lack of scalability of centralised monitoring in fig. 8 manifests as an increase in memory consumption but stabilised scheduler usage, as in fig. 7. Memory consumption and scheduler usage for centralised monitoring grow rapidly beyond $\approx 30\text{k}$ and $\approx 20\text{k}$ workers under the Steady and Burst workloads, respectively. Bottlenecks led our experiments to crash (shown as missing

bar plots in fig. 8). Crashes occur at $\approx 70k$ workers under the Steady and at $\approx 80k$ under Burst workload. By analysing the resulting dumps, we could attribute these crashes to memory exhaustion, which caused the EVM to fail. The dumps indicate severe memory pressure due to the vast backlog of trace event messages in the mailbox of the central tracer.

Inline and RIARC monitoring scale to accommodate the RV analysis slowdown. This is confirmed by cross-referencing the memory consumption and scheduler utilisation in fig. 8 for both monitoring methods. Each displays comparable overhead in their respective instrumentation and corresponding runtime monitoring bar plots. Fig. 8 (top) shows that inline and RIARC monitoring increase the latency, albeit for different reasons. The internal operation of RIARC enables us to deduce that its latency stems from message routing and dynamic tracer reconfiguration. Its scheduler utilisation plots support this observation. The latency due to inlining is a direct effect of RV analysis slowdown, provoked by the lock-step execution of monitors and the SuS. Other works, e.g. [46, 37], offer similar observations.

Dissecting our results uncovers further subtleties. The optimal scheduler utilisation of RIARC implies that its monitors are only active when triggered by trace events but remain idle otherwise. This inference is supported by the absence of sudden or continued memory growth for RIARC in fig. 8 (middle). The instrumentation and runtime monitoring latency bar plots for inline monitoring exhibit a growing pairwise gap that starts at $\approx 80k$ workers in fig. 8 (top right). The respective gap for RIARC at this mark is perceptibly lower. We credit this lower latency gap to outlining, which absorbs the slowdown effect of RV analyses. This leads us to conjecture that RIARC could accommodate monitors that perform richer RV analyses with minimal impact on the SuS. Our calculations from fig. 8 (top right) put the latency at 1093ms for inline monitoring vs. 1547ms for RIARC at a peak Burst workload of 3.7k workers/s: a 454ms difference, which is *lower* than the 519ms gap measured in sec. 5.4.1. Sec. 5.5 shows this gap is negligible in moderate concurrency scenarios.

5.4.3 Resource usage

We employ platform P_G with high concurrency C_H to confirm that our observations about inline and RIARC monitoring transfer to general cases. Secs. 5.4.1 and 5.4.2 deem centralised monitoring to be impractical. We, thus, omit it from the sequel; see [8, app. C.6.3] for results.

Our experiments now use 16 scheduling threads, $n = 500k$ workers, and $w = 100$ requests per worker, producing $\approx 100M$ messages and $\approx 200M$ trace events; [8, fig. 13 in app. C.4] render these Steady, Pulse, and Burst workload models. Secs. 5.4.1 and 5.4.2 bound the memory and scheduler metrics to the period the SuS executes to portray the *actual overhead* impact on the system. We refocus that view to assess the monitoring overhead in *its entirety* – from the point of SuS launch until monitors complete their RV analysis. Doing so reveals how inline and RIARC monitoring optimise the use of added memory and processing capacity. Results show that inline and RIARC monitoring are elastic and dynamically adapt to changes in the applied workloads; [8, app. C.6.3] confirms that centralised monitoring lacks this trait.

Fig. 9 gives a complete benchmark run under the Steady and Burst workloads. We relabel the x -axis with the benchmark duration and omit the response time plots since response time is inapplicable to these experiments (latency is an attribute of the SuS, not the monitors). In this run, the Steady workload generates a sustained load of $\approx 5k$ workers/s whereas Burst peaks at $\approx 17.8k$ workers/s under maximum load at $\approx 5s$; see [8, fig. 13 in app. C.4].

Fig. 9 (top) illustrates the memory consumption patterns for inline and RIARC monitoring, which exhibit *elasticity*. This elastic behaviour occurs at different points in the plots. Inline monitoring peaks at $\approx 3.7GB$ at $\approx 72s$ and RIARC at $\approx 5.7GB$ at $\approx 100s$ under the Burst workload. The memory consumption for both methods stabilises at around $\approx 36s$ under the Steady workload, with $\approx 2.3GB$ for inline and $\approx 2.7GB$ for RIARC monitoring.

Elasticity in these methods is due to different reasons: it is intrinsic to inline monitoring (see sec. 1), whereas the RIARC spawns and garbage collects monitors on demand (secs. 3.1 and 3.6). These observations are certified by [8, fig. 16 in app. C.6.3] under the Pulse workload. Centralised monitoring is *insensitive* to the workload applied, as [8, figs. 17 and 18 in app. C.6.3] reconfirm.

The effect of dynamic message routing and tracer reconfiguration that RIARC performs is evident in the scheduler utilisation plots of fig. 9. Under the Steady and Burst workloads, scheduler utilisation oscillates continually due to the sustained influx of trace events. Oscillations corroborate our observation in sec. 5.4.2 about RIARC, namely, that monitors are activated by trace events but remain idle otherwise. Active monitor periods manifest as peaks in fig. 9. Idle periods, where monitors are placed in the EVM waiting queues, are reflected as regions with low and stable scheduler utilisation. These oscillations showcase the message-driven aspect of RIARC, which analyses events asynchronously. Inlining exhibits minimal scheduler utilisation oscillations due to its lock-step execution with the SuS.

5.5 Moderate concurrency benchmarks

Our last experiment studies moderate concurrency scenarios C_M . The general-case platform P_G sets $n = 5k$ workers and $w = 10k$ requests per worker, and uses 16 EVM schedulers. We show that under these loads, RIARC induces overhead on par with inline monitoring.

Moderate concurrency alters the execution of the master-worker model, compared to our benchmarks of secs. 5.4.1–5.4.3. In this set-up, the master creates most of its worker processes at the initial stage of benchmark runs and spends the remaining time allocating work requests. This change grows the request throughput, e.g. see [8, tbl. 5 in app. C.4]. One consequence is that centralised monitoring consistently crashes under the rapid accumulation of messages in its mailbox. We, thus, limit our study to inline and RIARC monitoring.

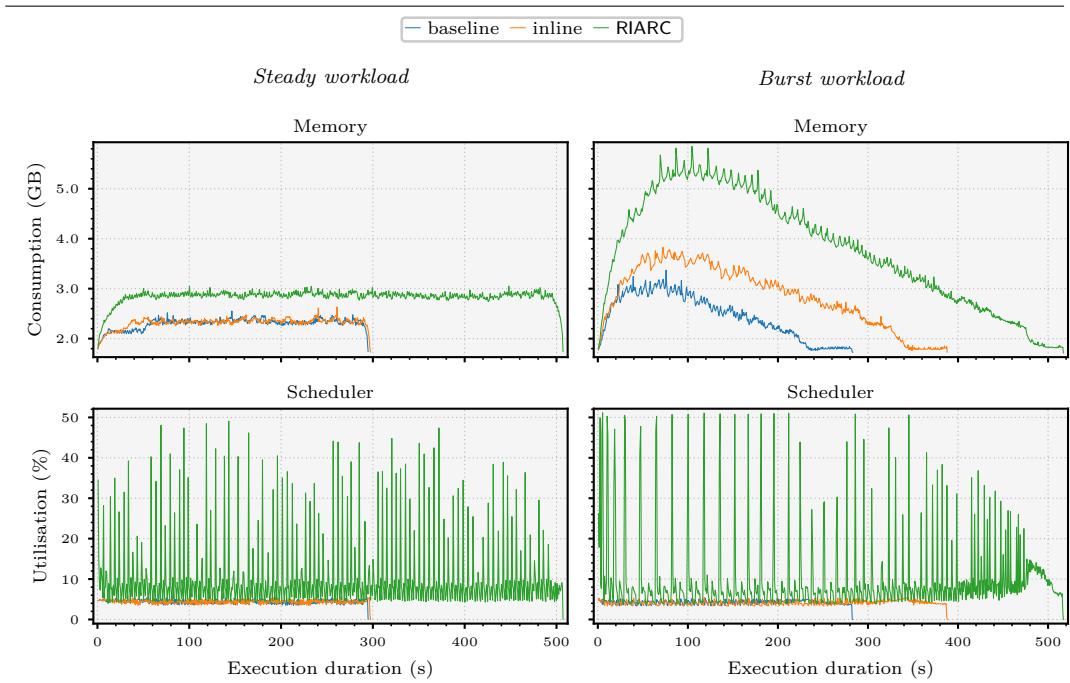

Figure 9 Inline and RIARC monitoring resource usage (*high* workload, 500k workers).

Tbl. 3 compares the results taken on platform P_G from sec. 5.4.3 with 500k workers (high concurrency, C_H) against the ones on P_G with 5k workers (moderate concurrency, C_M). The figures shown estimate the percentage overhead w.r.t. the baseline systems C_H and C_M at this *maximum* load. Our ensuing discussion is limited to the overhead under the Steady and Burst workloads since each respectively captures the SuS operation in *typical* and *severe* load conditions. Readers are referred to [8, fig. 20 in app. C.6.4] for the overhead comparison given in absolute metric values for the entirety of benchmark runs.

Tbl. 3 indicates that the memory consumption overhead due to inline monitoring is not affected under the Steady workload, which remains at 1% in both the high and moderate concurrency scenarios C_H and C_M . However, it decreases from 16% in C_H to 1% in C_M . We observe the opposite effect on the scheduler utilisation overhead for inline monitoring. For the moderate concurrency case C_M , the scheduler overhead under the Steady and Burst workloads increases to 3% and 4% respectively.

Tbl. 3 also shows that under the Steady workload, RIARC induces a 23% memory overhead in concurrency scenario C_H vs. 8% in concurrency scenario C_M , a decrease of 15%. Under the Burst workload, this overhead is reduced by 46%, from 56% in C_H to 10% in C_M . The scheduler utilisation overhead for RIARC from C_H to C_M also registers drops of $\approx 71\%$ under both Steady and Burst workloads. We attribute these overhead improvements to the lower number of worker processes the master creates in the moderate concurrency set-up, C_M . The long-running worker processes induce stability in the SuS. RIARC adapts to this change favourably by performing fewer trace event routing and tracer reconfigurations. The ramification of this adaptability is perceivable in the latency overhead discussed next.

RIARC inflates the latency overhead from 95% in C_H to 194% in C_M under the Steady workload (+99%), and from 97% in C_H to 190% in C_M under the Burst workload (+93%). However, RIARC induces *less latency* overhead than inline monitoring. Tbl. 3 reveals that the latency overhead for inline monitoring grows from 4% in the high concurrency set-up C_H to 246% in the moderate concurrency set-up C_M under the Steady workload (+242%). It also grows under the Burst workload, from 55% in C_H to 193% in C_M (+138%). In fact, our calculations confirm that the *absolute* response time for inline monitoring is slightly worse than that of RIARC in C_M : 116ms vs. 98ms under the Steady, and 182ms vs. 179ms under the Burst workloads respectively. This latency degradation for inline monitoring stems from the $\approx 5\mu s$ slowdown induced by the RV analysis, which results in frequent “pausing” of worker processes. Monitors comprising richer analyses produce longer pauses in worker processes, which can degrade the response time further [46, 37, 69].

■ **Table 3** Percentage overhead on C_H (500k) and C_M (5k) w.r.t. baseline at *maximum* workload.

Concurrency	Workload	Response time %	Memory consumption %	Scheduler utilisation %	
		Inline	RIARC	Inline	RIARC
C_H (500k)	Steady	4	95	1	23
	Burst	55	97	16	56
C_M (5k)	Steady	246	194	1	8
	Burst	193	190	1	10
				0	0
				3	3
				4	4
				123	123
				52	52
				50	50

5.6 Discussion

The RIARC scheduler utilisation in tbl. 3 is higher than the reported values for inline monitoring. This should not be construed as an inefficiency. From a reactive systems perspective, growth in the scheduler utilisation indicates *scalability*, as the low memory consumption in tbl. 3 affirms. RIARC benefits from the ample schedulers to improve the overall system response time *without* overtaxing the system. Indeed, [8, fig. 20 in app. C.6.4] demonstrates that the mean absolute scheduler utilisation in the benchmarks of sec. 5.5 is just $\approx 10\%$ under both the Steady and Burst workloads. Tbl. 3 shows that the reduction in latency makes RIARC comparable to inline monitoring in moderate concurrency scenarios.

Sec. 1 names *responsiveness* as a key reactive systems attribute [94]. RIARC prioritises responsiveness by isolating its monitors into asynchronous concurrent units. This design naturally exploits the available processing capacity of the host platform by maximising monitor *parallelism* when possible. Inline monitoring reaps fewer benefits in identical settings because its lock-step execution with the SuS robs it of potential parallelism gains.

Secs. 5.4.1 – 5.4.3 attest to the impracticality of centralised monitoring for reactive systems. Bottlenecks hinder its ability to scale, compelling it to consume inordinate amounts of memory, which can lead to failure, as sec. 5.4.2 shows. Despite these shortcomings, many RV tools in this setting use centralised monitoring, e.g. [50, 18, 126, 65, 81, 110, 72, 37, 41, 38, 2, 103].

6 Conclusion

Reactive software calls for instrumentation methods that uphold the responsive, resilient, message-driven, and elastic attributes of systems. This is attainable *only if* the instrumentation exhibits these qualities. Runtime verification imposes another demand on the instrumentation: the trace event sequences it reports to monitors must be *sound*, i.e., traces do not omit events and preserve the ordering with which events occur locally at processes.

This paper presents RIARC, a novel decentralised instrumentation algorithm for outline monitors meeting these two demands. RIARC uses outline monitors to decouple the runtime analysis from system components, which minimises latency and promotes *responsiveness*. Outline monitors can fail independently of the system and each other to improve *resiliency*. RIARC gathers events non-invasively via a tracing infrastructure, making it *message-driven* and suited to cases where inlining is inapplicable. The algorithm is *elastic*: it reacts to specific events in the trace to instrument and garbage collect monitors on demand.

Our asynchronous setting complicates the instrumentation due to potential trace event loss or reordering. RIARC overcomes these challenges using a next-hop IP routing approach to rearrange and report events soundly to monitors. We validate RIARC by subjecting its corresponding Erlang implementation to rigorous systematic testing, confirming its correctness. This implementation is validated via extensive empirical experiments. These subject the implementation to large realistic workloads to ascertain its reactiveness. Our experiments show that RIARC optimises its memory and scheduler usage to maintain latency feasible for soft real-time applications. We also compare RIARC to inline and centralised monitoring, revealing that it induces *comparable* latency to inlining under moderate concurrency.

Related work. Other work on inlining besides that cited in sec. 1, e.g. [78, 25, 50, 49, 53], does not separate the instrumentation and runtime analysis. This view is commonplace in monolithic settings, where the instrumentation is often assumed to induce minimal runtime overhead. As a result, many inline approaches focus on the efficiency of the analysis but neglect the instrumentation cost (e.g. [63] attributes overhead solely to the analysis). These

arguments for monolithic systems are often ported to concurrent settings. For instance, [107, 126, 29, 46, 125, 66, 21] propose efficient runtime monitoring algorithms but do not account for, nor quantify, the overhead due to gathering trace events. Tools that measure the runtime overhead, such as [41, 37, 19, 34, 72, 133], coalesce the instrumentation and runtime analysis costs, making it difficult to gauge the source of inefficiencies. Some literature [39, 52] even extends the assumption about minimal instrumentation overhead to offline monitoring, stating that the instrumentation consists of “only” capturing trace events. Sec. 5.4.1 shows this *not* to be the case. We are unaware of empirical studies such as ours that concretely distinguish between and quantify the instrumentation and runtime analysis overhead.

Sec. 5.6 remarks that centralised monitoring is used for concurrent runtime verification despite its evident limitations. One plausible reason for this is that the empirical scrutiny of such tools lacks proper benchmarking (e.g. [50, 18, 126, 65, 81]) or uses insufficient workloads that fail to expose the issues of centralised set-ups (e.g. [110, 72, 37, 41, 38, 2, 103]). Gathering inadequate metrics can also bias the interpretation of empirical data; see sec. 5.4.1. Works, such as [38, 19, 34, 124], consider the memory consumption and latency metrics. Our evaluation of inline, centralised, and RIARC monitoring uses (i) *combinations* of hardware and software, with (ii) two concurrency models that test *edge-case* and *general-case* scenarios, under (iii) *high* workloads that go beyond the state of the art, applying (iv) *realistic* workload profiles, interpreted against (v) *relevant* performance metrics that give a multi-faceted view of runtime overhead. To the best of our knowledge, this is generally not done in other studies, e.g. [114, 113, 47, 46, 119, 30, 106, 38, 41, 19, 50, 51, 53, 72, 59, 60, 27, 110, 97, 34].

Outline instrumentation decouples the execution of the SuS and monitor components in space (i.e., isolated threads) and time (i.e., asynchronous messaging). The tracing infrastructure outline instrumentation uses mirrors the publish-subscribe (Pub/Sub) pattern [129]. In this set-up, consumers subscribe to a *broker* that advertises events. Centralised instrumentation follows a Pub/Sub approach: the SuS produces trace events and deposits them into *one* global trace buffer that tracers receive from (see fig. 1b). Despite similarities, e.g. tracers register and deregister with the tracing infrastructure at runtime, RIARC differs from conventional Pub/Sub messaging in three fundamental aspects. Chiefly, Pub/Sub publishers are unaware of the subscribers interested in receiving messages because this bookkeeping task is appointed to the broker. By contrast, next-hop routing relies on knowing the *explicit* address of recipients to forward messages. Furthermore, in Pub/Sub messaging, subscribers do not communicate with publishers, whereas RIARC tracers exchange *direct* detach requests between one another to reorganise the choreography (refer to sec. 3.4). Lastly, Pub/Sub brokers are typically predefined and remain fixed, while trace partitioning *reconfigures* the tracing topology, creating and destroying brokers in reaction to dynamic changes in SuS.

One assumption we make about process tracing is A₄, i.e., tracing gathers the spawn events of parent processes before all the events of child processes. While A₄ induces a partial order over trace events, it is *weaker* than happened-before causality [95], as the events gathered from sets of child SuS processes need not be causally ordered. Demanding the latter condition would entail additional computation on the part of the tracing infrastructure and could increase runtime overhead. Maintaining minimal overhead is critical to our instrumentation because it preserves the responsiveness attribute of reactive systems. Tracing assumption A₄ and the RIARC logic detailed in sec. 3 guarantee trace soundness (def. 1), which suffices for RV monitoring. Since our work targets soft real-time systems [94, 92] scoped in a reliable messaging setting (see sec. 1), we do not tackle the problem of ensuring time-bounded causally-ordered message delivery [20] nor implement exactly-once delivery semantics [83]. We will address these challenges in future extensions of this work.

Abstract

Verification of smart contracts is an important topic in the context of blockchain technology. We study an approach to verification that is based on symbolic execution.

As a formal basis for symbolic execution, we design a dynamic logic for Michelson, the smart contract language of the Tezos blockchain, and prove its soundness in the proof assistant Agda. Towards the soundness proof we formalize the concrete semantics as well as its symbolic counterpart in a unified setting. The logic encompasses single contract runs as well as inter-contract runs chained in a single transaction.

1 Introduction

Blockchain technology and smart contracts provide decentralized and immutable systems for secure transactions and automated agreements. Smart contracts have been targets of spectacular and costly attacks as contracts are immutable and their source code is publicly available on the blockchain. Hence, it is vital as well as challenging to ensure the correctness of smart contracts before their deployment. Formal methods and various verification techniques have been proposed to address this challenge.

The Tezos blockchain [14] and its smart contract language Michelson have been designed from ground up with verification in mind. Several frameworks have been developed based on, e.g., interactive theorem proving [10], refinement typing [27], and automated theorem proving [5]. We are interested in automated verification of Michelson programs, which rules out interactive approaches. Symbolic execution [20, 11] is one of the standard approaches to automatically obtain verification conditions like weakest preconditions for failures as well as normal termination from a program. Next, an SMT-solver discharges these verification conditions. There is a wide range of approaches that apply symbolic execution combined with SMT-solving to smart contracts, mostly for the Ethereum blockchain (see Section 6).

While there are many approaches to symbolic execution [12, 13, 30], we choose one based on dynamic logic. Dynamic logic (DL) [16] is a modal logic for reasoning about programs. Its signature features are modalities for program execution. These modalities enable the expression of assertions about program behavior as logical formulas. For instance, the formula

3:2 Dynamic Logic for Symbolic Execution for Michelson

$[p]\Psi$ states partial correctness: if program p terminates, then Ψ is true. That is, a Hoare triple $\{\Phi\} p \{\Psi\}$ can be encoded by $\Phi \rightarrow [p]\Psi$. DL also provides a modality $\langle p \rangle$ for total correctness, but we do not consider it in this work.

Dynamic logic comes with proof rules for the modality derived from the structure of p . For example, if $p; q$ stands for sequential execution of p and q , then the proof rule $[p; q]\Psi \leftrightarrow [p][q]\Psi$ states that execution of p enables execution of q such that Ψ holds in the end. Similarly, the rule $[\varepsilon]\Psi \leftrightarrow \Psi$ states that the empty program ε does not modify the validity of Ψ .

In the past, dynamic logic has been used successfully for as a basis for symbolic execution in the context of the verification of Java programs [9], as it is particularly well suited to keep track of a changing environment (i.e., mutable objects on Java’s heap). We design a DL to model Michelson execution because we want to reason about transactions that span several contract runs. In Michelson terminology, these transactions are called *chained contract executions*, where an externally started contract run initiates further internal contract runs. Our DL design models the relevant parts of the blockchain run-time system on top of the purely functional execution of Michelson programs. On the level of the run-time system contracts are very similar to objects: they are identified by an address and they come with mutable attributes (state and balance).

The DL treatment of the functional part of Michelson is quite intuitive: programs are sequences of Michelson instructions, we model the execution state of a Michelson program by a formula of the form $\Phi \rightarrow [p]\Psi$, and the proof rules for $[i;p]\Psi$ (where i is a single instruction) define the semantics of symbolic execution.

Gas is an important aspect of computation on the blockchain. The initial caller of a contract has to pay for executing the transaction (consisting of one or more chained contract runs) in terms of gas. A transaction that runs out of gas is rolled back by the run-time system of the blockchain as if it never happened. As Michelson does not suffer from reentrancy problems (cf. Section 2), gas does not affect reasoning about the functional correctness of (chained) contract execution. For that reason, our DL design does not account for gas.

It is the sole goal of this paper to provide a **machine verified specification** of symbolic execution for Michelson, rather than an efficient or otherwise realistic implementation. For that reason, the paper does not cover all instructions, but rather a carefully chosen representative subset. This is in contrast to related work [10, 27, 5] that describes **actual verification tools**. To be useful for a wide range of programs, such a tool must support as many Michelson instructions as possible¹, it must be reasonably efficient, and it must deal with loops and nontermination in an appropriate way. None of these issues are concerns for our specification.

Contributions

1. We select a representative subset of Michelson instructions so as to provide proof templates for all current and future instructions that work similarly.
2. We provide a parameterized semantics definition with instances for the concrete semantics as well as for an abstract semantics, which implements the dynamic logic for Michelson.
3. We prove the soundness of this logic first for single programs, and then for several programs chained in a transaction.

The Agda implementation of the contributions is available.²

¹ Keeping up with the rapid evolution of the language is challenging for those tools. As of this writing, most of them support the instruction set available in late 2022.

Overview

Section 2 gives an overview of Michelson, introduces its type system and our intrinsically typed representation of the language. Section 3 defines the execution model of Michelson, first for single contracts, and then for the chained execution of several contracts that call each other. Section 4 introduces dynamic logic and its symbolic execution rules, again first for single execution, and then for chained execution. Section 5 explains the major components of the soundness proof of the dynamic logic. Section 6 discusses related work and conclusions.

The paper contains many excerpts from the live, type checked definitions and proofs in Agda. In particular, all major definitions and statements of theorems are shown in Agda notation to ensure consistency of the paper with the machine-checked proofs.

2 Michelson

Michelson [25, 28] is the native language for smart contracts on the Tezos blockchain. It is a low level, stack-based, simply-typed, purely functional programming language. That is, all computation is driven by transforming an input stack into an output stack. There are no mutable data structures; blockchain transactions are handled outside of Michelson. All contracts are statically typed to avoid run-time type errors.

Each Michelson instruction transforms a given input stack into an output stack where some of its values have been changed, added, or removed. For example, the ADD instruction accepts any stack whose two topmost elements are numbers, and returns a stack where these two values have been replaced by their sum. The remaining stack is unchanged.

`ADD : 15 :: 27 :: remainingStack \mapsto 42 :: remainingStack`

2.1 Types

Michelson supports the usual data types like numbers, pairs, and lists as well as some blockchain-specific types for tokens and contracts. Figure 1a contains Agda definitions for a select subset of Michelson types `Type`. As some base types can be treated alike later on, we represent them with a separate type `BaseType`.

Most types' names are self explanatory. The base type '`mutez`' stands for tokens, `addr` stands for blockchain addresses in Tezos. We introduce shorthand patterns for base types for readability. The type `operation` consists of blockchain operations that can be emitted during contract execution. This mechanism implements token transfers from the current contract to other accounts or contracts. The type `contract P` represents such a contract which accepts a parameter of type `ty` represented by `P : Passable ty`. The type predicate `Passable : Type \rightarrow Set` originates from the Michelson specification and characterizes types that can be passed as parameters to contracts. Its declaration is mutually recursive with `Type`.

The semantics of types is defined by a mapping to Agda types. Most Michelson types have obvious Agda counterparts, except `addr`, `contract`, and `operation`. Addresses and contracts are both represented by natural numbers. The difference is that a value of type `contract` is known to be a valid address of a contract of suitable type. We only define one alternative of the `Operation` datatype: `transfer-tokens v m c`, which models a token transfer to contract `c` while passing the parameter value `v` and tokens `m`.³

³ At the time of writing this paper, full Michelson also supports the operations `CREATE-CONTRACT`, `EMIT` (deliver an event to an external application), and `SET-DELEGATE` (delegate stakes to another account).

```

Addr = N - blockchain addresses
Mutez = N - Tezos currency
data Operation : Set

data BaseType : Set where
  'unit 'nat 'addr 'mutez : BaseType

data Type where
  operation : Type
  base      : BaseType → Type
  pair      : Type → Type → Type
  list option : Type → Type
  contract   : ∀ {t} → Passable t → Type

pattern unit  = base 'unit
pattern nat   = base 'nat
pattern addr  = base 'addr
pattern mutez = base 'mutez

[ ] : Type → Set
[ unit ]     = T
[ nat ]      = N
[ addr ]     = Addr
[ mutez ]    = Mutez
[ operation ] = Operation
[ pair t1 t2 ] = [ t1 ] × [ t2 ]
[ list t ]   = List [ t ]
[ option t ] = Maybe [ t ]
[ contract P ] = Addr

data Operation where
  transfer-tokens : ∀ {P : Passable t}
    → [ t ] → [ mutez ] → [ contract P ]
    → Operation

```

(a) Syntax.

(b) Semantics.

Figure 1 Michelson Types.

2.2 Programs and Instructions

Michelson programs are intrinsically typed, that is, only well-typed programs can be written. Accordingly, they are represented in Agda by a datatype `Program` indexed by the types on the input stack and the types on the output stack. We assume that `Stack` = `List Type`.

```

data Program : Stack → Stack → Set
data Instruction : Stack → Stack → Set

data Program where
  end : Program S S
  _ ;_ : Instruction Si So → Program So Se → Program Si Se

```

Instructions are indexed in the same way: If instruction `inst` maps an input stack of type `Si` to an output stack of type `So` and `prg` maps that output stack `So` to the final stack of type `Se`, then `inst ; prg` is a program that maps `Si` to `Se`. The empty program `end` does not transform the stack.

We discuss a representative subset of Michelson instructions shown in Figure 2. The definition of `Instruction+` implements the pattern that most instructions only transform a fixed number of elements on top of the input stack and are parametric in the rest.

The first group of instructions operates on a fixed number of values on the stack and pushes the result. All arithmetic operations belong to this group and we just give two examples, `ADDnn` and `ADDm`, which perform addition of natural numbers and tokens, respectively. Michelson language overloads arithmetic operators, but as overloading is not supported by Agda, we supply separate instructions. We come back to this issue at the end of this section.

```

Instruction+ : Stack → Stack → Set
Instruction+ a b = ∀ {s} → Instruction (a ++ s) (b ++ s)

data Instruction where
  ADDnn : Instruction+ [ nat ; nat ] [ nat ]
  ADDm : Instruction+ [ mutez ; mutez ] [ mutez ]
  CAR : Instruction+ [ pair t1 t2 ] [ t1 ]
  CDR : Instruction+ [ pair t1 t2 ] [ t2 ]
  PAIR : Instruction+ [ t1 ; t2 ] [ pair t1 t2 ]
  NONE : ∀ t → Instruction+ [] [ option t ]
  SOME : Instruction+ [ t ] [ option t ]
  NIL : ∀ t → Instruction+ [] [ list t ]
  CONS : Instruction+ [ t ; list t ] [ list t ]
  TRANSFER-TOKENS : ∀ {P : Passable t} → Instruction+ [ t ; mutez ; contract P ] [ operation ]

  DROP : Instruction+ [ t ] []
  DUP : Instruction+ [ t ] [ t ; t ]
  SWAP : Instruction+ [ t1 ; t2 ] [ t2 ; t1 ]
  UNPAIR : Instruction+ [ pair t1 t2 ] [ t1 ; t2 ]

  AMOUNT : Instruction+ [] [ mutez ]
  BALANCE : Instruction+ [] [ mutez ]
  CONTRACT : (P : Passable t) → Instruction+ [ addr ] [ option (contract P) ]

  PUSH : Data t → Instruction+ [] [ t ]

  IF-NONE : Program S Se → Program (t :: S) Se → Instruction (option t :: S) Se
  ITER : Program (t :: S) S → Instruction (list t :: S) S
  DIP : ∀ n → {T (n ≤b length S)} → Program (drop n S) Se → Instruction S (take n S ++ Se)

```

■ **Figure 2** Instructions of Core Michelson.

CAR, **CDR**, and **PAIR** are the standard operations on pairs. **NONE** and **SOME** are the constructors for the **option** datatype, and **NIL** and **CONS** construct lists. The constructors for “empty” containers, **NONE** and **NIL** are indexed by the element type, otherwise that type can be inferred from the context.

The last instruction in this group is **TRANSFER-TOKENS**. Despite the name, this instruction does **not** directly transfer tokens to another account. It rather constructs a value **transfer-tokens** *v m c* of type **operation** from its arguments.

The instructions in the next group differ in that they push zero or more values on the output stack. **DROP** pops the stack, **DUP** duplicates the top of the stack, **SWAP** swaps the top entries, and **UNPAIR** eliminates a pair and pushes its contents. **UNPAIR** is a convenience instruction as it is equivalent to the instruction sequence **DUP**; **CDR**; **SWAP**; **CAR**.

The next group contains instructions that are blockchain specific. **AMOUNT** returns the tokens that were transferred with the currently running contract invocation and **BALANCE** returns the tokens currently owned by it. The **CONTRACT** instruction is indexed by a type *t* that must be **Passable**. It takes an address and checks on the blockchain whether this address is associated with a contract that accepts arguments of type *t*. The result is communicated as an **option** type. That is, the **contract** type carries a verified address.

The **PUSH** instruction pushes a value of type *t* on the stack. The value is encoded by a type-indexed datatype **Data** for pushable values. We elide its straightforward definition.

3:6 Dynamic Logic for Symbolic Execution for Michelson

The last group of instructions showcases control structures and an instruction that operates in a non-uniform way on the stack. The instruction **IF-NONE** eliminates a value of **option** type from the top of the stack. Its parameters are programs that implement the branches for case **None** and **Some**. The latter takes the value wrapped in the **Some** constructor as an argument on top of the stack.

The instruction **ITER** runs a sub-program on every element of its argument list. The instruction **DIP** n runs a sub-program at depth n on the input stack, that is, it skips over the first n elements of the stack, runs the sub-program, and reattaches those elements. The extra machinery in the implicit argument of the instruction makes sure that there are at least n elements on the stack. This mechanism is called reflection in the PLFA textbook [33].

Earlier, we remarked that Agda does not allow overloading of constructors in the same datatype. However, we can use reflection to define a “smart constructor” that almost suits the purpose.

```

overADD : (t1 t2 : Type) → Maybe (Ξ[ t ] Instruction+ [ t1 ; t2 ] [ t ])
overADD nat   nat   = just (nat   , ADDnn)
overADD mutez mutez = just (mutez , ADDm)
overADD _      _     = nothing

ADD : ∀ (p : map proj1 (overADD t1 t2) ≡ just t) → Instruction+ [ t1 ; t2 ] [ t ]
ADD{t1} {t2} {t} p with overADD t1 t2
... | just (t , add) with just-injective p
... | refl = add

```

The definition exploits the fact that the input stack of an instruction is always known in a Michelson program. The same fact also enables overloading in Michelson’s implementation to work. The function **overADD** specifies the resolution of overloading for the **ADD** instruction. If the argument types are both **nat**, then the result type is **nat** and the chosen instruction is **ADDnn**; and so on.⁴ If no overloading is known for a combination of arguments, the function returns **nothing**. The smart constructor **ADD** takes a proof that the overloading is defined on a given pair of input types. Then it extracts the selected instruction from the overloading.

Compared to “real” Michelson, the smart constructor requires an extra argument to work:

```

exnat : Program [ (pair nat nat) ] [ (pair nat nat) ]
exnat = DUP ; UNPAIR ; ADD refl ; DROP ; end

```

2.3 Blockchain Interface

A contract on the Tezos blockchain is indexed by a parameter type p and a store type s . The type p must be **Passable** and the type s must be **Storable**. Moreover, each contract comes with a current balance of tokens and a store of type s . The implementation of the contract is a program that maps a **pair** $p\ s$ to a **pair** (**list operation**) s , that is, it consumes the parameter paired with the current store and produces a list of operations (e.g., to invoke further contracts) paired with the updated store. The program itself is pure; any side effects, i.e., store update and contract calls, are managed by the blockchain runtime.

⁴ The full Michelson language has ten different overloadings of **ADD**.

```
record Contract (Mode : MODE) (p s : Type) : Set where
  constructor ctr
  field Param  : Passable p
  Store     : Storable s
  balance   : M Mode mutez
  storage   : M Mode s
  program   : Program [ pair p s ] [ pair (list operation) s ]
```

The *Mode* argument abstracts over the semantics of types. Its type has three components, one \mathcal{M} for the semantics and the others, \mathcal{F} and \mathcal{G} , are used by the abstract semantics in Subsection 4.2.

```
record MODE : Set1 where
  field M : Type → Set ; F : Set ; G : Set
```

Its instantiation for the concrete semantics installs the standard semantics of types from Section 2.1. The remaining components are instantiated to the unit type \top .

```
CMode : MODE
CMode = record { M = [] ; F = ⊤ ; G = ⊤ }
```

With this definition, the contract store of the blockchain is just a partial mapping from addresses to contracts.

```
Blockchain : (Mode : MODE) → Set
Blockchain Mode = Addr → Maybe (Ξ[ p ] Ξ[ s ] Contract Mode p s)
```

To start executing a contract, we initiate a blockchain transaction to its address, i.e., we ask the blockchain runtime to transfer tokens to its address along with its parameter. Once a contract has terminated, the runtime updates the stored value and processes the list of operations.

On the Tezos blockchain a normal account with deposit *init* corresponds to a contract with a unit parameter, unit store, and a trivial program that issues no operations.

```
Account : Mutez → Contract CMode unit unit
Account init = ctr unit unit init tt (CDR ; NIL operation ; PAIR ; end)
```

3 Michelson Reference Implementation

Program execution is defined in a small-step manner by a function that maps the current execution state of a program to a new state resulting from executing the first instruction:

```
prog-step : CProgState ro → CProgState ro
```

The type `CProgState ro` is a record that contains an input stack type ri , a program that maps an ri stack to an ro stack, an input stack of type ri , and the execution environment. `prog-step` executes the first instruction that must map an ri stack to an intermediate stack of type re , say. Consequently, the program in the output `CProgState` maps an re stack to an ro stack. As instructions as well as programs are intrinsically typed, the intermediate stack type re is sure to match. Likewise, the typing of `prog-step` ensures type preservation.

```

record ProgState (Mode : MODE) (ro : Stack) : Set where
  constructor state
  field {ri} : Stack
    en : Environment Mode
    prg : ShadowProg{M Mode} ri ro
    stk : All (M Mode) ri
    Φ : F Mode

prog-step ρ | fct ft ; p
= record ρ { prg = p ; stk = app-fct ft (H.front (stk ρ)) H.++ H.rest (stk ρ) }
prog-step ρ | DROP ; p
= record ρ { prg = p ; stk = H.rest (stk ρ) }

```

■ **Figure 3** Program state and single program step execution (excerpt).

3.1 Program Execution

So far we only concerned ourselves with the type of a Michelson stack. For program execution, both the types and values of stack elements are relevant. To this end, we have to lift the interpretation of a single type, i.e., a function from `Type` to `Set`, to the interpretation of a list of types. The library predicate `All` does exactly that: it “maps” a `Set`-typed function over a list, which yields (the type of) a heterogeneously typed list.

For example, the value interpretation of a type stack is a value stack where corresponding elements t and v are related by the type interpretation, that is, $v : \llbracket t \rrbracket$.

$$\begin{array}{ll} \text{Int} : \text{Stack} \rightarrow \text{Set} & \text{a-stack} : \text{Int} (\text{nat} :: \text{unit} :: \text{option addr} :: []) \\ \text{Int} = \text{All } \llbracket _ \rrbracket & \text{a-stack} = 42 :: \text{tt} :: \text{nothing} :: [] \end{array}$$

The definition of a program state (see Figure 3) abstracts over a `Mode` which contains a type interpretation that allows us reuse the same structure for concrete execution and abstract execution. A program state contains the program that is currently executed, the stack, and an environment which provides the context information to execute blockchain instructions like `AMOUNT` and `BALANCE`. It is parameterized by the output stack type, which does not change during execution. When executing more than one contract as we demonstrate in Sec. 3.4, this parameterization ensures that the results from completed contract executions are well typed.

The function `prog-step` executes the first instruction of a program on the current state. We explain two exemplary cases shown in Figure 3. To explain the first stanza of the code we have to make a confession. As several instructions have very similar semantics, our internal representation of instructions is a refinement of the datatype shown in Figure 2. For example, all instructions that just apply a function to the top of the stack are grouped under a constructor `fct` and `func-type` is the type defining these instructions.

$$\text{fct} : \text{func-type} \text{ args results} \rightarrow \text{Instruction}^+ \text{ args } [\times \text{ results}]$$

The function `app-fct` applies such a function to a concrete stack. Roughly speaking, if the underlying function has type $a_1 \rightarrow \dots \rightarrow a_n \rightarrow (r_1 \times \dots \times r_m)$ it gets transformed into a function between heterogeneously typed lists $[a_1, \dots, a_n] \rightarrow [r_1, \dots, r_m]$. We elide the

definition and just remark that the function $[\times _]$ implements the transformation between $(r_1 \times \dots \times r_m)$ and $[r_1, \dots, r_m]$. The functions `H.front` and `H.rest` (in Fig. 3) split the input stack according to the stack types expected by the function `ft`. The function `H.++` is concatenation of heterogeneous lists.

The `DROP` instruction drops the top of the stack.

3.2 Execution of Control Flow Instructions

We have chosen a small-step semantics because its stepwise progression matches the stepwise proof rules of the dynamic logic. However, the Michelson specification defines the semantics in terms of a big-step judgment.⁵

```
record Configuration (ri : Stack) : Set where
  constructor Conf
  field cenv : CEnvironment ; stk : Int ri

  data [_._]↓ : Configuration ri → Program ri ro → Int ro → Set
```

It relates a configuration (environment and input stack of type ri) and a program to an output stack of type ro . The definition of the semantics in the Michelson specification takes some liberties that require some extra machinery in a small-step execution model. We discuss these issues with some representative instructions.

The instruction `IF-NONE p-none p-some` expects a value of type `option` on top of the stack. If that value is `nothing` (the encoding of `NONE`), the $p\text{-}none$ branch is executed on the rest of the stack:

```
↓-IF-NONE : ∀ {p-none : Program txs tys} {p-some : Program (tx :: txs) tys}
  → [ Conf ce xs , p-none ]↓ ys
  -----
  → [ Conf ce (nothing :: xs) , IF-NONE p-none p-some ]↓ ys
```

If however the top of the stack is `just x` (encoding `SOME x`), the $p\text{-}some$ branch is executed on the stack where `just x` is replaced with x :

```
↓-IF-SOME : ∀ {p-none : Program txs tys} {p-some : Program (tx :: txs) tys}
  → [ Conf ce (x :: xs) , p-some ]↓ ys
  -----
  → [ Conf ce (just x :: xs) , IF-NONE p-none p-some ]↓ ys
```

To specify the corresponding small-step rule we introduce a type-respecting concatenation operator $\text{;}\bullet$ on programs. The program `IF-NONE p-none p-some ; p-rest` either transitions to $p\text{-}none ;\bullet p\text{-}rest$ or to $p\text{-}some ;\bullet p\text{-}rest$, depending on the value on top of the stack.

The instruction `DIP n p` executes program p on the stack that results from removing the first n elements of the current stack and reattaches them afterwards.

```
↓-DIP : ∀ {n} {q : T (n ≤b length txs)} {p-dip : Program (drop n txs) tys}
  → [ Conf ce (H.drop n xs) , p-dip ]↓ ys
  -----
  → [ Conf ce xs , DIP n {q} p-dip ]↓ (H.take n xs H.++ ys)
```

⁵ For typing reasons the implementation splits it in four judgments for programs \Downarrow , instructions \downarrow , shadow programs \Downarrow , and shadow instructions \downarrow^t .

3:10 Dynamic Logic for Symbolic Execution for Michelson

In the small-step version, dropping the first n elements of the stack is easy, but reattaching them requires extra machinery. Thus, a mechanism for holding on to the top of the stack while executing the subprogram and retrieving it afterwards is necessary.

Execution of **ITER** requires the same feature in a slightly different way. It consumes the list on top of the current stack. If the list is empty, it is dropped from the stack:

$$\begin{aligned} \downarrow\text{-ITER-NIL} : & \forall \{p\text{-iter} : \text{Program } (t :: t_{xs})\ t_{xs}\} \\ & \dashline \\ & \rightarrow [\text{Conf } ce ([\] :: xs), \text{ITER } p\text{-iter}] \downarrow xs \end{aligned}$$

Otherwise the subprogram is applied to the first list element v and then the **ITER** instruction is reissued on the rest of the list vs and the current stack:

$$\begin{aligned} \downarrow\text{-ITER-CONS} : & \forall \{v : [\] t\} \{vs : [\] \text{list } t\} \{xs\ ys\ zs : \text{Int } t_{xs}\} \{p\text{-iter} : \text{Program } (t :: t_{xs})\ t_{xs}\} \\ & \rightarrow [\text{Conf } ce (v :: xs), p\text{-iter}] \Downarrow ys \\ & \rightarrow [\text{Conf } ce (vs :: ys), \text{ITER } p\text{-iter}] \Downarrow zs \\ & \dashline \\ & \rightarrow [\text{Conf } ce ((v :: vs) :: xs), \text{ITER } p\text{-iter}] \Downarrow zs \end{aligned}$$

The typing for **ITER** requires that the type of the underlying stack is preserved, but the subprogram $p\text{-iter}$ is entitled to access and modify the stack beyond the first element x . Let's now consider stepwise execution. If the list on top has the form $v :: vs$, we need to stash the tail list vs somewhere while the subprogram processes the stack with v on top. After execution of the subprogram, we have to recover vs and try again with **ITER**.

As subprograms can be arbitrarily complex, in particular, they may contain **DIP** and **ITER**, we need a nestable solution. To this end, we add a single new instruction **MPUSH1** that pushes a single value on the stack. This instruction is different from the normal **PUSH** instruction, which is limited to **Pushable** values that have a textual representation.

$$\begin{aligned} \text{data } \text{ShadowInst } \{\mathcal{M} : \text{Type} \rightarrow \text{Set}\} : \text{Stack} \rightarrow \text{Stack} \rightarrow \text{Set} \text{ where} \\ \text{MPUSH1} : \forall \{t : \text{Type}\} \rightarrow \mathcal{M} t \rightarrow \text{ShadowInst } rS (t :: rS) \end{aligned}$$

We call the new instruction a *shadow instruction* because it does not appear in input programs. It is indexed by two stack types like any other instruction. A *shadow program* is defined like **Program**, but its first instruction can be a normal instruction or a shadow instruction. Shadow programs only appear at the top-level, never as subprograms nested in instructions. We elide the definition of **ShadowProg** as it is analogous to **Program**. Moreover, we provide a utility function **mpush** to generate a sequence of **MUSH1** instructions from a list of values.

$$\begin{aligned} \text{mpush} : & \forall \{\mathcal{M} : \text{Type} \rightarrow \text{Set}\} \{ri\} \{ro\} \{front : \text{Stack}\} \\ & \rightarrow \text{All } \mathcal{M} \ front \rightarrow \text{ShadowProg}\{\mathcal{M}\} (\text{front} ++ ri) ro \rightarrow \text{ShadowProg}\{\mathcal{M}\} ri ro \\ \text{mpush } [\] & sp = sp \\ \text{mpush } (x :: xs) & sp = \text{mpush } xs (\text{MPUSH1 } x \bullet sp) \end{aligned}$$

The small-step version of **DIP** n dp takes the top n elements from the stack and starts executing the program dp followed by the new instruction **mpush** $front$ where $front$ is the list of the n values that were removed from the stack.

$$\begin{aligned} \text{prog-step } \rho \mid \text{DIP } n\ dp ; p \\ = \text{record } \rho \{ \text{prg} = dp ; \bullet \text{mpush } (\text{H.take } n (\text{stk } \rho)) p ; \text{stk} = \text{H.drop } n (\text{stk } \rho) \} \end{aligned}$$

```
example-ITER : Program [ list nat ; nat ] [ nat ]
example-ITER = ITER (ADDnn ; end) ; end
```

■ **Figure 4** Simple program using **ITER**.

■ **Table 1** Program states during execution of Figure 4.

rSI	prg
[18 , 24] :: 0 :: []	ITER (ADD)
18 :: 0 :: []	ADD ; MPUSH [24] ; ITER (ADD)
18 :: []	MPUSH [24] ; ITER (ADD)
[24] :: 18 :: []	ITER (ADD)
24 :: 18 :: []	ADD ; MPUSH [] ; ITER (ADD)
42 :: []	MPUSH [] ; ITER (ADD)
[] :: 42 :: []	ITER (ADD)
42 :: []	end

The small-step version of **ITER** *ip* just pops the stack if the list is empty. Otherwise, if the top contains *v :: vs*, it pops this value, puts *v* on top of the stack and executes *ip* followed by **mpush** [*vs*] and then **ITER** *ip* and the rest of the program.

```
prog-step  $\rho$  | ITER ip ; p with stk  $\rho$ 
... | [] :: rsi = record  $\rho$  { prg = p ; stk = rsi }
... | (v :: vs) :: rsi = record  $\rho$  { prg = ip ;• (MPUSH1 vs • (ITER ip ; p)) ; stk = v :: rsi }
```

For illustration, Table 1 gives the stacks and shadow program of each intermediate state resulting from applying **prog-step** to the program in Figure 4 until program termination for the given input stack interpretation (omitting **end** for readability). This program adds a list of numbers on top of the stack to the number below.

3.3 Relation to Big-Step Semantics

Executing a program requires iterating the **prog-step** function. Our implementation drives this iteration by a step counter that is counted down at each instruction.

```
prog-step* :  $\mathbb{N} \rightarrow \text{CProgState } ro \rightarrow \text{CProgState } ro$ 
prog-step* zero  $\rho = \rho$ 
prog-step* (suc n)  $\rho = \text{prog-step* } n \text{ (prog-step } \rho\text{)}$ 
```

We prove that the original big-step semantics and our small-step semantics are equivalent in the usual sense.

```
bigstep $\Rightarrow$ smallstep :  $\forall (prg : \text{ShadowProg } txs tys)$ 
   $\rightarrow$  [ Conf ce xs , prg ] $\Downarrow$  ys
   $\rightarrow$   $\exists [ n ] \text{ prog-step* } n \text{ (cstate ce prg } xs\text{)} \equiv \text{cstate ce end } ys$ 

smallstep $\Rightarrow$ bigstep :  $\forall n \rightarrow (prg : \text{ShadowProg } txs tys) \rightarrow \{xs : \text{Int } txs\} \{ys : \text{Int } tys\}$ 
   $\rightarrow$  prog-step* n (cstate ce prg xs)  $\equiv$  cstate ce end ys
   $\rightarrow$  [ Conf ce xs , prg ] $\Downarrow$  ys
```

3:12 Dynamic Logic for Symbolic Execution for Michelson

```

record PrgRunning (Mode : MODE) : Set where
  constructor pr
  field {pp ss x y} : Type
    self      : Contract Mode pp ss
    sender    : Contract Mode x y

  MPstate : RunMode Mode
  pending : List (Transaction Mode)

```

■ **Figure 5** Contract execution state.

3.4 Contract Execution and Execution Chains

The `prog-step` function can execute any Michelson program, not only those that comply to the typing restrictions of a contract. But it does not provide a mechanism to update the blockchain after successful contract execution nor one to execute other blockchain operations which might be emitted by a contract.

To implement these aspects of contract execution, the `ProgState` is augmented with further information as shown in Figure 5. The record `PrgRunning` holds the contracts involved in the current execution: `self` is the current contract and `sender` is the sender (the account that started the current contract). The `ExecState` holds the `Blockchain`, where contract execution results are saved, and a list of pending blockchain transactions to be executed. A value of type `Transaction` comprises a list of operations and the address of the sender of these operations. The field `MPstate` encodes the current mode of execution. `Run` indicates that a contract is currently executing the program in `PrgRunning` where we can take a step. `Cont` indicates the transition between one contract and the next; execution proceeds with the next pending blockchain operation. The \mathcal{F} argument is used by the abstract execution to propagate information between contract invocations. `Fail` indicates a failure along with an error code in its \mathcal{G} argument.

```

exec-step σ@(exc accts (Run (pr self _ (state en end [ new-ops , new-storage ] _))) pend)
= record σ{ accounts = set (self-address en) (upd-storage self new-storage) accts
; MPstate = Cont tt
; pending = (new-ops , self-address en) :: pend }
exec-step σ@(exc _ (Run pr@(pr _ _ ρ)) _)
= record σ{ MPstate = Run (record pr{ ρ = prog-step ρ }) }

```

Figure 6 Program execution.

The function `exec-step : CExecState → CExecState` maps an execution state to its successor state just like `prog-step` did for program states. It only implements the features mentioned above that cannot be modeled by the program state alone. Its definition is too big to include it in full; instead we briefly explain its implementation, giving each case in the same order as in the implementation.

Figure 6 contains the cases when a contract is executing.

1. When execution of the current contract has terminated (i.e., `MPstate` is `Run pr` and `ProgState.prg` matches `end`), then intrinsic typing ensures that the stack interpretation contains the emitted blockchain operations `new-ops` paired with the new storage value `new-storage`. We add the emitted operations to the `pending` field, update the terminated contract’s storage on the blockchain, and switch to `RunMode Cont`.
2. In all other cases of a running program, its `ProgState` evolves using `prog-step`.

In the remaining cases `MPstate` is `Cont tt` which means that no contract is currently executed. In this case `pending` is checked for other operations to be executed. Our model only implements the `TRANSFER-TOKENS` operation that initiates a new contract execution. We perform the following checks in this case:

- we fail unless the operation was emitted from a valid account;
- we fail unless the type of the parameter matches the input type of the called contract;
- we fail unless the target is a valid account;
- we fail unless the sender’s balance contains sufficient tokens to support the transfer.

The first three cases can never occur during an actual execution of a Michelson smart contract execution chain: The `TRANSFER-TOKENS` instruction only works for values of type `contract t`, which ensures validity of the target address and that the parameter type is `t`. Moreover, operations can only be emitted by valid accounts. The checks are needed in our model because it does not maintain information about which addresses are valid contract addresses. We chose not to include this information as it adds complexity without contributing to our goal of proving the soundness of symbolic execution.

4 Dynamic Logic for Michelson

To obtain a dynamic logic suitable for symbolic execution we follow the Key approach [9] and extend first order logic with a modality $[p]$, where p is a program state. The intuitive meaning is that $[p]\Psi$ holds for a formula Ψ , if running p terminates in a state such that Ψ holds. That is, the formula $\Phi \rightarrow [p]\Psi$ has a similar meaning as the Hoare triple $\{\Phi\} p \{\Psi\}$.

In the following, we concentrate on the proof rules for the modality. For instance (and ignoring the details of the program state for now), $\Phi \rightarrow [end]\Psi \equiv \Phi \rightarrow \Psi$ if the program is empty. Many simple proof rules have the form $\Phi \rightarrow [i; p]\Psi \equiv \Phi_i \wedge \Phi \rightarrow [p]\Psi$ where the formula Φ_i describes the effect of instruction i . If the instruction is a branch instruction on a predicate Q , like `if Q p1 p2`, the resulting formula is a disjunction as in $\Phi \rightarrow [(if Q p1 p2); p]\Psi \equiv Q \wedge \Phi \rightarrow [p1; p]\Psi \vee \neg Q \wedge \Phi \rightarrow [p2; p]\Psi$.

```

data _ $\vdash$ _ ( $\Gamma$  : Context) : Type → Set where
  var   :  $t \in \Gamma \rightarrow \Gamma \vdash t$ 
  const : [[ base bt ]] →  $\Gamma \vdash \text{base } bt$ 
  contr :  $\forall \{P : \text{Passable } t\} \rightarrow \text{Addr} \rightarrow \Gamma \vdash \text{contract } P$ 
  func  : 1-func args result → Match  $\Gamma$  args →  $\Gamma \vdash result$ 

data Formula ( $\Gamma$  : Context) : Set where
  'false  : Formula  $\Gamma$ 
  _:=_   :  $t \in \Gamma \rightarrow \Gamma \vdash t \rightarrow \text{Formula } \Gamma$ 
  _<_m_ : mutez ∈  $\Gamma \rightarrow \text{mutez } \in \Gamma \rightarrow \text{Formula } \Gamma$ 
  _≥_m_ : mutez ∈  $\Gamma \rightarrow \text{mutez } \in \Gamma \rightarrow \text{Formula } \Gamma$ 

```

■ **Figure 7** Terms and formulas.

We start by defining the formulas of the logic in Subsection 4.1.

4.1 Terms and Formulas

At the core of any symbolic execution there are symbolic (i.e., logical) variables representing the unknown operands. We represent such variables by a typed deBruijn index into a given Context = List Type. An abstract stack is then a list of typed variables:

```

Match : Context → Stack → Set
Match  $\Gamma$  = All (_ $\in$   $\Gamma$ )

```

Any knowledge that we have about the values on the stack is encoded in the list of formulas (over the variables on the stack) that we maintain in the program state. Figure 7 shows the terms and formulas used for the logic. Term comprise variables, constants of base type and of contract type, and simple functions. Here, “function” stands for proper functions as well as data constructors. For convenience, we restrict function arguments to variables and rely on variable equality in the formulas to specify complex terms.

As an example for the interplay between context, stack, and formulas, suppose the context defines three variables of type nat like this $\Gamma_1 = \text{nat} :: \text{nat} :: \text{nat} :: []$. An abstract stack for this context might just contain a single variable $x = 0$, where the 0 refers to the first variable in Γ_1 .

```

a-stack : Match  $\Gamma_1$  (nat :: [])
a-stack = [ x ]

```

If we further want to enforce that $x = y + 3$ (on natural numbers), then we have to encode that in two simple formulas, one that associates 3 to variable v , and another that states $x = y + v$. We do not impose a constraint on y , so it serves as an unconstrained symbolic variable.

```

x=y+3 : List (Formula  $\Gamma_1$ )
x=y+3 = x := func 'ADDnn (y :: v :: [])
          :: v := const 3
          :: []

```

Formulas are mainly used to express equality of a variable with a term. The inequalities express the ordering on tokens. The latter is used for token transfers where we have to know that the sender has sufficiently many tokens to satisfy the requirements of the transfer. The reader may wonder about conjunction and disjunction: the proof rules only generate them in the form of a disjunction of conjunctions of simple formulas. We represent this structure as a list of lists of simple formulas. Repetition does not matter in this representation for two reasons: 1. disjunction and conjunction are both idempotent; 2. we are only interested in validity of a formula, but do not transform it in any way.

4.2 Representing Michelson Program State in DL

We simplify the handling of formulas of the form $\Phi \rightarrow [p]\Psi$ by reusing our previous definition of the type `ProgState` in a different mode as an *abstract* state.

```
AMode : Context → MODE
AMode Γ = record { M = _ ∈ Γ
                    ; F = List (Formula Γ)
                    ; G = List (Formula Γ) ↗ List (Formula Γ)
                    }
```

That is, we replace the normal representation of values in \mathcal{M} by symbolic variables, in \mathcal{F} we maintain a list (i.e., conjunction) of formulas, and in \mathcal{G} we maintain a tagged list of formulas to represent different modes of failure.

The meaning of an abstract state is a conjunction that specifies the value for `AMOUNT` and `BALANCE` in the environment, it specifies the size of the stack and all values on it, and it collects further constraints generated by application of the proof rules.

Informally, an abstract program state represents $\Theta \implies [prg]\Psi$ where

$$\Theta \equiv \text{state of environment} = \text{en} \wedge \text{state of stack} = \text{stk} \wedge \bigwedge_{\phi \in \Phi} \phi$$

The encoding of the implication in the abstract program state corresponds exactly to the abstract instance of the `ProgState` type (see Figure 3). Reusing the type in this way makes the formalization of symbolic execution very similar to the concrete execution model presented in Section 3. This similarity in turn makes the soundness proof easier and more concise. All constructs for concrete execution are reused in the abstract by instantiating their `MODE` parameter. Thus, they are automatically parameterized by a `Context` Γ and the names of the structures are the same as for concrete execution but prefixed with an α (only the abstract blockchain is called β lockchain).

Symbolic execution of control flow can lead to disjunctions over such states, which is represented using a list of abstract program states. Each of the branch comes with its own state, which requires existential quantification over the types of the variables in Γ .

```
⊕Prog-state : Stack → Set
⊕Prog-state ro = List (Ξ[ Γ ] αProg-state Γ ro)
```

Using Agda lists to represent conjunctions and disjunctions is convenient for two reasons.

1. Conjunctions and disjunctions do not mix: Φ always represents a conjunction over its elements and disjunctions can only occur as a result of some symbolic execution rules that implement control flow. In this case, the disjunction always affects every aspect of the abstract program state (i.e., the remaining programs will always differ).
2. Agda’s “element of” relation for lists makes the implementation of the rules of the calculus simple and efficient.

4.3 Proof Rules for Michelson

The rules for symbolic execution are formalized by a function that maps an abstract program state into a set (list) of abstract program states.

$$\alpha_{\text{prog-step}} : \forall \{\Gamma ro\} \rightarrow \alpha_{\text{Prog-state}} \Gamma ro \rightarrow \cup_{\text{Prog-state}} ro$$

It mimics `prog-step` and gives a deterministic way of symbolic execution. Every (non-environmental) functional instruction can be executed concretely with a single rule as shown in Figure 6. During symbolic execution, the only thing that is guaranteed is that the stacks contain values of the expected type. For example, if the next instruction is `ADDnn`, we can conclude that there are two values of type `nat` on top of the stack before the instruction and one value of type `nat` afterwards. Moreover, we can say that this value is the sum of the two values that were on top of the stack before, but we have to express that with a constraint, i.e., a logical formula.

That is, symbolic execution of `ADDnn` introduces a new variable v_r that replaces the variables v_x and v_y from the top of the stack, and adds a clause that equates this new variable with the sum of the former two:

$$v_r := \text{ADDnn } v_x v_y$$

In this way, we can give a single symbolic execution rule for all functional instructions that return a single result.

$$\begin{aligned} \alpha_{\text{prog-step}} \{\Gamma\} (\text{state } \alpha_{\text{en}} (\text{fct } (\text{D1 } \{result = result\} f) ; prg) \alpha_{\text{st}} \Phi) \\ = [(result :: \Gamma) \\ , \text{state } (\text{wk}\alpha_{\text{E}} \alpha_{\text{en}}) (\text{wkSP } prg) (0\in :: \text{wkM } (\text{H.rest } \alpha_{\text{st}})) \\ (0\in := \text{wkL- } (\text{func } f (\text{H.front } \alpha_{\text{st}})) :: \text{wk}\Phi \Phi)] \end{aligned}$$

Let's decompress this definition. We pattern match against the current (abstract) state to obtain the environment α_{en} , the current instruction, the rest of the program prg , the stack α_{st} , and the formula Φ . The constructor `fct` indicates a functional instruction and the constructor `D1` indicates that f returns a single result of type `result`.

As the instruction does not implement any control flow, there is only a single next state. Its description starts with the extended context $result :: \Gamma$, which introduces a new variable of type `result` for the result. The name, rather the deBruijn address, of this variable is `0E`, which denotes the first entry in the context. The second component describes the new state, which (ignoring the `wk` functions for the moment) keeps the environment, moves to the rest of the program, pushes the result on the stack after removing the arguments using `H.rest`, and pushes a new equation that defines the value of `0E` as the result of applying f to the front of the stack. The functions `H.front` and `H.rest` operate on heterogenous lists and are defined such that $\alpha_{\text{st}} \equiv \text{H.front } \alpha_{\text{st}} \text{ H.++ H.rest } \alpha_{\text{st}}$ where the actual division is driven by the type of f . The operation `H.++` is concatenation of heterogenous lists. The `wk` functions are a consequence of using deBruijn indices for variables: if we introduce new variables, all existing variables have to be incremented by the number of new variables (i.e., weakened). We do not show their definition, as this manipulation of deBruijn indices is standard.

We do not have a general mechanism for the other functional instructions (see Figure 8), as they behave very differently in a symbolic context: `UNPAIR` requires two new variables and clauses, while `SWAP` only changes the position of two stack values. No new variables or clauses are necessary because `SWAP` only reconfigures the stack.

The instruction `PUSH` needs special treatment because it can handle arbitrarily complex compound values. When pushing a value x of primitive type, it is sufficient to add a new variable and a clause which sets this variable equal to the term `const x`. But if x has a list

```

 $\alpha\text{prog-step } \{\Gamma\} (\text{state } \alpha en (\text{fct } (\text{Dm } ('UNPAIR \{t1\} \{t2\})) ; prg) (p \in :: \alpha st) \Phi)$ 
 $= [ (t1 :: t2 :: \Gamma)$ 
 $, \text{state } (\text{wk}\alpha E \alpha en) (\text{wkSP } prg) (0 \in :: 1 \in :: \text{wkM } \alpha st)$ 
 $(0 := \text{func } 'CAR [ \text{wkE } p \in ] :: 1 := \text{func } 'CDR [ \text{wkE } p \in ] :: \text{wk}\Phi \Phi )]$ 

 $\alpha\text{prog-step } \alpha @ (\text{state } \alpha en (\text{fct } (\text{Dm } 'SWAP) ; prg) (x \in :: y \in :: \alpha st) \Phi)$ 
 $= [ -, \text{record } \alpha \{ \text{prg} = prg ; \text{stk} = y \in :: x \in :: \alpha st \} ]$ 

 $\alpha\text{prog-step } \{\Gamma\} (\text{state } \alpha en (\text{fct } ('PUSH } P x) ; prg) \alpha st \Phi)$ 
 $= [ (\text{expand}\Gamma P x ++ \Gamma)$ 
 $, \text{state } (\text{wk}\alpha E \alpha en) (\text{wkSP } prg) ((\text{ewk } (0 \in \text{ex}\Gamma P)) :: \text{wkM } \alpha st)$ 
 $(\Phi \text{wk } (\text{unfold } P x) ++ \text{wk}\Phi \Phi)]$ 

```

■ **Figure 8** Functional instructions (excerpt).

type or an option type, its value cannot be expressed with a `const` term. In general, the symbolic execution of a single `PUSH` instruction may create arbitrarily many (but linear in the size of the pushed value) new variables and clauses.

To this end, the function `unfold` $P x$ creates all clauses required to express the value x . This process defines a list of new variables of types defined by `expand Γ` $P x$.⁶ For example, `PUSH {list ty} P (y :: ys)` gives rise to two new variables r_y of type `ty` for y and r_{ys} of type `list ty` for ys and an equation $r := \text{func } (\text{CONS } [r_y, r_{ys}])$, where r is the variable for the result. The function `unfold` proceeds recursively: if $ys = []$, its variable can be set to `func (NIL ty) []`, otherwise it will be further decomposed. Similarly for y : if ty is a primitive type, it can be set to `const y`, otherwise it must be further decomposed as well.

As an example, we show the result of unfolding the list $[0, 1] : \text{list nat}$. The generated context is $\Gamma_2 = \text{list nat} :: \text{list nat} :: \text{list nat} :: \text{nat} :: \text{nat} :: []$ and the generated list of equations to represent the list is as follows.

```

eqn : List (Formula  $\Gamma_2$ )
eqn = c1 := func 'CONS (x0 :: c2 :: [])
:: c2 := func 'CONS (x1 :: c3 :: [])
:: c3 := func ('NIL nat) []
:: x0 := const 0
:: x1 := const 1
:: []

```

We finish with the abstract execution of the conditional instruction `IF-NONE` (see Figure 9). This instruction expects a value of type `option t` on top of the stack. Here we have two possible next states, depending on whether the value is present. The first disjunct deals with the case where the value is `NONE`. In this case, the stack is popped, the `thn` branch is taken, and the equation enforcing the value to be `NONE` is added. There are no new variables, so there is no weakening in this disjunct.

⁶ We do not include the tedious definitions of these auxiliary functions here, but encourage the interested reader to check the supplementary material.

```

$$\alpha_{\text{prog-step}} \{\Gamma\} (\text{state } \alpha_{en} (\text{IF-NONE } \{t = t\} \text{ thn } \text{els} ; \text{prg}) (\text{o} \in :: \alpha_{st}) \Phi) \\
= [\Gamma, \text{state } \alpha_{en} (\text{thn} ; \bullet \text{prg}) \alpha_{st} (\text{o} \in := \text{func} (\text{'NONE } t) [] :: \Phi) \\
; (t :: \Gamma), \text{state } (\text{wk}\alpha_{\text{E}} \alpha_{en}) (\text{els} ; \bullet \text{wkSP prg}) (\text{o} \in :: \text{wkM } \alpha_{st}) \\
(\text{wk}\in \text{o} \in := \text{func} \text{'SOME } [0 \in] :: \text{wk}\Phi \Phi)]$$

```

Figure 9 Symbolic execution of IF-NONE.

The second disjunct models the case where the value on top of the stack is **SOME** y . Here we need a new variable of type t for y , pop the stack and push the new variable, we take the els branch, and add an equation that forces the value to be **SOME** y .

4.4 Proof Rules for the Blockchain Run-time

Just like the symbolic execution rules for the Michelson DL, those for the DL on blockchain operations are given analogously.

```

\alpha_{\text{ExecState}} : \text{Set} \\
\alpha_{\text{ExecState}} = \text{List } (\exists[\Gamma] \alpha_{\text{ExecState}} \Gamma)

```

```

\alpha_{\text{exec-step}} : \forall \{\Gamma\} \rightarrow \alpha_{\text{ExecState}} \Gamma \rightarrow \alpha_{\text{ExecState}}

```

The switch from concrete to abstract execution state is achieve by changing the *Mode* parameter of the **ExecState** (see Figure 5). Its \mathcal{F} field replaces concrete semantics by abstract semantics throughout all state components.

Unfortunately $\alpha_{\text{exec-step}}$ cannot represent **exec-step** exactly, if **MPstate** is **Cont** Φ , that is: a contract has terminated and we need to check the **pending** field for further operations to be executed. At this point, the predicate Φ has to supply sufficient information about the values of the variables representing the pending operations to proceed in a meaningful way. The **pending** list contains pairs of a list of operations and a sender address. While the latter is a concrete address, the former is a variable of type **list operation** $\in \Gamma$. To proceed, we have to know if the list is empty (so that we can proceed to the next block of pending operations) or not. In the latter case, we need to ensure that the first element of the operation list is a **TRANSFER-TOKENS**, and so on.

To this end, we defined several auxiliary functions to inspect the constraints in Φ for patterns that restrict the models sufficiently. For example, the function **find-tt-list** takes a conjunction of formulas and a variable of type **list t** and tries to find a formula that restricts this variable to **NIL** or **CONS**:

```

\text{find-tt-list} : \forall \{\Gamma\}\{t\} \rightarrow \text{List } (\text{Formula } \Gamma) \rightarrow \text{list } t \in \Gamma \\
\rightarrow \text{Maybe } (\text{Match } \Gamma [] \uplus \text{Match } \Gamma [t ; \text{list } t])

```

```

\text{find-tt-list-soundness} : \forall \{\Gamma\}\{t\} \rightarrow (\Phi : \text{List } (\text{Formula } \Gamma)) \rightarrow (l \in : \text{list } t \in \Gamma) \\
\rightarrow \text{find-tt-list } \Phi l \in \equiv \text{just } (\text{inj}_1 [])
\rightarrow \forall (\gamma : \text{Int } \Gamma) \rightarrow \gamma \models \Phi \\
\rightarrow \text{lookup } \gamma l \in \equiv []

```

$$\begin{aligned}
 \text{val}\vdash : \forall \{ty \Gamma\} \rightarrow \text{Int } \Gamma \rightarrow \Gamma \vdash ty \rightarrow \llbracket ty \rrbracket \\
 \text{val}\vdash \gamma (\text{var } v \in) &= \text{lookup } \gamma v \in \\
 \text{val}\vdash \gamma (\text{const } b) &= b \\
 \text{val}\vdash \gamma (\text{contr } adr) &= adr \\
 \text{val}\vdash \gamma (\text{func } f \text{ args}) &= \text{appD1 } f (\text{map } (\text{lookup } \gamma) \text{ args})
 \end{aligned}$$

$$\begin{aligned}
 _ \models \varphi : \forall \{\Gamma\} \rightarrow \text{Int } \Gamma \rightarrow \text{Formula } \Gamma \rightarrow \text{Set} \\
 \gamma \models \varphi \text{ 'false} &= \perp \\
 \gamma \models \varphi (v \in := trm) &= \text{lookup } \gamma v \in \equiv \text{val}\vdash \gamma trm \\
 \gamma \models \varphi (x <_m x_1) &= \text{lookup } \gamma x < \text{lookup } \gamma x_1 \\
 \gamma \models \varphi (x \geq_m x_1) &= \text{lookup } \gamma x \geq \text{lookup } \gamma x_1
 \end{aligned}$$

■ **Figure 10** Semantics of terms and formulas.

We only show the soundness lemma for **NIL**, as the one for **CONS** is analogous. This approach is not complete as the implementation of **find-tt-list** is tailored to the constraints as they are produced by symbolic execution.

The full implementation is quite involved and relies on several further lemmas that examine constraints (for example if the current balance of a sender is sufficient for a token transfer) in a similar way. We refer the interested reader to the supplement.

The remaining cases deal with a terminated contract execution where the new state is written back to the blockchain or the execution of an abstract program step for the contract under execution. The first case is similar to the concrete implementation where new variables are introduced for the updated values. The second case is more complicated because the context extensions from the abstract program step are encoded in the list of resulting disjunctions, so an additional term has to be supplied proving that these contexts are actually an extension of the original context.

5 Semantics and Soundness

5.1 Values and Models

As a context is just a list of types like a stack, its interpretation is also a heterogeneous list of values as defined by **Int**. For a given context interpretation γ , the semantics of a term and a formula is defined as usual (see Figure 10).

For a given context interpretation γ and abstract and concrete (program or execution) states, the predicates **modp** and **modσ** express that under this interpretation the given abstract state models the concrete state. This is the case when the formulas in Φ are true under γ and the real and variable values are the same for the stacks and every other element.

$$\begin{aligned}
 \text{MODELING} : \text{Context} \rightarrow (\text{MODE} \rightarrow \text{Set}) \rightarrow \text{Set}_1 \\
 \text{MODELING } \Gamma F = \text{Abstract } F \Gamma \rightarrow \text{Concrete } F \rightarrow \text{Set} \\
 \\
 \text{modp} : \forall \{\Gamma\} \rightarrow \text{Int } \Gamma \rightarrow \text{MODELING } \Gamma \lambda M \rightarrow \text{Prog-state } M \text{ ro} \\
 \text{modp } \gamma (\text{state } \{ri = \alpha r_i\} \alpha en \alpha prg rVM \Phi) \\
 \quad (\text{state } \{ri\} en prg stk tt) \\
 = \Sigma (\alpha r_i \equiv ri) \lambda \{ \text{refl} \rightarrow \\
 \quad \text{modE } \gamma \alpha en en \times \text{modprg } \gamma \alpha prg prg \times \text{modS } \gamma rVM stk \times \text{modF } \gamma \Phi \}
 \end{aligned}$$

```

soundness  $\gamma$  (state  $\alpha en$  (IF-NONE  $thn$   $els$  ;  $aprg$ ) ( $o \in :: rVM$ )  $\Phi$ )
           (state  $en$  (.IF-NONE  $thn$   $els$  ;  $cprg$ ) (just  $x :: stk$ ) tt)

```

■ **Figure 11** Prog-step soundness for IF-NONE (excerpt).

They all have a similar structure expressed by the **MODELING** function as they relate an abstract thing with a concrete thing. They are implemented by several auxiliary **modX** predicates for every subcomponent of program and execution states. For example, **ModE** relates execution environments, **modprg** relates shadow programs, **modS** relates stacks, and **mod Φ** checks that the formulas are all true. The definition of **mod σ** is similar.

To show that a disjunction of abstract states models a concrete state, we show that one of the states in the disjunction models the state:

```

mod $\Psi\sigma$  :  $\forall \{\Gamma\} \rightarrow \text{Int } \Gamma \rightarrow \Psi\text{ExecState} \rightarrow \text{CExecState} \rightarrow \text{Set}$ 
mod $\Psi\sigma$   $\{\Gamma\} \gamma \Psi\sigma \sigma = \exists [\alpha\sigma] (\Gamma, \alpha\sigma) \in \Psi\sigma \times \text{mod}\sigma \gamma \alpha\sigma \sigma$ 

```

5.2 Soundness of the DL

We prove the soundness of the logic by showing that when an abstract state models a concrete one, the result of one-step symbolic execution models the result from concrete execution of the same step. Here are the types of the proof terms for program steps and execution steps.

```

soundness :  $\forall \{\Gamma ro\} \gamma \alpha\rho \rho \rightarrow \text{mod}\rho \{ro\} \{\Gamma\} \gamma \alpha\rho \rho$ 
            $\rightarrow \exists [\Gamma'] \exists [\gamma'] \text{mod}\Psi\rho \{\Gamma = \Gamma' ++ \Gamma\} (\gamma' \text{H}.\text{++} \gamma) (\alpha\text{prog-step} \alpha\rho) (\text{prog-step} \rho)$ 

soundness :  $\forall \{\Gamma\} (\gamma : \text{Int } \Gamma) \rightarrow \forall \alpha\sigma \sigma \rightarrow \text{mod}\sigma \gamma \alpha\sigma \sigma$ 
            $\rightarrow \exists [\Phi] \text{ExecState.MPstate} \alpha\sigma \equiv \text{APanic} \Phi$ 
            $\Psi \exists [\Gamma'] \exists [\gamma'] \text{mod}\Psi\sigma \{\Gamma' ++ \Gamma\} (\gamma' \text{H}.\text{++} \gamma) (\alpha\text{exec-step} \alpha\sigma) (\text{exec-step} \sigma)$ 

```

The first **soundness** statement addresses soundness of **αprog-step**. As the modeling relation is mostly composed of equalities, the proof gets accepted by Agda, once we supply sufficiently precise arguments to match the cases in the definition of **αprog-step**. We pattern match against **refl** and parts of the arguments, as well as we show that the weakened parts of the formula are still modeled with the extended context (if new variables were introduced in the case).

Figure 11 shows the case for the **IF-NONE** instruction. Without going into details, it is easy to spot the handling of the concrete and abstract stack and that the outcome of the test determines which of the possibilities of the abstract outcome is chosen (cf. $0 \in$ and $1 \in$).

The most complicated case of this proof establishes soundness for any scalar function (see Figure 12). It works by showing that applying the front of the previous stack interpretation to the given function yields the same result as applying the extended interpretation of the top of the previous stack matching to it.

```

soundness  $\gamma$  (state  $\alpha en$  (fct (D1 f) ; aprg) rVM  $\Phi$ )
  (state  $en$  (.fct (D1 f) ; cprg) stk tt)
  (modp( mE , mrS , (refl , refl , mPRG) , m $\Phi$  ))
with modS++ rVM stk mrS
... | mfront , mrest =
let result = appD1 f (H.front stk) in
_ , [ result ] , _ , 0 $\in$  , (refl ,
wkmodE mE , wkmodprg mPRG , (refl , wkmodS mrest) ,
(cong (appD1 f) (trans (sym (modIMI mfront)) (wkIMI { $\gamma$ ' = [ result ]})) , wkmod $\Phi$  m $\Phi$ ))

```

■ **Figure 12** Prog-step soundness for scalar functions (excerpt).

The second **soundness** statement establishes soundness for those cases of **α exec-step** where a contract execution is active. This part appears simple because it only covers two cases: Either we are in the middle of running a contract, in which case we reuse the soundness proof for program state execution, or the current contract execution has terminated and we have to prove that the blockchain and the pending list are updated correctly. The first case is straightforward, but tedious because we need to copy parts of the previous proof. The second case is fairly technical as it involves getting the proof in sync with the definitions of concrete and abstract execution.

6 Related Work

Research on formal verification of blockchain-based applications has experienced rapid growth in the last decade. Various techniques and frameworks have been applied to enhance the safety of smart contracts. In this section, we discuss some key approaches, particularly those employing symbolic execution in the context of smart contracts.

6.1 Verification of Smart Contracts

Symbolic execution is a powerful technique for systematically exploring program paths and identifying potential vulnerabilities in smart contracts. Most of the existing tools focus on the Ethereum platform. Tsankov et al. introduced SECURIFY [32], a tool that utilizes symbolic execution to perform practical security analysis on Ethereum smart contracts. It targets common vulnerability security patterns specified in a designated domain-specific language. SECURIFY symbolically encodes the dependence graph of the contract in stratified Datalog to extract semantic information from the code. After obtaining semantic facts, it checks whether the security patterns hold or not. Similarly, Manticore [26] and KEVM [18] use symbolic execution to analyze Ethereum smart contracts. KEVM is an executable formal specification built with the K Framework for the Ethereum virtual machine’s bytecode (EVM), a stack-based and low-level smart contract language for the Ethereum blockchain. Since tokens can hold a significant amount of value, they are often targeted for attacks. Therefore, several tools [18, 29] conduct case studies for the implementations of token standards.

Several approaches use existing formal verification frameworks to ensure the correctness and security of smart contracts. Amani et al. [3] proposed the formal verification of Ethereum smart contracts in Isabelle/HOL. Hirai [19] formalizes the EVM using Lem, a language to specify semantic definitions. The formal verification of smart contracts is achieved using

the Isabelle proof assistant. Mi-cho-Coq [10] is a framework for the proof assistant Coq to verify functional correctness of Michelson smart contracts. They formalize the semantics of a Michelson in Coq using a weakest precondition calculus and verify several contracts. It provides full coverage of the language whereas our goal is to give a blueprint for a soundness proof of symbolic execution.

There are several tools for automated verification including solc-verify [15], VerX [4], and Oyente [22]. solc-verify processes smart contracts written in Solidity and discharges verification conditions using modular program analysis and SMT solving. It operates at the level of the contract source code, with properties specified as contract invariants and function pre- and post-conditions provided as annotations in the code by the developer. This approach offers a scalable, automated, and user-friendly formal verification solution for Solidity smart contracts. The core of solc-verify involves translating Solidity contracts to Boogie IVL (Intermediate Verification Language), a language designed for verification.

Nishida et al. [27] developed HELMHOLTZ, an automated verification tool for Michelson. While both research efforts aim to build a verification tool for smart contracts written in Michelson, HELMHOLTZ is based on refinement types, whereas we consider symbolic execution. HELMHOLTZ has better coverage of Michelson instructions than we currently have, but it can only verify a single contract whereas our model and soundness proof covers full inter-contract verification. The HELMHOLTZ developers plan to extend Helmholtz with inter-contract behavior.

Bau et al. [8] implement a static analyzer for Michelson within the modular static analyser MOPSA that is based on abstract interpretation. It is able to infer invariants on a contract's storage over several calls and it can prove the absence of errors at run time.

Da Horta et al. [5] aim at automating as much of the verification process as possible by automatically translating a Michelson contract into an equivalent program for the deductive program verification platform WHY3. However, they found that sometimes user intervention was required, and their tool can only verify single contracts individually.

6.2 Symbolic Execution for Bytecode Interpretation

As there are some parallels between Michelson and bytecode languages, we discuss symbolic execution methods for some selected bytecode languages.

Albert et al. [2] transform Java bytecode into a logic program to utilize analysis techniques from logic programming, specifically symbolic semantics, for the formal verification of the bytecode. They verify properties such as termination and run-time error freeness and infer resource bounds. The dynamic aspects of bytecode, such as control flow and data flow, are effectively handled through the analysis performed on the logic program. Balasubramanian, Daniel et al. [7] include dynamic symbolic execution tailored for Java-based web server environments. Their tool analyzes the bytecode interactions within the Java Virtual Machine and focuses on bytecode instructions, method calls, object manipulations and memory interactions to detect vulnerabilities and bugs.

Several approaches address formal semantics and analysis for WebAssembly (Wasm) [24, 21, 34]. Watt, Conrad et al. [34] present Wasm Logic, a formal program logic for WebAssembly. The authors mechanize Wasm logic and its proof of correctness in Isabelle/HOL. To this end, they propose an alternative semantics. Just like our work (we propose a logic on an alternative semantics, mechanize it, and prove its soundness in Agda), their aim is to provide a logical basis for static analysis tools.

Marques et al. [24] present a concolic execution engine that systematically explores different program paths by combining concrete and symbolic execution to enable automated testing and fault detection. It models execution behavior and uses constraint solvers to

generate inputs and explore paths, taking into account the complexity of Wasm’s stack-based execution and binary format. Unlike our work, their work is geared towards implementing a realistic tool.

6.3 Related Uses of Dynamic Logic

The idea of using dynamic logic for symbolic execution can be traced back to Heisel et al. [17]. They formalize Burstall’s verification method [11] using symbolic execution and induction in the framework of dynamic logic.

Maingaud et al. [23] define a program logic for imperative ML programs based on dynamic logic and prove its soundness. Their goal is to use this logic as a basis for symbolic execution.

Similar to our approach, the research of Ahrendt et al. [1] emphasizes data integrity in Solidity smart contracts. This framework verifies smart contracts and ensures strong data integrity and functional correctness under various conditions. It introduces a specification language for defining contract properties and behaviors that are critical for security and reliability. Similar approaches to ours aim to verify the correctness and security of smart contracts, but differ in methodology and target languages. Their approach uses dynamic logic for invariant-based specifications with prototype-based tools, while our approach uses dynamic logic for symbolic execution and focuses on formal proofs.

Abstract execution [31] is a static verification framework based on symbolic execution. It is geared at schematic programs, i.e., programs with placeholders for program fragments, so that it can be used to prove certain program transformations correct. Its logical basis is dynamic logic extending earlier work for Java [9].

7 Conclusion

We presented a dynamic logic for Michelson as well as its extension to blockchain operations on a small but representative subset of Michelson. The goal was to create a core model that covers instances of all kinds of operations and that can be easily extended with further Michelson instructions. We achieved full coverage of scalar functional instructions, the majority of Michelson instructions. To include any further scalar instruction, one only has to specify its typing rule and its implementation in Agda. The symbolic execution rule and the soundness proof for that rule is already provided by our model. Further instructions that retrieve information from the execution environment can be added easily as well by extending the [Environment](#) record and its subcomponents to include such information.

We cover three exemplary instructions for control flow, because most other conditional and looping instructions are either very similar or very simple and thus easy to include in the presented model. One aspect of Michelson that is not covered is first-class functions. Including them might require some reworking of the current model to store such values on the stack.

Efficient symbolic execution is **not** a goal of this work: Agda can normalize a concrete or symbolic execution state to enable inspection of the state after one or more execution steps, but in our experiments normalization was sometimes infeasible after less than ten symbolic execution steps. Nevertheless, we plan to use our soundness proof as the basis for an efficient symbolic interpreter for Michelson in ongoing work.

Abstract

Interprocedural static analyses require a complete and precise callgraph. Since third-party libraries are responsible for large portions of the code of an app, a substantial fraction of the effort in callgraph generation is therefore spent on the library code for each app. For analyses that are oblivious to the inner workings of a library and only require the user code to be processed, the library can be replaced with a summary that allows to reconstruct the callbacks from library code back to user code. To improve performance, we propose the automatic generation and use of precise pre-computed callgraph summaries for commonly used libraries. Reflective method calls within libraries and callback-driven APIs pose further challenges for generating precise callgraphs using static analysis. Pre-computed summaries can also help analyses avoid these challenges.

We present CGMINER, an approach for automatically generating callgraph models for library code. It dynamically observes sample apps that use one or more particular target libraries. As we show, CGMINER yields more than 94% of correct edges, whereas existing work only achieves around 33% correct edges. CGMINER avoids the high false positive rate of existing tools. We show that CGMINER integrated into FlowDroid uncovers 40 % more data flows than our baseline without callback summaries.

1 Introduction

Static analyses are commonly used for checking software for security vulnerabilities, quality defects, privacy leaks, and other properties. The callgraph is a core data structure of interprocedural static analysis. It encodes which statements in the code call which methods. When an analysis encounters a method call, it queries the callgraph for the set of callees in which to continue the analysis. If the callgraph misses edges, the respective callees are not considered and the analysis is incomplete. If the callgraph, on the other hand, contains spurious edges, irrelevant subtrees in the callgraph must be processed. This may not only impact performance and scalability, but may also lead to false positives.

4:2 Dynamically Generating Callback Summaries for Enhancing Static Analysis

Computing a complete and precise callgraph is non-trivial due to virtual dispatch and exceptional control flow. Approaches such as SPARK [16] already handle polymorphism well. SPARK builds upon the Escape Analysis in Soot [14] to handle exceptional control flow precisely. Nevertheless, several problems remain unsolved. Firstly, software commonly [17] uses third-party libraries, which can contribute significant amounts of code. Large code bases, in turn, pose scalability challenges for callgraph generation. Secondly, libraries can be complex and, e.g., use reflective method calls, contain asynchronous control flow, or manage callbacks in collections. A callgraph analysis must be able to handle all these language features correctly. Some libraries such as the popular OKHTTP3 library have separate callbacks for successful and failed requests. The failure callback is only executed when an exception is thrown within the library code. An approach without support for exceptional flows misses these callbacks. In practice, existing callgraph analyses apply approximations that lead to spurious or missing edges, or are too complex to scale to large programs.

We observe that, from the perspective of most client analyses, only the interface of a library is relevant. Callgraph edges inside the library only need to be computed as a means to obtain edges that cross the library’s interface through callbacks. We therefore argue that these API edges can be summarized once as a one-time effort. Only the information which API calls trigger which callbacks must be retained. Intuitively, the summary is a list of such target callbacks. When a client analysis encounters a call to an API method for which a summary is available, it plugs in the summary instead of analyzing the library. More precisely, it adds a callgraph edge to each callback described in the summary. A similar reasoning has already been applied to the data flow behavior of libraries [2].

Manually assembling these summaries is inefficient, since many libraries use callbacks. Furthermore, each new version of each library would need to be studied to reflect the changes made to the library API in the model. Consequently, the generation of these callback models must be automated. Static approaches [8] share the shortcomings of static callgraph analyses and require coarse approximations, leading to false positives as we show.

Our approach CGMINER is based on dynamic analysis instead. CGMINER takes a set of programs that use libraries of interest. It statically instruments these programs such that each call to a library function reports dynamic callgraph data to an analyzer. CGMINER executes all instrumented programs and combines the resulting execution traces into a *callback summary* for the respective library. It abstracts away from all program-specific behavior and reduces the summaries to edges between methods in the public interface of the library, omitting calls within the library itself leading eventually to the execution of a callback. If a library, for example, takes a callback as the first argument on an API call and then invokes a method on the object passed as the first argument, there is an edge between this API method and its first parameter. This edge exists regardless of which program uses the API and what the concrete callback implementation is. CGMINER captures such abstract callback semantics on the API level. With its focus on dynamic analysis, CGMINER avoids many of the common challenges in static analysis such as precisely modeling reflective method calls and complex collection types.

In this work, we focus on Android apps. On Android, libraries are compiled into the apps that use them, rather than being shared between apps. Consequently, a wide variety of libraries is used in apps [26], and handling them efficiently is vital for each app analysis. Furthermore, almost 2 million apps are available in the official Play Store. Since for each library, CGMINER requires a sample set of apps that use the respective library, such a freely accessible data source is beneficial. In addition, Android is widely used for dealing with sensitive data and functions, making client analyses that depend on callgraphs for,

e.g., finding data leaks, highly relevant in practice. We show that CGMINER can identify efficiently complex callback edges. While other approaches lead to true positive rates of more than 33% with an additional 20% of edges being incomplete, CGMINER achieves more than 91% correct edges. Note that CGMINER focuses on control flow and is intended to be combined with analysis-specific summaries such as StubDroid [2] for data flow analysis. Even with a simple integration approach, CGMINER summaries lead to 28% more correct flows being discovered than without callback summaries.

The remainder of this paper is structured as follows. Section 2 contains some background information about Android. Section 3 shows a motivating example. Section 4 explains the CGMINER approach. We describe implementation details in Section 5, before explaining CGMINER’s limitations in Section 6. Our empirical research questions and evaluation data is contained in Section 7. Finally, we present related work in Section 8 and conclude in Section 9.

2 Android Background

Android applications are written predominately in Java and Kotlin. The compiler translates this code into Dalvik byte code, which is similar to Java byte code used by the JVM. After compilation, the Dalvik byte code is written into one or multiple *classes.dex* files. The dex files as well as the necessary resource files of the app are packaged in an APK file, which is ultimately just a ZIP file. Android apps may use system classes from the `java(x)` and `android` packages. The implementation of these system classes are shared between different apps and reside on the device. On the host computer, the Android SDK installs a stubbed version of this Android system classes, which only contains the method signatures and class hierarchies of the actual implementation. This stub jar is used to link against during compilation, but does not contain the actual implementation code. In contrast to the system implementation, all other third party libraries and their transitive dependencies are compiled to Dalvik byte code as well and placed alongside the application code in the same dex files, so that each application is self-contained.

3 Running Example

Listing 1 shows a program that uses a simplified API for communicating with a remote server once the app’s main activity is launched. The library is a slightly adapted version of the OKHttp library. For the sake of brevity, we omit the implementation of the library and instead explain it using the code of the example program.

The library’s main class `HttpLibrary` is responsible for communicating with the server. Each request is represented by an instance of the `HttpTask` class. Each task is scheduled for execution using the `schedule` method. Once all requests are scheduled, the program invokes the `runAll` method to run them against the remote server. Once a task is complete, i.e., the server has responded with results or an error, the respective callback is invoked. The implementation of the error callback is omitted in Listing 1 for brevity.

For demonstration purposes, we assume the following simplified implementation of the library. The constructor of `HttpTask` stores the callback that it receives as a parameter into a field in `HttpTask`. The `schedule` method adds the `HttpTask` to a list. Still, for not freezing the UI thread, the library is multi-threaded and performs the http request in the background. The `runAll` method spawns a worker thread that regularly polls the scheduled

■ Listing 1 Motivating Example Code.

```

1  ICompleted onComplete = new ICompleted(){
2      @Override
3      public void onCallback(String results){
4          Log.i("Web", "Results: " + results);
5      }
6  };
7  IHttpFailed onFailed = ...;
8  HttpTask task = new HttpTask("/api/do", onComplete, onFailed);
9  HttpLibrary lib = new HttpLibrary("http://www.company.com");
10 lib.schedule(task);
11 lib.runAll();

```

tasks, takes the task at the top of the worklist, and processes it. The worker thread sends the requests to the server, collects the results, and then invokes the callback. The callbacks are invoked on a different thread than the original call to `schedule` or `runAll`.

Callgraph algorithms traditionally do not model the delayed behavior of the callback and instead insert an edge from the call site that causes the callback to be executed to the callback implementation, e.g., from `Thread.start` to the `run()` method of the thread. CGMINER adopts the same behavior. Its callback summaries model an edge from `runAll` to the `onCallback` method of both completion and error callback. In other words, our model assumes that `runAll` immediately invokes both callbacks. The challenge in this example, which is not handled by existing approaches, arises because the callbacks are not in the scope of the call site for `runAll`. Instead, the summary generator must automatically infer the link to the `HttpTask` instances that were scheduled, and then to the actual callbacks that were passed to the constructor of the `HttpTask`.

Existing approaches such as EdgeMiner [8] model the callgraph edges in Line 8. This reduces the complexity of the example, because the callback is not passed across multiple classes. On the other hand, such a model is incompatible with a flow-sensitive analysis. To illustrate this, we change the example slightly as shown in Listing 2. For this example, suppose that the `source` method call in Line 9 returns sensitive information. Further assume that the parameter of the `sink` method (called in Line 4) is sent to a remote server. This example uses the field `data` to save the sensitive information, which is leaked in the callback method.

Consider we are running a flow-sensitive taint analysis such as FlowDroid [5] to detect this data flow from `source` to `sink`. FlowDroid starts at the source [4] statement in Line 9 and advances forward through the control-flow graph until it reaches a sink. It reports a leak when the sink is reached with a tainted parameter. During the propagation, it keeps track of all variables that may contain sensitive information (“tainted”).

Notice that the callback is passed to the library in Line 8, before the `source` method is called. During execution, the call to `runAll` in Line 12 invokes the callback which leaks the data. Nonetheless, EdgeMiner inserts an edge at Line 8 to the `onCallback` method. Because the call to `source` happens after the callback registration, FlowDroid does not encounter the sink statement when using the EdgeMiner summary. Consequently, the leak is missed. In this example, FlowDroid needs an edge from the `runAll` call in Line 12 to the callback method in order to reach the sink and thus detect the dataflow.

Listing 2 Flow-Sensitivity Example.

```

1 ICompleted onComplete = new ICompleted(){
2     @Override
3     public void onCallback(String results){
4         sink(data);
5     }
6 }
7 IHttpFailed = ...;
8 HttpTask task = new HttpTask("/api/do", onComplete, onFailed);
9 data = source();
10 HttpLibrary lib = new HttpLibrary("http://www.company.com");
11 lib.schedule(task);
12 lib.runAll();

```

Such approximations as in existing work have even greater negative consequences. In yet another modification of the example, imagine that the `runAll` method never calls `onFailed`, but throws an exception instead. The `onFailed` callback only exists for a second method `tryRun` that calls `onFailed` in the case of an error and that never throws an exception. In that case, EdgeMiner would still model the edge from the `HttpTask` constructor call in Line 8 to `onFailed`. This edge is clearly invalid if the program never calls `tryRun`. The EdgeMiner model does not contain any notion of `runAll` and `tryRun` and, hence, cannot make this distinction.

4 Approach

To avoid the inherent challenges of static analysis described in Section 1, CGMINER relies on dynamic analysis for inferring the callgraph summaries on libraries. Figure 1 shows the architecture of the analysis. CGMINER takes as input the original APK file and a list of classes that correspond to libraries. These apps are then instrumented with three analyses: a general-purpose dynamic callgraph analysis, a general-purpose dynamic taint analysis and a specialized callback analysis into the app. Since libraries (except for the Android Framework) are part of the application code in Android, library code can be instrumented as well.

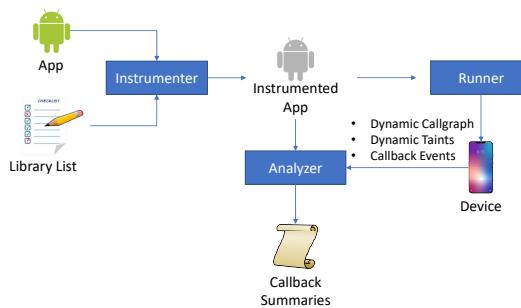

Figure 1 CGMINER Approach. The app is instrumented and then executed on a device, with runtime events being routed to the callgraph analysis. Events include dynamic callgraph, dynamic taint tracking, and specific callback analysis events.

The instrumented app is passed to the runner, which installs it on a device, and establishes a communication channel with the app. It forwards all events sent by the analysis code injected into the app to the analyzer. The analyzer is responsible for processing the events

and for inferring the callback summaries while the app is running. In the remainder of this section, we explain how the analyzer derives the callback summaries and how the different components (dynamic callgraph, dynamic taint analysis, callback analyzer) interact.

4.1 General Idea

CGMINER needs to identify which statements trigger which callbacks. The app is instrumented with event tracing that reports back to the analysis computer whenever a potential callback method is invoked on the phone. When such a method is invoked, CGMINER uses a combination of dynamic control flow analysis and dynamic taint tracking to identify all API calls between the point where the callback class was originally passed to the library (constructor of `HttpTask` in the example) and the callback method.

When arriving inside a callback, CGMINER must find the API call that triggered the callback (method `runAll` in the example). Intuitively, this can be done by searching backwards through the dynamic control flow graph. This approach, however, does not identify the necessary state changes to the `HttpLibrary` object. Recall from Section 3 that the `runAll` method would not invoke any callback unless the callback has previously been registered with the library using the `schedule` method. In other words, the inner state of the `HttpTask` object must be changed before calling `runAll`. More generally, the callback is passed through several objects along the way, and CGMINER must identify the API calls that lead to these state changes, i.e., that copy the callback around. In the example, the constructor of `HttpTask` assigns the callback to a field and the `schedule` method adds the task to the list, which is finally processed by `runAll` (see Section 3). We call such methods *transfer methods*. The user code must call this method for the callback to be registered, and it must therefore be part of the callback summary.

Intuitively, when an API method stores a callback in a field or collection inside of some object, the transfer method is the last API call that transitively lead to the assignment. To find the relevant assignments, CGMINER relies on dynamic data flow analysis. CGMINER taints each callback object when it is first passed to an API call (constructor of `HttpTask` in the example), i.e., each callback object is considered a source for the dynamic taint tracking algorithm. It then follows this taint through the library, until it arrives at the `this` object inside a callback method. The start of a potential callback method is considered a sink.

The taint state on the device is always mirrored to the analysis computer. When the analyzer observes that a callback has been called, it retrieves the taint paths, i.e., all statements that have passed the taint from one object to another on the path between the callback registration and the invocation of the callback method. Whenever a new object is tainted, e.g., through an assignment to a field, CGMINER searches the dynamic callgraph backwards to find the API call that triggered this taint transfer, i.e., the methods that user code must call before `runAll`.

4.2 Overview of the Approach

We define a *border edge* as an edge that is from library code to user code or vice versa. In other words, the caller is in library code and the callee is user code (i.e., a callback), or the caller is in user code and the callee is library code (traditional call to a library method). Edges in the first case, i.e., callbacks, are denoted *out* edges, whereas edges in the second case, i.e., normal library calls, are *in* edges. Figure 2 shows an abbreviated control flow graph for Listing 1. It further shows the *in* and *out* edges for the motivating sample. In the example, the `HttpTask` and `HttpLibrary` constructor calls and the calls to `schedule` and

`runAll` are *in* edges, because these calls in the application code directly call library methods. The `runAll` method iterates over all scheduled tasks, which were registered in the `schedule` method, and calls a library-internal `run` method. The `run` method calls the `onComplete` on the callback. Thus, this method call constitutes an *out* edge.

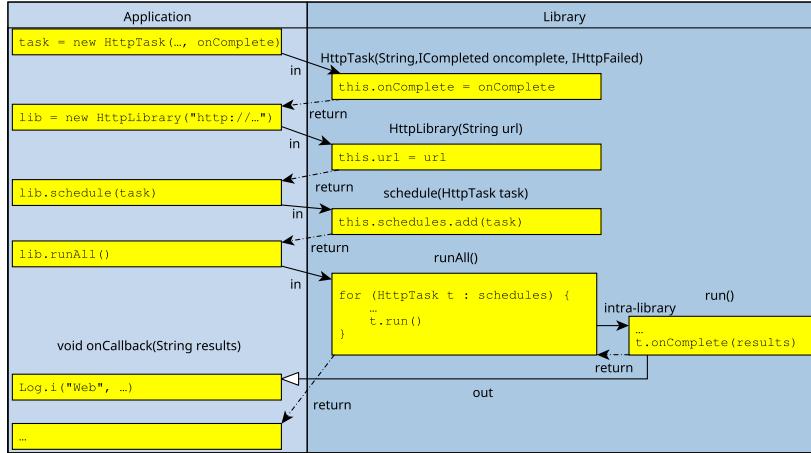

Figure 2 Shows *in* and *out* edges for Listing 1. *in* edges are regular arrows. The *out* edge is denoted by a white tip.

As a pre-analysis, CGMINER statically over-approximates the potential callback implementations, i.e., potential targets of *out* edges. We call these methods *callback candidates*. Afterwards, CGMINER statically approximates a set of all possible callback classes. In Listing 1, the constructor `HttpTask` may register a callback. All classes that (transitively) implement the interfaces `ICompleted` and `IHttpFailed` are potential callbacks. Specifically, we have the anonymous inner class implementing `ICompleted` and the (omitted) corresponding inner class for `IHttpFailed`. These classes override the interface methods, in this case only `onCallback`. These overridden methods represent the potential targets of *out* edges. These steps for identifying callback registration sites and potential callbacks are static over-approximations, which are used to bootstrap the dynamic analysis that follows later.

The dynamic analysis is used to determine which callback candidates are reached and to perform dynamic taint tracking in order to track which API calls (such as the `schedule` and the constructor calls in Listing 1) are necessary.

At the start of each callback candidate, we statically instrument a call to a method we call *reporting method*. This reporting method sends an event with information about the triggered callback to the analyzer. Because irrelevant callback candidates or spurious callback implementations will later not be reached during dynamic analysis, they will not become false positives. We provide details on how potential callbacks are identified in Section 4.3.

When a callback is invoked at runtime and the respective callback event is triggered, the analyzer uses the dynamic callgraph to find the corresponding *in* edge. The call site at the *in* edge represents the API method that triggers the callback. Note that the analyzer skips the library-internal calls between *in* and *out* edge. The *in* and *out* edges are trivial to identify based on the classes in which the respective calls and their corresponding callees are located. In the example from Listing 1, the analyzer deduces that a call to `HttpLibrary.runAll` invokes `IHttpCompleted.onCallback`. Further, CGMINER uses dynamic taint tracking to find the transfer methods. Therefore, the statements at the beginning of all potential callback

methods are marked as sinks for the dynamic taint analysis. To build the list of sources, CGMINER first collects all API sites that receive instances of potential callback classes as arguments. These API calls are then registered as sources in the dynamic taint analysis such that the respective potential callback classes, i.e., the call arguments, are tracked at runtime. Note that this approach is an over-approximation. When generating the callback summaries, CGMINER only relies on the taint paths that were actually taken at runtime. Therefore, marking too many classes as potential callbacks or registering too many APIs as sources does not reduce CGMINER’s precision. CGMINER assigns an unique ID number to each taint source in order to distinguish different sources.

Transfer methods do not need to operate on the original heap object. The `schedule` method in Listing 1 never touches the callback object. It operates on the `HttpTask` that encapsulates the callback. An approach based on object identity alone would miss the `schedule` method. Dynamic taint tracking, on the other hand, can taint the `HttpTask` object when it encounters the assignment inside the constructor of `HttpTask`. Recall that this constructor receives the callback and stores it in a field. Afterwards, the dynamic taint tracker follows the `HttpTask` object as well. Similar reasoning must be applied for the `schedule` method, which stores the `HttpTask` object in a list, i.e., the list must be tainted as well.

With this taint tracking information, CGMINER can identify all border edges by looking at the taint transfers. Recall that the first statement inside the callback is a sink. CGMINER can query the taint analysis for the corresponding source and all statements in between at which taint was transferred to fields or collections (details in Section 4.5). For each statement on the taint path, it queries the dynamic callgraph to identify the corresponding *in* edge, i.e., the call from the user code that lead to the taint transfer. In the example, this allows CGMINER to identify the call to the constructor of `HttpTask` (transfer: field assignment) and to `schedule` (transfer: collection). Approaches that only inspect the call chain that ends at the callback (`runAll` in the example) would miss these intermediate calls.

4.3 Identifying Potential Callbacks

Recall that the callback analysis is started when a callback is invoked. Consequently, each possible callback method must be instrumented with an event that notifies the analyzer about which method has been called at runtime. This section shows the static analysis phase of the CGMINER approach. In this phase, CGMINER first determines possible callbacks and then instruments code in order to be notified when a callback happens.

To find the potential callbacks, CGMINER identifies all statements in the app that call library methods. The approach then checks whether a reference to a callback object is passed as an argument. We define a callback argument as follows. The declared type of the respective parameter is a reference type from the library, i.e., a class or an interface, which must be non-final and accessible to user code according to its access modifiers. Further, if the library class is a class and not an interface, it must have a non-private constructor. The type of the argument that is passed must be a class type from the user code that (potentially indirectly) inherits from the library class or implements the library interface. This class type represents a potential callback implementation. The type of the callback class can be approximated statically, either by identifying the allocation site at which the callback object was instantiated, or by looking at the declared type of the callback variable that is passed as an argument. To be complete, CGMINER applies a Variable Type Analysis (VTA) style analysis [24] to identify all possible types based on the declared type if no precise allocation site is available. Considering too many potential callbacks only leads to more instrumentation effort and does not affect the precision of CGMINER, as these spurious callbacks are not triggered at runtime.

CGMINER only identifies a set of potential library classes in this step. The concrete library method to which the callback object is passed is irrelevant for the analysis in this stage and is discarded.

Potential callbacks must be instrumented. Since this is not possible for Android and Java system classes, CGMINER automatically wraps these classes. For example, when `java.lang.ArrayList` is instantiated in the application code, CGMINER replaces the call so that a wrapped version of `ArrayList` is called, which can then be instrumented. The wrapped variant inherits from `ArrayList` and forwards all protected and public methods to their corresponding super class implementations. CGMINER not only wraps constructor calls, but also values returned by system classes, e.g. `ArrayList.iterator()`.

4.4 Dynamic Callgraph Analysis

For building the dynamic call graph, CGMINER instruments the app as follows. Before each call, a `CALL` event is sent from the device to the analyzer with the unique ID of the call site. After the call site, i.e., when the call has returned, a `RETURN` event is sent for the same ID. At the beginning of each method, a `ENTER` event is sent. Before each `return` or `throw` statement, a `LEAVE` event is sent. These events allow the analyzer to reconstruct the call edges taken on the device. Due to memory and performance constraints, CGMINER does not build the dynamic callgraph on the device. Once the events are sent, they are immediately discarded on the device.

The analyzer maintains a separate call stack for each thread. For each `CALL` event, the respective call site is put on the stack. When the analyzer receives an `ENTER` event, it creates a call edge from the top call site on the stack to the method that was entered. Note that a `CALL` event may be followed by multiple pairs of `ENTER` and `LEAVE` events before the `RETURN` event occurs. The Dalvik / Java runtime calls the static initializer of a class when the class is loaded. Therefore, each call may first invoke the static initializer before the actual callee is called. CGMINER captures this semantic by leaving the call site of the static initializer on the stack until the `RETURN` event is encountered. CGMINER does not consider implicit calls to static initializers from statements that are not call sites, e.g., from assignments to static variables. In this case, the static initializer generates an `ENTER` event, but has no matching call site on the stack. Therefore, the `ENTER` event is discarded. As CGMINER reconstructs call chains to callbacks, non-call initializations are not relevant.

4.5 Dynamic Taint Analysis

As explained in Section 4.2, CGMINER uses dynamic taint tracking to track the callback object through the program, including all container objects that hold this callback object. Note that only heap objects are tracked, no primitives. Therefore, the runtime code that gets instrumented into the app can uniquely distinguish each tainted object by its identity hash code (`System.identityHashCode()`). The instrumented runtime code stores a map between the unique ID of the taint source and the identity hash code¹, and also transmits this map to the analyzer on every change, i.e., whenever a new object is tainted. These transmissions occur on the background based on a transmission queue. The events are sent as one message whenever a certain number of events have accumulated. Therefore, the transmissions do not affect the performance of the original app.

¹ The implementation takes care of checking referential equality in case of hash collisions.

All field assignments are instrumented to perform *taint transfers*. If a variable is assigned to a field, the runtime code checks whether the variable on the right side of the assignment is tainted, i.e., its identity hash code is in the taint map. If so, the base object that contains the field is tainted as well, i.e., its identity hash code is written into the map with the same source ID as the variable. These *derived taints* are field-insensitive by design. If a library stores two different callbacks in two fields of the same object, this object is associated with both sources.

Recall that the dynamic taint tracking in CGMINER is special, since the object that is tainted at the source (the callback object) is always the same object that arrives at the sink (the `this` object inside the callback). The taint tracking is only used to track the path between where the callback was registered in the library and where the control flow arrives inside the callback. This allows for some imprecision in the taint tracking, because flows where source and sink object are not identical can be discarded.

The Java Standard Library cannot be instrumented, because it is pre-installed on the device and not part of the app. For such cases, CGMINER relies on the static taint data flow summaries from StubDroid [2]. Based on these summaries, CGMINER adds instrumentation at the call site in the user code rather than instrumenting the library itself.

4.6 Callback Summary Modelling

In this section, we describe the model that we use for the callback summaries throughout the rest of the paper. Note that this section only contains the general principle of a summary. We will use this model in Section 4.7, where we describe the algorithm for generating the callback summaries.

In the simplest case, we model callback summaries as a single “fake” call edge $a \rightarrow \langle b, c \rangle$ from an API call a to a callback method b . The target is a pair $\langle b, c \rangle$, where c describes the object on which method b is called at the call site a . Recall that applying a callback summary corresponds to a virtual dispatch in the context of the original API call. In other words, the target method is called either on the same base object as the original API method, or an object passed to the original API call as a parameter. As an example, consider `AsyncTask`. `AsyncTask` is a class that is commonly used in Android, which is part of Android’s standard library, which is automatically available to every app. It is used to perform an action asynchronously, similar to a Java thread. Developers extend the `AsyncTask` class and override the `doInBackground` method, which is the callback method called in a background thread. In order to start the task, developers invoke the `execute` method on their `AsyncTask` instance. In the case of the `AsyncTask` class, the summary would be `AsyncTask.execute → ⟨AsyncTask.doInBackground, -1⟩`. The special value $c = -1$ stands for the base object of the call to `execute`, i.e., the `AsyncTask` object itself. A $c \geq 0$ would denote the c th parameter object of the caller statement using zero-indexing. Note that there may be more than one edge that originates in the same API method a . In the example, the Android OS also calls methods such as `onPostExecute` and `onPreExecute`, each of which is modelled as a separate summary edge.

The case from the example in Listing 1 is more complex, since the callback object is passed through multiple intermediate API calls, i.e. transfer functions. When applying the callback summary in a callgraph algorithm, i.e., when identifying the method that shall receive calls to `HttpLibrary.runAll`, the intermediate edges are processed in reverse order. The method `schedule` is called on the base object (index -1) of the previous call to `runAll`. The constructor of `HttpTask`, is called on the object that was the first argument (index 0) on the previous call to `schedule`. The original callback method `onCallback` is invoked on the object that was the second argument (index 1) in the previous call to the constructor of `HttpTask`.

In the callback summary, these intermediate calls are modelled as intermediate edges: $\langle \text{HttpLibrary.runAll}, -1 \rangle \rightarrow \langle \text{HttpLibrary.schedule}, -1 \rangle \rightarrow \langle \text{HttpTask.cons}, 0 \rangle \rightarrow \langle \text{IHttpCompleted.onCallback}, 1 \rangle$.

4.7 Callback Reconstruction

Algorithm 1 shows the details of how callback summaries are created. Function `BuildCallbackSummaries` is the main entry point that builds the callback summaries. It is called when the analyzer receives an event that callback method m has been called at runtime.

`BuildCallbackSummaries` uses the method `GetLastLibraryCallSite` to get the last library call site. `GetLastLibraryCallSite` in turn uses a helper method `GetDynamicTraces`, which returns a set of call traces that end in statement s by performing a graph search on the dynamic callgraph. The call graph is flattened into a set T of sequences of call sites c . Recursions are unrolled once in `GetDynamicTraces`, since repeating the same sub-sequence of calls does not provide any additional insights for the purpose of callgraph analysis. For not bloating the description, we do not present the implementation of the helper method `GetDynamicTraces` in the pseudocode.

Given a statement inside library code, method `GetLastUserCodeCallSite` uses the traces returned by `GetDynamicTraces` and returns the last user code statement that happened before and that transitively triggered the given library code statement. Similarly, method `GetLastUserCodeCallSite` takes a statement inside a callback in user code and identifies the last library statement that happened before and (transitively) invoked the given statement from the callback method. The helper method `Predecessor` takes a statement and returns the predecessor statement on the dynamic callgraph. For simplifying the presentation, we assume that this statement is unique. Our implementation can handle multiple candidates.

The main summary generator `BuildCallbackSummaries` first obtains the last statement in the library code before the callback was invoked (line 20). This is the last statement in the library before the control flow is passed back to user code, i.e., the *out* edge. The relevant interactions between user code and library API occur between this statement and the statement that originally passed the callback to the library (the *in* edge and source for the dynamic data flow analysis). We will explain the special case of $S_c = \epsilon$ (first branch in line 21) later. In line 25, CGMINER uses the method `GetPathsBetween` to query the dynamic taint graph for all taint paths between the two statements. A taint path is a sequence of statements that assigns a tainted variable or field to another variable or field, i.e., passes around a reference to a tainted object. This definition implies that method calls are part of the taint path as well, because they assign the value of the tainted argument at the call site to the corresponding parameter variable inside the callee. Note that there can be more than one path between source and sink, so \mathbb{P} is a set of lists of statements. CGMINER first iterates over all paths and then over the statements in each path. It builds a new summary for each path. Hence, the initialization of the summary (line 27) is inside the loop over the paths.

The summary starts with the statement that passes the callback object to the library, i.e., the *in* edge. This statement is simply the source from which taints arrive in the callback method, as shown in line 27. Method `GetSource` returns the API at which the source was registered. The assignment statements on the taint path that copy around the callback object inside the library are not directly visible to the user code. Instead, the user code calls API methods that transitively trigger these statements through library-internal call chains. In the example, an assignment somewhere inside `schedule` or one of its transitive callees assigns the parameter with the task to a field. This assignment is on the taint path, but only the preceding call to the transfer method `schedule` is relevant as a part

```

of the summary. In line 29, CGMINER uses the helper method `GetLastUserCallSite` to identify this corresponding API method by conducting a backward search in the dynamic callgraph. For statements that are already in user code, i.e., the first statement on the path, `GetLastUserCallSite` is an identity function.

Each identified transfer statement in user code maps to one fragment of a summary. In line 30 the current API method is concatenated to the summary built so far. For example, if the summary $\text{HttpLibrary.runAll} \rightarrow \langle \text{HttpLibrary.schedule}, -1 \rangle$ existed before, a new right arrow is appended to the next method and parameter index. As explained above, for the last statement of a taint path, $S_u = S_c$ holds, i.e., a taint path always ends with the API call that finally invokes the callback. S_c is the last library call site (line 20 in Algorithm 1), i.e., the last statement that was executed in the library before invoking the callback.

For extending the summary, CGMINER uses two helper functions: ω and γ . The ω method performs the generalization from concrete statements and methods to API interfaces. For call sites, ω retrieves the API signature. For callback methods, ω retrieves the name of the interface or abstract API class that declares the method. The γ method takes a call statement and identifies the tainted parameter, i.e., the parameter that contains the callback object, by querying the dynamic data flow graph. As explained in section 4.6, CGMINER uses the special value -1 if the base object of the call is tainted.

Note that Algorithm 1 also works for cases without transfer methods. Android's `AsyncTask.execute` method is part of the Android SDK, i.e., a pre-installed library on the device. It cannot be instrumented. Conceptually, the *in* edge points to a fake node (a method for which we have no implementation) and the *out* edge points from this node to the callback method `doInBackground`. In this case, the summary is a simple edge from a single API call site to a single callee method as explained in Section 4.6. In the algorithm, $S_c = \epsilon$ holds, and the first branch is taken in line 21. CGMINER retrieves the taint source, i.e., the *in* edge and construct an edge to the callback method m . The parameter index is derived from the taint graph using an overload of γ that processes the parameter variables of m instead of the call arguments at a call site.

4.8 Extensions and Special Cases

For simplicity, the algorithm presented in the pseudocode assumes that a single callback method is only connected to a single source, i.e., `GetSource` returns a single method. In other words, the developer does not re-use the same callback implementation for different independent API calls. Our implementation supports such re-uses.

Further, recall from Section 4.5 that CGMINER uses StubDroid summaries to model the effects of methods that cannot be instrumented in the dynamic taint analysis. In these cases, the transfer method cannot be found using a backwards search on the dynamic callgraph as shown in line 29. Instead, CGMINER marks these statements and directly uses statement s in such a case.

4.9 Applying Summaries

Many static analysis approaches require a callgraph. Computing the callgraph on the application code as well as the code of all libraries required by the application can require significant computational resources and time. Therefore, it makes sense to replace the libraries by summaries. These summaries must capture the control flow of the library with respect to its external interface, i.e., it must correctly model callbacks back to the application code. CGMINER generates such summaries. They can be applied whenever a callgraph is needed on an application that uses a library for which a summary was previously computed.

As such, we want to apply the generated callback summaries during the callback construction. In the case of the motivating sample in Listing 1, we want to apply the edge summary $\text{HttpLibrary.runAll} \rightarrow \langle \text{HttpLibrary.schedule}, -1 \rangle \rightarrow \langle \text{HttpTask.cons}, 0 \rangle \rightarrow \langle \text{IHttpCompleted.onCallback}, 1 \rangle$. In this section, we introduce Algorithm 2. In the case of the motivating example, the algorithm outputs an edge from `runAll` to the anonymous implementation referenced by `onComplete` and `onFailed`, resulting in a precise callgraph. This shows that we need the intermediate edges in order to determine the link between the implementation supplied at the constructor call (referenced by `onComplete` in the sample) and the call to `runAll`. Without these intermediate edges we have no information on the actual type of the callback object at the callback invocation site. Without such information, we would need to create edges from `runAll` to all possible implementations of `ICompleted`, even if they are not used as a callback.

Given a call site s and a set of callback summaries Δ , method `FindReceivers` in Algorithm 2 enumerates the potential callees at s . `FindReceivers` performs a traditional callgraph search via `QueryCallgraph`. It then augments these callees with the callbacks that are found by applying the callback summaries.

Algorithm 2 Summary Application Algorithm.

```

1 Function FindReceivers( $s, \Delta$ ):
    INPUT:  $s$  – the call site for which to find the receivers,
     $\delta := \langle \alpha_1, \beta_1 \rangle \rightarrow \dots \rightarrow \langle \alpha_n, \beta_n \rangle$ 
    – the callback summaries
    OUTPUT: The potential callees for the given call site

2    $\mathbb{R} = \{ \text{QueryCallgraph}(s) \}$ 
3   foreach  $(\delta := (\omega(s) \rightarrow \dots \rightarrow \langle \alpha_n, \beta_n \rangle)) \in \Delta$  do
4      $\hat{\delta} := \langle \alpha_1, \beta_1 \rangle \rightarrow \dots \rightarrow \langle \alpha_1, \beta_1 \rangle$ 
5      $\mathbb{R} = \mathbb{R} \cup \text{ApplySummary}(s, \hat{\delta}, -1)$ 
6   return  $\mathbb{R}$ 
7

8 Function ApplySummary( $s, \delta, i$ ):
    INPUT:  $s$  – the call site for which to find the receivers,  $\delta$  – the summary,  $i$  – the
    argument index
    OUTPUT: The potential callees for the given call site

9    $\hat{\delta} := \langle \alpha_2, \beta_2 \rangle \rightarrow \dots \rightarrow \langle \alpha_n, \beta_n \rangle$ 
10   $v = \text{VariableOf}(s, i)$ 
11   $S = \text{GetCallsOn}(v)$ 
12   $\mathbb{R} = \emptyset$ 
13  foreach  $\hat{s} \in S$  do
14    if  $\hat{\delta} = \epsilon$  then
15       $\mathbb{R} = \mathbb{R} \cup \{\kappa(\hat{s}, v)\}$ 
16    else
17       $\mathbb{R} = \text{FindReceivers}(\hat{s}, \hat{\delta}, \gamma(\hat{s}, v)))$ 
18

```

For applying the callback summaries, line 3 iterates over all summaries δ in the database Δ . It looks for those summaries that reference the API call from the given statement. Recall from Section 4.7 that $\omega(s)$ extracts the generic API method signature from a concrete statement. Each summary is applied using method `ApplySummary`. Note that the source statement $\omega(s)$ is removed from the sequence of calls inside the summary and only the remaining calls are passed. Method `ApplySummary` processes these intermediate calls recursively and removes one call per iteration until the final call, i.e., the one that invokes the callback method, is found. We included the structure of δ in line 1 for clarity. Line 9 shows the derived $\hat{\delta}$ with the first element removed from the summary.

For the structure of the individual calls on the summary, recall from Section 4.6 that the first element a encodes the API method, and b encodes the base object on which the API method is called. $b = -1$ refers to a call on the base object, $b \geq 0$ references the parameter with the respective index.

Method `VariableOf` in line 10 obtains the variable v that corresponds to index i in the context of statement s . CGMINER then obtains all virtual call sites $\hat{s} \in \mathbb{S}$ where variable v is the base object using method `GetCallsOn`. For each of these call sites, CGMINER continues the search for the element of the call summary using a recursive call to `ApplySummary` in line 16. Method γ takes a statement, which must be a call site, and a variable, and returns the index of that variable in the argument list of the call (or -1 if the variable is the variable is the base object of the call).

The recursion ends if the summary has no further calls to analyze (line 14). Method κ takes a statement and a variable, e.g., `s.onCallback()` and s . It returns the method that is called (`onCallback` in this case), which is the final callee that is added to the callgraph. Note that `ApplySummary` calls `FindReceivers` again once the statement and variable of the callback are known. This is necessary, because callbacks usually rely on virtual dispatch, i.e., the actual receiver depends on the possible types of the base object. In the example from Listing 1, multiple classes could implement `IHttpCompleted` and depending on some conditional, variable `completedCallback` could be any one of them at line 11. CGMINER detects that `completedCallback.onCallback` is line 11. Finding the final receivers of this virtual call is an orthogonal problem and CGMINER relies on the existing callgraph algorithm.

CGMINER only summarizes callgraph data and must be extended with summaries that capture the semantics of the client analysis. CGMINER integrates well with StubDroid [2], which summarizes data flow, but does not address control flow.

5 Implementation

We run the sample apps on real devices using DFarm [19]. For instrumenting the code and interacting with the devices, we rely on the VUSC commercial code analyzer. VUSC provides an API for instrumenting value requests into Jimple [25] code and for associating the events received at runtime with the Jimple statements at which they were generated. The device communication is derived from FuzzDroid [23] and uses Soot for instrumentation [3].

The runtime overhead of the additional code injected by CGMINER is not relevant as long as the app does not crash with an Application Not Responsive (ANR) exception. The Android system automatically sends ANRs when foreground threads (such as the UI thread) are blocked for an extended amount of time. In order to avoid ANRs, we queue events in the corresponding thread in which they occur and sent them asynchronously. The communication with the control computer happens in a separate thread controlled by an Android Service.

For the list of library classes that serves as an input to CGMINER, we crawled the Maven central repository as well as the Google Gradle repository. To limit the size of the database, we only include libraries that are referenced by at least five other Maven artifacts. For these relevant libraries, we extract the package names of all classes contained in the respective JAR file. When running CGMINER, we consider a class to be a library class when it is contained in one of these known library packages. Note that library identification is orthogonal to the callback analysis, and CGMINER is agnostic to how the list of library classes is built.

6 Limitations

CGMINER instruments the Dalvik code inside an app. If parts of the control flow between API call and callback are implemented in native code, no runtime data can be obtained from these parts. If the native code contains border edges, the callback summary will be incomplete. If a taint transfer occurs in native code, CGMINER relies on StubDroid summaries, which exist for methods from the Java Standard Library, such as `System.arraycopy`.

Note that Android requires each APK file to be signed. Therefore, when instrumenting an app, the app needs to be resigned. Since CGMINER modifies the app for the dynamic analysis, it must be signed anew before it can be installed on the device. If the app performs integrity checking, these checks will fail. While the individual app cannot be analyzed in this case, the CGMINER approach still works if, for each library, enough apps that use the respective library can be processed.

Not every callback may be invoked in each run of each app. In our example in Listing 1, the error callback is only invoked if the HTTP connection fails. Since the callback summaries are merged over many apps in CGMINER, we consider edges that are never triggered even with dozens of apps to be irrelevant in practice.

Our evaluation is partly based on Monkey [10] for exploring the apps' user interface. Monkey is part of the official Android SDK and randomly clicks on the screen for a given amount of time. Note that CGMINER is agnostic to the input generation tool. It can be replaced with a more capable approach in future work. We also used manual exploration in order to augment the automatic analysis.

We currently do not consider Android lifecycle methods such as `onCreate`, as they are few, well-known, change rarely, and are already precisely modeled, e.g., in FlowDroid [5].

7 Evaluation

In this section, we evaluate CGMINER with regard to the following research questions:

- RQ1** How many callback edges does CGMINER identify?
- RQ2** Are the callback summaries correct and complete?
- RQ3** How long does the instrumentation take?
- RQ4** How often do transfer functions occur?
- RQ5** How does CGMINER compare to EdgeMiner?
- RQ6** Which summaries have been found (case study)?
- RQ7** How do summaries affect data flow analysis?

7.1 Experiment Setup

We used a machine with 144 Intel Xeon Gold 6154 CPU cores and 3 TB of physical memory using OpenJDK 16. A maximum of 50 GB was assigned as Java heap space. The machine was chosen due to the performance requirements of FlowDroid for RQ6. Our DFarm installation

is equipped with around 90 devices in total, comprising Samsung Galaxy XCover Pro phones distributed over 9 device controller boards and a single master controller. Note that each run of CGMINER only uses a single device. We use a combination of manual and automatic exploration. For automatic exploration, we used the Monkey tool from the Android SDK to explore the user interface of the app at runtime. Despite its simplistic approach, Monkey achieves code coverage results comparable to more complex approaches [9]. We run each app for five minutes with automatic and the same time using manual exploration. In apps where a login was needed in order to proceed the exploration of the app, we manually created user accounts.

For our callback generation, we randomly collected 700 apps from the Google Play Store between 2008 and 2021, augmented with apps from AndroZoo [1]. We include older apps to merge the callback summaries over multiple versions of a library, and to also include error cases, e.g., failing HTTP connections due to the server no longer being operational. In our experience, newer versions of libraries return the old methods (including their callbacks) for backwards compatibility. On the other hand, new versions may introduce new additional methods with callbacks, requiring us to run CGMINER again on the new version.

For research questions 2 and 5, we inspected callback summaries manually. Two researchers conducted the manual inspection. Upon disagreeing, a third researcher has been involved and these cases were discussed until a consensus was reached.

7.2 Baseline over the Dataset

To better understand the performance of CGMINER, we measure the sizes of the original apps in our dataset, i.e., before the instrumentation. The number of classes ranges from 6 to 37,175 with an average of 14,371 and a median of 13,136. The apps contain between 108 and 226,966 methods, with an average of 85,270 and a median of 69,360 methods. In the Jimple intermediate representation, the apps contain between 693 and 2,793,272 units (i.e., Jimple instructions), with an average of 1,107,276 and a median of 1,008,848 units.

7.3 RQ1: Number of Generated Callbacks

From the 700 apps in our dataset, CGMINER created callback summaries for 338 apps. Not all apps contain callback-driven libraries according to our definition. Hybrid apps, for example, implement their logic in JavaScript and only present HTML content to the user via Android's `WebView` component. Other apps use libraries that our library detection does not recognize, or simply do not use callbacks. Some apps contain native code, which is not supported in CGMINER. Recall that CGMINER creates summaries for libraries rather than apps. Furthermore, some apps are merely add-ons such as themes for other applications and do not have any launchable main activity. Therefore, as long as a single app uses the library's callback-driven API, a summary can be generated.

In total, CGMINER constructed 1,476 summaries, which is around 8 summaries per app on average. Figure 3 shows the cumulative distribution of the number of callbacks found per app. The x axis is the number of edges, and the y axis shows how many apps lead to the given number of edges. The maximum number of edges obtained from one app is 67, the minimum is zero, with a median of 5. For each summary, we recorded the number of API methods that must be called to invoke the callback. On average, one call is required, with a maximum of 2 calls and a minimum of one call. The median is one call.

To augment our callback summaries, we automatically generated artificial apps in an attempt to trigger the callback candidates for which CGMINER did not yield an edge on our original app set. This is a best effort approach. We accept that some of these apps will

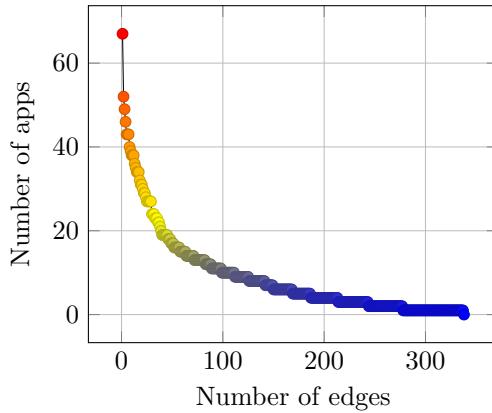

Figure 3 Distribution of callback edge counts over the apps.

crash or fail to invoke the callback. Recall that callback candidates are over-approximated, i.e., it may be impossible to generate a working app for some candidates. However, since CGMINER is a dynamic approach, broken apps do not lead to false positives in the callback summaries generated by observing these apps. The generated artificial apps yielded 1,871 edges.

7.4 RQ2: Correctness of Generated Callbacks

We manually verified the callback summaries generated by CGMINER. We merged the summaries from apps in the dataset with the generated apps mentioned in RQ1. We found 94.62% of all callback summaries to be correct. 38 edges out of 2046 were false positives. Transfer statements were missing in 72 cases.

Since CGMINER is a dynamic approach, it is inherently an underapproximation. To better understand the degree of unsoundness, we manually inspected a random subset of 100 callback candidates which for which CGMINER did not find an edge. We found that 95% of these callback candidates are indeed not callback methods. 5% were callback candidates that were missed due to not triggering the respective method in an app at runtime, i.e., actual false negatives.

Another approach to check for missing callbacks is to use benchmark suites. To our best knowledge, there is no ground truth benchmark specifically for callback edges. Therefore, we used the artificially generated apps introduced in Section 7.3 as a base. On these apps, CGMINER retrieved edges for 82 % of the callback candidates. For 5%, the generated apps missed at least one method call to actually trigger the callback. For the rest, these are not valid callbacks, i.e. these are true negatives.

7.5 RQ3: Instrumentation Performance

Our implementation of CGMINER integrates into an analysis framework that schedules jobs for processing and performs them when free capacity is available on a system consisting of analysis server, DFarm device farm server, DFarm controllers, etc. We therefore measure the performance of the relevant parts of the analysis individually, because the overall time is dominated by the infrastructure.

First, an APK file is imported into the analysis framework and its code is transformed to Jimple. This step takes 59 seconds on average (minimum: 8s, maximum: 130s, median: 54s). Note that this time also includes decoding the app's resource files and manifest, because

the instrumentation framework assumes that they can be modified as well. In fact, the framework injects an application class (if not yet present), services, and permissions as part of the communication infrastructure between device and analysis server.

After the app has been imported, the instrumentation is performed, which takes 9 seconds on average (minimum: 4s, maximum: 14s, median: 4s). This time includes the part specific to CGMINER, i.e., defining the callback events. The CGMINER part alone never takes more than one second with an average of 0.3 seconds and a mean of 0.2 seconds. Translating the callback event definitions into statements, along with the other required modifications to establish the connection between device and analysis host, is part of the VUSC analysis framework. It counts into the 9 seconds and not the one second. On average, the overall analysis performs 432,000 instrumentation steps (maximum: 556,000 steps, minimum: 302,000 steps, median: 396,000 steps). Each step can be a single statement added or removed, a change to a value in a statement, etc.

Next, the transformed Jimple code and resource files including the manifest are written back into an APK file. This step takes 44 seconds on average (maximum: 52s, minimum: 27s, mean: 43s). The total time spent before running the app is 112 seconds on average (minimum: 40s, maximum: 208s, median: 106s). After building, we run the apps for a fixed period of time and send inputs manually and afterwards by using Monkey. Therefore, measuring the runtime performance is not informative. We observe that the apps still meet the responsiveness requirements of the Android operating system.

We conclude that CGMINER’s runtime is dominated by the dynamic exploration (5 minutes in our configuration), and not by the analysis and instrumentation beforehand (roughly 2-3 minutes). Note that CGMINER is intended to be used as a tool to generate callback summaries as a one-time effort. The performance numbers shown correspond to the time needed to generate the summaries. In contrast, applying the callback summaries generated by CGMINER does not require any dynamic analysis.

7.6 RQ4: Prevalence of Transfer Functions

In contrast to previous approaches from the literature [8], CGMINER supports complex callback registration that require transfer functions. In this research question, we evaluate how important transfer edges are in real-world apps. Conceptually, disregarding transfer functions via approximations may lead to a loss of flow-sensitivity as well as false positive callgraph edges as shown in Section 3.

During callback identification (see Section 7.3), CGMINER discovered CGMINER 2046 edges, 146 of which require transfer functions (6.00%). Note that these numbers are on API level. Even a single transfer edge can be highly important if the respective API is used frequently in apps.

To measure the impact of these 146 edges, we therefore check how often these APIs that require transfer functions are called in real-world apps. To avoid any bias from the apps on which the transfer edges were originally identified, we chose a separate evaluation dataset. We randomly picked 1988 apps from the same Play Store and AndroZoo data source explained in Section 7.1. On this app set, 1928 apps (96.98 %) use transfer functions in their code. On average, each app uses 103.65 different transfer functions. For comparison, apps in the dataset use 1089.24 callbacks on average. These results show that transfer functions are highly relevant in practice.

Table 2 shows the ten most frequently-used transfer functions and their edges together with the number of times the respective transfer function was encountered in our evaluation app set. Six of the most found functions are related to wrapped IO calls. For example, a `read` method call on an `BufferedReader` instance triggers the `read` callback on the reader which was specified during the construction of the `BufferedReader` object.

■ Listing 3 Transfer Function Code.

```

1  StringReader sr = new StringReader(str) {
2      public void close() {
3          // additional callback code
4          super.close();
5      }
6  };
7 BufferedReader br = new BufferedReader(sr);
8 br.read();

```

In other words, the constructor of the `BufferedReader` is a transfer function. Listing 3 shows a code example for such a case. Without modeling the transfer function, approaches such as EdgeMiner must model an edge from the call to the `BufferedReader` constructor in Line 7 to all methods of the `Reader` that is passed as the first argument. In the example, this would even be a call to `close`, even though the `StringReader` is never closed².

In total, 19.55 % of the callbacks that EdgeMiner has identified require transfer functions. All of them are missed. In contrast, CGMINER only misses 3.52% of the transfer functions that are required for the callbacks identified by CGMINER.

7.7 RQ5: Comparison with EdgeMiner

For a comparison on the Android system we used Android 4.2, since the since the Edgeminer paper used Android 4.2 for evaluation. EdgeMiner yields 5,125,472 edges in total for Android 4.2, whereas CGMINER yields 2046 edges. We found that the EdgeMiner output contains reference to non-existing parameters or callbacks with incompatible types. First, we removed these edges automatically. Furthermore, we noticed that EdgeMiner's output may contain multiple callback edges overloads referencing all implementations albeit an edge for the abstract superclass or interface was enough. We therefore removed the edges of these overloads automatically and made sure that the removal process does not change the semantics. After this cleanup, 17298 callback edges remain (0.36% of the original edge set). This constitutes as our new base set for EdgeMiner, which we verified manually.

On this base set we compute a false positive rate of 47.42% for EdgeMiner. Manually checking the CGMINER edges only yields a false positive rate of 1.86%. CGMINER's dynamic analysis avoids the false positives that arise from EdgeMiner's VTA callgraph and the resulting imprecise points-to set for that is used to derive the types of registers / variables that store callback objects. We make available the annotated outputs of EdgeMiner and CGMINER as part of our data package. We removed Android APIs not present in Android 4.2 from CGMINER results, since EdgeMiner cannot possibly have results involving these APIs and apps in RQ1 may use newer API methods than those present in Android 4.2.

Note that EdgeMiner's data is based on the Android system's implementation JAR alone without third-party libraries. For a fair comparison, we used the library detector integrated in VUSC to obtain maven coordinates of libraries used in apps in RQ1. We downloaded the JAR files of the library and executed EdgeMiner on these JARs. Table 1 shows the results for the Android system (comprising the Android SDK and the Java standard library) as well as third party libraries. While EdgeMiner has more edges on

² The `StringReader` has no finalizer either that would call `close`.

the Android system jar, it has significantly more false positives and significantly more incomplete edges than CGMINER. Incomplete edges are edges that lack one or more necessary transfer functions. For example, in the motivating example of Section 3, an edge $\langle \text{HttpTask.cons}, 0 \rangle \rightarrow \langle \text{IHttpCompleted.onCallback}, 1 \rangle$ would be incomplete, because it is missing the necessary transfer edges to `schedule` and `runAll`.

To get a better understanding of the sources of imprecision, we analyzed the false positives and the incomplete edges produced by EdgeMiner in detail. Setters and constructors are particularly relevant sources of imprecision. In total, EdgeMiner reports 2826 constructor edges and 1516 setter edges. EdgeMiner places edges from these methods to the callbacks. In reality, however, these methods do not invoke any callback function, neither directly or transitively. Instead, the references to callback objects are saved into fields. Only later, when other methods are called, these references are read back from the field and the respective callback is invoked.

Table 1 Results on different libraries for CGMINER and EdgeMiner. TP: true positive edges, FP: false positive edges, IE: incomplete edges (missing transfers). Regarding “Other”: We have included several other libraries, which we made sure to supply to EdgeMiner as well.

Library	CGMiner			EdgeMiner		
	TP	FP	IE	TP	FP	IE
Android	1051	27	21	4957	7704	2586

Other	118	0	0	0	0	0
Total	1936	38	72	5714	8203	3381
Rate	94.62%	1.86%	3.52%	33.03%	47.42%	19.55%

We next describe some examples of such false edges. One constructor of the `ConcurrentSkipListSet` class, for example, takes a `Comparator` as a parameter. A `ConcurrentSkipListSet` is a sorted set, which orders elements according to this comparator. The constructor only saves the comparator instance to a field, and the callback is triggered when a new element is inserted into the set using the `add` or `addAll` methods. EdgeMiner places an edge from the constructor to the Comparator’s `compare` method, although these methods are only called upon adding an element. In total, EdgeMiner reports incomplete edges in 1734 out of the 2826 constructor edges, and 779 are false positives (11.08 % correctness rate). In contrast, CGMINER

yields only 13 incomplete and 16 false positive edges on 323 constructor edges (91.02 %). Similarly, most setters set a field to a specific value and do trigger callbacks. For example, EdgeMiner assumes an edge from `LayoutInflater.setFactory(LayoutInflater$Factory)` to `LayoutInflater$Factory.onCreateView`, although this is only the registration site of the call. Android calls the callback only upon inflating a layout using the `inflate` method. Since EdgeMiner does not support transfer edges, it misses the corresponding transfers on these edges. For EdgeMiner, out of 1516 setter edges, 663 are incomplete and 195 are false positives. This constitutes a correctness rate of 43.4 % on these edges for EdgeMiner. On 467 edges on setter methods reported by CGMINER, 21 are incomplete and 0 false positive, resulting in a correctness rate of 95.5 %.

7.8 RQ6: Case Study on Individual Callbacks

Using CGMINER, we have identified non-obvious multi-step callbacks. The *ActionBarSherlock*³ library allows a developer to integrate a tab view into his app. New tabs are added using `addTab` on an `ActionBar` object which takes the tab as a parameter. With `Tab.setTabListener`, the developer can register a callback that is notified when the user selects the tab. Therefore, `addTab`, which automatically opens the new tab, triggers the `onTabSelected` callback previously registered on the tab. This callback involves two interactive objects, `ActionBar` and `Tab`. Other tools such as EdgeMiner [8] cannot precisely identify and model such a callback. In case of the `AsyncTask`, CGMINER detects that a call to `AsyncTask.execute` results in several callbacks being called: `onPreExecute`, `doInBackground`, `onPostExecute`.

CGMINER identifies similar API calls that trigger multiple callbacks in the API for the SQLite database engine. A call to `getWritableDatabase` or `getReadableDatabase` triggers the callbacks `onOpen`, `onConfigure` and `onCreate`. Some callbacks are triggered by the operating system upon external events, such as new sensor data. In this case, the last user code call site for this callback is the statement that registered the callback. Even though this statement does not immediately invoke the callback, modeling an edge from the registration site to the callback is still a common and useful approximation. CGMINER, for example, finds a connection between Android's `registerListener` method and the `onSensorChanged` of the `SensorEventListener` interface.

7.9 RQ7: Effect on Client Analysis

We next evaluate the effect of callback summaries on data flow analysis. We ran FlowDroid on 200 randomly selected apps, chosen from the same data source already explained in Section 7.1. Note that this data flow analysis is distinct from the data flow analysis we perform in our approach in Section 4.5. The purpose of the data flow analysis in Section 4.5 is to track all container objects that hold callback objects. This is only relevant when generating new summaries. In contrast, this section performs data flow analysis to determine sensitive flows. For this, we use already computed summaries from Section 7.3 to extend the call graph. We configured a timeout of 3 minutes for callgraph construction and 15 minutes for the main data flow analysis. The analysis was assigned 250 GB of heap space and a maximum of 7 cores. This configuration allowed us to parallelize multiple runs on the same machine. We evaluated three different configurations. As our baseline, we perform the FlowDroid data flow

analysis without any callback edges. We then ran FlowDroid again with callback summaries generated by EdgeMiner and with summaries generated by CGMINER. For each run, we recorded the discovered flows.

■ **Listing 4** Callback Parameter Analysis.

```

1 class MyTaskRunnable implements Runnable {
2     public String data;
3     public void run() {
4         sink(data);
5     }
6 }
7 ThreadPoolExecutor executor = new ThreadPoolExecutor(...);
8 Runnable r = new MyTaskRunnable();
9 r.data = source();
10 executor.execute(r);

```

Recall that CGMINER and EdgeMiner only model control flow, but not data flow. In the example in Listing 4, the first parameter of Line 10 becomes the base object inside the callee `run`. This relationship is important, because the field `data` inside the callback object, i.e., the access path `r.data`, is tainted in Line 9. When the data flow analysis processes the sink call in Line 4, the taint must be available as `this.data`. In other words, FlowDroid's IFDS call edge must re-write the access path from `r.data` to `this.data`.

Neither CGMINER nor EdgeMiner create data flow summaries. Therefore, our initial runs had the required callgraph edges, but could not track data flows across the callback edges. With this configuration, our baseline yielded 2021 flows. With EdgeMiner summaries, FlowDroid found 3575 flows (77 % more than baseline). With CGMINER summaries, 2554 flows were detected, which is 26 % more than the baseline. As expected, FlowDroid discovers

more flows when provided with callback summaries. Further, since EdgeMiner has more (true positive) callback edges than CGMINER as shown in Table 1, it is unsurprising that EdgeMiner leads to more flows as well. FlowDroid tracks flows across the interprocedural data flow graph. Every additional callgraph edge has the potential to lead to more flows.

We next augment the callgraph summaries with data flow information using heuristics. Firstly, we map the base object on which the callback is invoked (which is known from the callback summary) to the `this` object of the callee. In the example in Listing 4, this leads to a data flow edge from variable `r` to the `this` object of the callback. This allows FlowDroid to map `r.data` to `this.data`. Secondly, if there is an edge from a call site to a callback method and the call site accepts a parameter that is cast-compatible to a parameter of the callback method, we assume a data flow edge. We stress that these heuristics are not meant to be complete. We use them as part of our evaluation to better estimate the effect of callback edges for data flow analyses.

With these data flow mappings, FlowDroid finds 2717 flows with EdgeMiner and 2830 flows (40 % more than the baseline) with CGMINER. In the baseline without callback summaries, no data flow mapping is possible. We observe that when we use parameter mappings, FlowDroid with CGMINER finds more data flows than FlowDroid with EdgeMiner, although CGMINER has vastly fewer callgraph summary edges than EdgeMiner. The number of flows found using EdgeMiner callbacks drops from 3575 flows when using no parameter mapping to 2717 when using parameter mappings. The explanation lies in FlowDroid’s sanity checking. For example, when FlowDroid propagates taints along edges in the interprocedural control flow graph, it propagates types along as well. In each propagation step, these propagated types are checked for cast-compatibility with the target variables. EdgeMiner’s spurious callback edges lead to many cast-incompatible propagations. This leads to taints being discarded. For EdgeMiner with many false positive edges or incomplete edges, i.e., edges placed at the wrong statement, this leads to a significant amount of flows being discarded. On the other hand, the increase in data flows with CGMINER summaries represents actual taint propagation along the callback edges. This is expected for examples such as the one shown in Listing 4. Since CGMINER only has few false positives, it is almost unaffected by FlowDroid’s type checks, but benefits from parameter mappings being available. We then analyzed the correctness of the data flows. Due to the large amount of data flow results, we only looked at a subset of 50 flows of each evaluation run. EdgeMiner shows a precision of 94.34% on these flows. Recall that FlowDroid already discards flows with cast-incompatible assignments along the taint propagation path. Therefore, it can eliminate some false-positive flows during propagation. CGMINER delivers a true positive rate of 100%.

As stated in the beginning of this section, we evaluated on FlowDroid using 200 randomly selected apps. From these apps, we found that 94 % invoke at least one callback method. Filtering apps with no callback methods yields the following results: Without data flow mappings, the baseline has 1,987 flows (compared to 2,021 flows w/o filtering). With EdgeMiner summaries, FlowDroid finds 3,505 flows (compared to 3,575). With CGMINER summaries, FlowDroid finds 2,511 flows (compared to 2,554). With data flow mappings and EdgeMiner summaries, FlowDroid then finds 2,681 flows (compared to 2,717). With data flow mappings and CGMINER summaries, FlowDroid finds 2,787 flows (compared to 2,830).

8 Related Work

EdgeMiner [8] statically analyzes the Android framework to build models for callbacks in API methods. Due to the large code size of the Android framework, EdgeMiner over-approximates virtual dispatch using a CHA callgraph. It further suffers from the inherent challenges

of static analysis, such as dealing with reflective method calls. CGMINER avoids such imprecision and only generates edges that are possible at runtime. EdgeMiner tries to find registration and callback pairs using def-use chains. The search starts at a potential callback and follows the definitions of the base object through the library code until it reaches the start of a method that has no more potential callers within the library. In case the callback object is read from a field on the path, all writes to the field are considered as potential definitions and are thus followed, regardless of their context. EdgeMiner does not provide support for collections or arrays and would not be able to generate a correct summary for our example from Listing 3. Perez and Le [20] present Predicate Callback Summaries (PCS) that model under which conditions a callback or Android lifecycle method is invoked. Their static tool Lithium works on the Android source code and suffers from the same challenges of large-scale static callgraph analysis as EdgeMiner. It does not support our complex example either. Callback Control Flow Automata (CCFA) [21] integrates PCS and Window Transition Graphs (WTGs) [27], and focuses mainly on UI callbacks and lifecycle methods. We consider integrating a predicate analysis into CGMINER as future work. Zhang and Ryder [31] propose a static library analysis based on data reachability. Similarly, Guo et al. present an approach based on backward data dependency analysis [12]. These analyses must be conducted for each call site, which is costly in practice [15].

Some work has focused on Android UI callbacks [28], e.g., for context-sensitive linking of parameterized callbacks to their respective UI elements. The same callback may be used for multiple buttons. The clicked button is passed to the callback as a parameter, and the shared implementation may follow different control flow paths depending on that parameter value. The information which API methods may trigger callbacks is usually an external input to these algorithms, which CGMINER can provide. Other work has increased the coverage of dynamic analyses by reasoning about UI callbacks using a combination of static and dynamic analysis [6, 29]. CGMINER is more generic and therefore cannot exploit specific properties of Activities or Intents. TamiFlex [7] uses dynamic analysis to record the runtime values at reflective method calls and build models of known callees for such call sites. Harvester [22] uses static slicing and dynamic execution to extract runtime values at reflective call sites. It rewrites these call sites into explicit calls to deobfuscate apps. The outputs of these approaches are specific to a concrete target program and do not generalize over re-usable libraries. HeapDL [11] uses heap dumps to reconstruct callgraph edges. It can be used to discover callback registration methods, which directly or transitively call callback methods when such a call is present on the stack of some thread in the heap dump. However, when a callback is saved as a field during callback registration and used later on, this approach would require multiple heap dumps taken at precisely the correct timings. Otherwise, either the callback registration, the callback invocation or both are missed. StubDroid [2] statically generates data flow summaries for libraries. It requires a complete and precise callgraph of the library to work properly and can therefore benefit from the callgraph models generated by CGMINER. Our callback summaries are relevant for various analyses (power analysis, privacy analysis, injection analysis, etc.) that currently rely on manual callback models [5, 30, 18, 13].

9 Conclusion

We have presented CGMINER, an approach for dynamically monitoring apps to derive callback summaries for commonly-used libraries. These summaries can then be applied to static analyses that require a callgraph. We have shown that CGMINER yields a precision of more than 94%. With the CGMINER summaries, FlowDroid detects 40 % more flows in comparison to our baseline. In the future, we will run CGMINER on more apps to generate and provide to the community summaries of lesser-used libraries.

Data Availability. The data and implementation have been published to <https://github.com/Fraunhofer-SIT/DynamicCallbackSummaries/>. Since CGMINER is built upon the VUSC commercial scanner, you need to apply for a free academic license for VUSC to build and run CGMINER.

Abstract

We provide support for polymorphism in static typestate analysis for object-oriented languages with upcasts and downcasts. Recent work has shown how typestate analysis can be embedded in the development of Java programs to obtain safer behaviour at runtime, e.g., absence of null pointer errors and protocol completion. In that approach, inheritance is supported at the price of limiting casts in source code, thus only allowing those at the beginning of the protocol, i.e., immediately after objects creation, or at the end, and in turn seriously affecting the applicability of the analysis.

In this paper, we provide a solution to this open problem in typestate analysis by introducing a theory based on a richer data structure, named typestate tree, which supports upcast and downcast operations at any point of the protocol by leveraging union and intersection types. The soundness of the typestate tree-based approach has been mechanised in Coq.

The theory can be applied to most object-oriented languages statically analysable through typestates, thus opening new scenarios for acceptance of programs exploiting inheritance and casting. To defend this thesis, we show an application of the theory, by embedding the typestate tree mechanism in a Java-like object-oriented language, and proving its soundness.

1 Introduction

Modern software engineering practices, e.g., Continuous Delivery [21], produce reliable software at high pace, through automatic pipelines of building, testing, etc. However, programming errors such as dereferencing null pointers [19] or using objects wrongly (e.g. reading from a closed file; closing a socket that timed out¹) are often subtle and difficult to catch, even during the automated testing process. As put by Dijkstra [14]: “*program testing can be used to show the presence of bugs, but never to show their absence*”. So, tools to (statically) catch bugs are essential. Formal methods like deductive verification are difficult to adopt given the effort required [26], but lightweight static program analysis techniques can greatly improve the quality of the source code by detecting at compile-time logic errors, i.e., an unexpected action or behaviour. Beckman et al. [6] observe:

In the open-source projects in our study [...] approximately 7.2% of all types defined protocols, while 13% of classes were clients of types defining protocols. [...] This suggests that protocol checking tools are widely applicable.

To tackle the challenge of finding bugs in object-oriented code, where objects naturally have protocols, in this paper we provide a protocol checking approach, supported by a tool, based on typestates [31, 15]. The work we present is applicable to most object-oriented languages, following the approach in closely related work [18, 11]: attach protocols (essentially, allowed orders of method calls) to classes and type check classes (i.e., their method bodies) following the protocol, thus gaining typestate-based nullness checking (ensuring memory-safety), protocol compliance, and protocol completion (under program termination).

In our previous work [3], we applied the approach to Java, proposing the JaTyC tool, exploiting the seminal simulation-based notion of subtyping [16] to check that the protocol of a class was a subtype of the protocol of its superclass. However, only upcasts and downcasts at the beginning of an object protocol (i.e., just after object creation) or at the end (i.e., in the `end` state) were allowed. Additionally, to determine if a typestate was a subtype of another, the simulation was only applied to the initial typestates of the protocols. It is crucial to overcome these limitations to make JaTyC applicable to real-world scenarios since, as shown in the study of Mastrangelo et al. [25], *casts are widely used*. The type checker was developed following a research methodology based on an iterative/incremental approach (see figure in **Appendix A** for details), based on the theory, which together with motivating examples, drove the type checker implementation (built upon the Checker Framework [30]).

Running example. To emphasise the relevance of our contribution, consider an example inspired from the automotive sector where driving dynamics control allows to customise the drive mode²; for SUVs, in particular, we consider a `Comfort` and a `Sport` modalities, where each allows specific features: `EcoDrive` and `FourWheelsDrive`, respectively.³ List. 1 and List. 2 describe the behaviours of the controllers of a `Car` and a `SUV`, respectively, where class `SUV` extends `Car`. All cars have two base states: `OFF`, which models a powered off car, and `ON`, which represents a powered on car that can perform certain actions, e.g., set a concrete speed. In `OFF`, it is possible to `turnOn` the car and then access features like `setSpeed`. Dually, in `ON`, it is possible to `turnOff` the car. The `turnOn` action may, by some

10    void setEcoDrive(boolean): COMF_ON
11  }
12   SPORT_ON = {
13     void turnOff(): OFF,
14     void setSpeed(int): SPORT_ON,
15     Mode switchMode(): <SPORT:SPORT_ON, COMFORT:COMF_ON>,
16     void setFourWheels(boolean): SPORT_ON
17  }
18 }
```

technical reason, fail, and so, depending on the returned value, either the resulting case is `ON` or `OFF`. SUVs are described by the protocol in Listing 2: when they are successfully powered on by means of `turnOn`, they are set in Comfort mode (`COMF_ON`), and in turn they enjoy specific operations, e.g., `setEcoDrive`. The mode can be changed by executing `switchMode`, whose result depends on the reached mode being still Comfort (as the operation may fail, e.g., if the speed is too high), or Sport (`SPORT_ON`). Similarly, the Sport mode provides the `switchMode` actions and also specific ones, e.g., `setFourWheels`. Note that `setSpeed` is overridden in the SUV class: if eco-drive is active, the speed must respect a given threshold, otherwise it can be set to any value. As we will see, in Section 6, overriding correctness is checked based on typestate variance, thus dynamic dispatch is guaranteed to work safely. Section 8 explains how our work compares with others dealing with inheritance.

Each protocol is defined by a set of *typestates* (e.g., in List. 1, `OFF` and `ON`), each one defining a set of callable methods and subsequent states, possibly depending on return values: e.g., if `turnOn` returns `true` in state `OFF` of the SUV protocol, then the next state is `COMF_ON`. By applying the subtyping algorithm by Gay and Hole [17] to the initial typestates (i.e., `OFF` in Car and SUV protocols), we see that the SUV protocol is a subtype of the Car one.

Listing 3 upcast/downcast limitation protocol.

```

1 public static void dispatch(@Requires("ON") Car c) { ... }
2 public static void providePoweredSUV(@Requires("OFF") SUV c) {
3   if (c.turnOn()) dispatch(c); // Upcast rejected by current typestate analysis
4 }
```

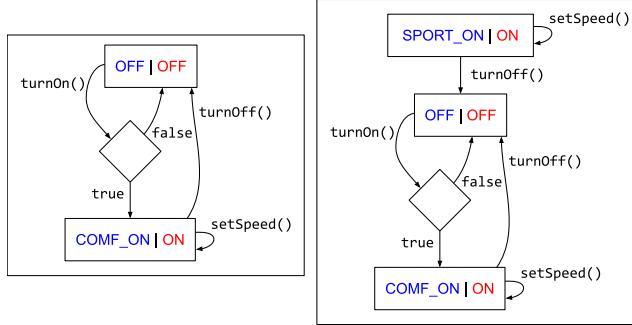

Key insight. Even for simple classes as `Car` and `SUV`, limiting casts only at the beginning/end of the protocols seriously reduces the programs we are able to typestate-check, such as the one in List. 3, where an automotive system dispatches already powered on cars (i.e., required in typestate `ON`), whether they are SUVs or not. Removing this limitation is challenging. The solution relies on the key insight that one has to run the subtyping algorithm not only on the pair of initial typestates, but on all pairs, to find all typestates in both protocols that are in a subtyping relation. For example, the `limitSpeed` method in List. 4 expects a `Car` in typestate `ON`. Since `SPORT_ON` is a subtype of `ON`, code passing a `SUV` in typestate `SPORT_ON` to `limitSpeed` is type-safe. However, if we run the subtyping algorithm starting from the pair of initial typestates of the given protocols (i.e., `(OFF, OFF)`), the generated simulation relation [4, 17] (in Figure 1, where boxes represent input states, and diamonds output ones), will not include `(SPORT_ON, ON)` (leftmost graph). If we provide `(SPORT_ON, ON)`, we realise that this pair is in the *typestate subtyping* relation (rightmost graph).

■ Listing 4 Limitation of the Subtyping Algorithm Application.

```

1 void limitSpeed(@Requires("ON") Car c, int speed) {
2     c.setSpeed(Math.min(speed, 50));
3 }

```

■ Figure 1 Subtyping simulations starting with (OFF, OFF) (left) and (SPORT_ON, ON) (right). Blue depicts typestates of the SUV protocol and red those of Car.

A theory of typestate upcast and downcast. With this key insight, we devise the following mechanism: when downcasting, we look for the typestates (in the protocol of the target class) that are subtypes of the current one; when upcasting, we look for the typestates that are supertypes of the current one. Since multiple typestates may be found, we need a structured notion of *types* to combine them. When downcasting, we combine the subtypes in a *union type* [5, 29] (modelling the fact that the actual type is unknown) so that a method call is allowed only if it is permitted by both elements of the union. Union types are also useful to allow branching code to be typed with different types so that subsequent code, complying with either branch, is accepted (e.g., after an `if` statement). This is more flexible than some other approaches (like session types ones [32]), which require both branches to have the same type. When upcasting, dually, we combine the supertypes in an *intersection type* so that a method call is allowed if it is permitted by at least one element of the intersection.

However, we need more than just intersection and union types. To illustrate the problem, consider a class for an Electric Car (`ECar`) which also extends `Car`. Consider the code in List. 5. After the `if` statement, is `c` an instance of `SUV` or `ECar`? Because of these scenarios, we associate classes with *types* and track all possibilities. To that end, we introduce *typestate trees*, which resemble the class hierarchy. Herein, the typestate tree would have a root for class `Car`, with child nodes for `SUV` and `ECar`. Each node corresponds to a class and maps to the type of the object, accounting for the case in which the object is indeed an instance of that class. In this way, in case of a future downcast to the `SUV` or `ECar` classes, we just consider the corresponding subtree corresponding to that class.

■ Listing 5 Typestate Tree motivation.

```

1 Car c;
2 if (cond) c = new SUV();
3 else c = new ECar();

```

Discussion. The solution we devise is language agnostic, applicable to many object-oriented languages. To test its expressiveness, we applied it to Java, extending JaTyC to now support (up/down)casting in the middle of a protocol. By doing this, we advance related work (Section 8). Kouzapas et al. [24] mention, in the future work section, that to cope

with protocol inheritance between two classes one just needs “a subtyping relation between their typestate specifications”. This is enough if one is only concerned with extending class inheritance but, as we showed, is not adequate to deal with casting, a very common feature.

Furthermore, we support *droppable typestates* (see typestate OFF in List. 1), the final typestates of a protocol – where one can either safely stop using the protocol or perform more actions (if there are any). A droppable typestate with no actions is similar to the **end** state in session types. To fully support droppable typestates, we provide a definition of subtyping over these, extending Gay and Hole’s session type subtyping definition.

Contributions. In short, the main contributions of this work are:

- sound support for safely performing **upcasts** and **downcasts** at any point of a protocol (assuming class downcasts are performed to a class of which an object is a subtype of);
- formalisation of **subtyping over droppable typestates** (generalising Gay and Hole’s session type subtyping);
- **mechanisation** of all definitions and proofs of our results in Coq (artifact available);
- implementation of the presented concepts in our **type checker for Java**, **JaTyC**, where we successfully run all examples included in this paper.

Advances with respect to the state of the art. As far as we know, no previous work deals with casts in the middle of protocols. Moreover, droppable states allow to mark states when the protocol can be safely stopped, another key concept. So, our work advances the state of the art with expressive support for inheritance and casting in object-oriented languages, leveraging on behavioural types [2, 22].

Structure of the paper. **Section 2** presents the subtyping relation, shown to be a pre-order, and a complete and sound algorithm to check typestates subtyping (Theorems 8 and 9). **Section 3** presents upcast and downcast, and the crucial result that each operation preserves subtyping (Theorems 23 and 28). Moreover, we show that, as expected, each operation reverses the other (Corollaries 29 and 30). Finally, we show that method calls make the typestates evolve, preserving subtyping (Theorem 33), and evolution on types commutes with upcast and downcast (Theorems 34 and 35). **Section 4** presents typestate trees, the crucial structure to allow up/down-casting in the middle of a protocol, and main results (Theorem 46 and 51). **Section 5** presents a key result to safely equip a programming language with our subtypestate mechanism – operations on typestate trees preserve their soundness (Theorem 54). **Section 6** discusses how to safely develop a type checking system with typestate trees. Notice that the main contribution of this paper is the provably safe subtypestates theory, paving the way to its use in (most) object-oriented languages. **Section 7** explains how the example presented in List. 6 is type checked with our tool and describes a suite of examples showing the expressiveness of our approach. **Section 8** discusses related work. **Section 9** concludes by envisioning future challenges, e.g., the mechanisation of a type(state tree)-safe object calculus with inheritance to use as basis for our Java implementation. **Appendix A** provides insights on the research methodology we adopted, while **Appendix B** provides a glossary listing all the notations used in the paper.

2 Types and subtyping

In this section, we present the types one can assign to terms of an object-oriented language taken into account, and the corresponding subtyping relations. We first describe typestates, which encode the current state of an object and specify the available methods (Section 2.1).

Then, we compose these in union and intersection types (Section 2.2). Unions track the possible typestates an object might be in, and intersections combine behaviour of two distinct typestates. These will be important when we present how casting works (Section 3).

2.1 Typestates

The following grammar (Def. 1) defines our typestates language. It is very similar to the one presented by Bravetti et al. [11]. The meta-variable m ranges over the set of *method identifiers* **MNames**, o ranges over the set of *output values* **ONames**, and s ranges over the set of *typestate names* **SNames**. The wide tilde stands for a sequence of values.

States are basically of two forms: input and output states. *Input states* $d\{\tilde{m : w}\}$ denote a set like $\{m_1:w_1, m_2:w_2, \dots, m_n:w_n\}$ offering methods (being $n \geq 0$ a natural number), seen as input actions (i.e., external choices), followed by arbitrary states; the meaning is that by selecting method m_i , the input state transitions to state w_i . Input states may optionally be marked as *droppable* (with the subscript `drop` at the left of the set). This marks which input states are final. For example, in List. 1, the typestate **OFF** is defined as a droppable input state (which in the user defined protocol associated with the Java code is represented by the `drop:end` option). *Output states* $\langle \tilde{o : u} \rangle$ denote a set like $\langle o_1:u_1, o_2:u_2, \dots, o_n:u_n \rangle$, presenting all possible outcomes of a method call (values o_1 to o_n , being n a positive natural number), seen as output actions (i.e., internal choices), followed by input states or typestate names. We only consider boolean and enumeration values as outputs.

To deal with recursive behaviour, protocols use equational definitions of typestates.

► **Definition 1.** Typestates, ranged over by meta-variable u , are terms generated by the following grammar. States are terms ranged over by meta-variable w .

$$\begin{array}{lll} u ::= d\{\tilde{m : w}\} \mid s & d ::= \varepsilon \mid \text{drop} \\ w ::= u \mid \langle \tilde{o : u} \rangle & E ::= s = d\{\tilde{m : w}\} \end{array}$$

We assume that in $\langle \tilde{o : u} \rangle$ we have at least one output, while in $d\{\tilde{m : w}\}$, we can have no inputs: `drop{}` represents the protocol ending state, also denoted by `end`. Moreover, in an equation E , typestate names s do not occur unguarded (i.e., we disregard equations like $s = s'$). We write $w^{\tilde{E}}$ to denote state w associated with a set of defining equations. Therefore, we assume that each typestate name s that is used in w and in the body of equations \tilde{E} has a unique defining equation in \tilde{E} . Let \mathcal{W} be the set of terms $w^{\tilde{E}}$ and \mathcal{U} be the set of terms $u^{\tilde{E}}$. Furthermore, let \mathcal{X} be the subset of \mathcal{W} containing only input states $d\{\tilde{m : w}\}$ and \mathcal{Y} be the subset of \mathcal{W} with only output states $\langle \tilde{o : u} \rangle$. Meta-variables x and y range over \mathcal{X} and \mathcal{Y} , respectively. Hereafter, whenever the finite set of equations \tilde{E} is clear from the context, we consider states w implicitly associated with \tilde{E} . Moreover, we omit writing ε .

We can use the grammar introduced in Def. 1 to formally specify *protocols* associated to classes. A protocol is represented by $s^{\tilde{E}}$, with s being the initial typestate name. For example, the protocol associated with class **Car** (List. 1) is **OFF** $^{E_{\text{car}}}$ with E_{car} being:

$$\begin{array}{ll} \text{OFF} & = \text{drop}\{ \text{turnOn} : \langle \text{true : ON}, \text{false : OFF} \rangle \} \\ \text{ON} & = \{ \text{turnOff : OFF}, \text{setSpeed : ON} \} \end{array}$$

The **OFF** typestate is marked as *droppable* and offers a single method (i.e., `turnOn`) which, depending on the returned value (`true` or `false`), leads to either **ON** or **OFF**, respectively. The **ON** typestate offers two methods, `turnOff` and `setSpeed`, leading to **OFF** and **ON**, respectively.

State subtyping is key to support behavioural casting. In our setting, subtypes offer a superset of the supertype methods (input contravariance), and a subset of the supertype outputs (output covariance). To define it properly (with the intended properties), we follow

the work by Gay and Hole on session types subtyping [17]. Therefore, we define the subtyping relation as a simulation one (as protocols can be infinite state systems), and present a sound and complete algorithm to check if one state is a subtype of another. We first introduce function \mathbf{def} to unfold typestate name definitions. The simulation relation follows.

► **Definition 2** (Typestate name definitions). *Function $\mathbf{def} : \mathcal{W} \rightarrow \mathcal{W} \setminus \mathbf{SNames}$ is such that, given a state $w^{\tilde{E}} \in \mathcal{W}$, if it is a typestate name, $\mathbf{def}(w^{\tilde{E}})$ yields the body of its defining equation; otherwise, $\mathbf{def}(w^{\tilde{E}})$ yields the given state $w^{\tilde{E}}$. Formally,*

$$\mathbf{def}(w^{\tilde{E}}) = \begin{cases} x^{\tilde{E}} & \text{if } w^{\tilde{E}} = s^{\tilde{E}' \cup \{s=x\}} \text{ for some } s, E', x \\ w^{\tilde{E}} & \text{otherwise} \end{cases}$$

► **Definition 3** (State simulation). *A relation $R \subseteq \mathcal{W} \times \mathcal{W}$ is a state simulation, if $(w_1^{E_1}, w_2^{E_2}) \in R$ implies the following conditions:*

1. *If $\mathbf{def}(w_1^{E_1}) = d_1\{\widetilde{m:w}\}_1^{E_1}$ then $\mathbf{def}(w_2^{E_2}) = d_2\{\widetilde{m:w}\}_2^{E_2}$ and:*
 - a. *for each $m':w'_2$ in $\{\widetilde{m:w}\}_2$, there is w'_1 such that $m':w'_1$ in $\{\widetilde{m:w}\}_1$ and $(w'_1^{E_1}, w'_2^{E_2}) \in R$.*
 - b. *if $d_2 = \mathbf{drop}$ then $d_1 = \mathbf{drop}$.*
2. *If $\mathbf{def}(w_1^{E_1}) = \langle \widetilde{o:u} \rangle_1^{E_1}$ then $\mathbf{def}(w_2^{E_2}) = \langle \widetilde{o:u} \rangle_2^{E_2}$ and:*
 - a. *for each $o':u_1$ in $\langle \widetilde{o:u} \rangle_1$, there is u_2 such that $o':u_2$ in $\langle \widetilde{o:u} \rangle_2$ and $(u_1^{E_1}, u_2^{E_2}) \in R$.*

Now we define subtyping, following standard approaches.

► **Definition 4** (Subtyping on states). *We say w_1 is a subtype of w_2 , i.e., $w_1^{E_1} \leq_S w_2^{E_2}$, if and only if there exists a state simulation R such that $(w_1^{E_1}, w_2^{E_2}) \in R$.*

An example of a state simulation (Def. 3) follows (also depicted in rightmost graph of Figure 1). It is then easy to check, using Definition 4, that $\mathbf{SPORT_ON}^{E_{SUV}} \leq_S \mathbf{ON}^{E_{Car}}$.

$$\{(\mathbf{SPORT_ON}^{E_{SUV}}, \mathbf{ON}^{E_{Car}}), (\mathbf{OFF}^{E_{SUV}}, \mathbf{OFF}^{E_{Car}}), \\ (\langle \mathbf{true} : \mathbf{COMF_ON}, \mathbf{false} : \mathbf{OFF} \rangle^{E_{SUV}}, \langle \mathbf{true} : \mathbf{ON}, \mathbf{false} : \mathbf{OFF} \rangle^{E_{Car}}), \\ (\mathbf{COMF_ON}^{E_{SUV}}, \mathbf{ON}^{E_{Car}})\}$$

Notice that the common rule for session type subtyping of `end` states (i.e., `end` \leq_S `end`) is derivable from the previous definitions by just picking the relation $R = \{(\mathbf{drop}\{\}, \mathbf{drop}\{\})\}$ and observing that it is a state simulation (Def. 3), thus $\mathbf{drop}\{\} \leq_S \mathbf{drop}\{\}$ holds by Def. 4.

As a sanity check, we show basic subtyping properties on states: reflexivity and transitivity.

► **Lemma 5** (Reflexivity). *For all w , then $w \leq_S w$.*

► **Lemma 6** (Transitivity). *For all $w_1^{E_1}, w_2^{E_2}, w_3^{E_3}$, if $w_1^{E_1} \leq_S w_2^{E_2}$ and $w_2^{E_2} \leq_S w_3^{E_3}$, then also $w_1^{E_1} \leq_S w_3^{E_3}$.*

Defining an algorithm to check state subtyping is crucial, not only because it shows that subtyping is decidable, but also for implementing a type checking procedure (Def. 7). To obtain an algorithm for checking state subtyping, we guarantee termination by always applying ASSUMP, whenever applicable. The initial goal of the algorithm is the judgement $\emptyset \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}$. This approach is similar to the session type subtyping algorithm presented by Gay and Hole [17]. We also show in Theorems 8 and 9 that the subtyping algorithm is complete and sound with respect to the coinductive definition \leq_S (Def. 4).

► **Definition 7** (Algorithmic state subtyping). *The following inference rules define judgements $\Sigma \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}$ in which Σ is a set of typestate pairs, containing assumed instances of the subtyping relation.*

$$\frac{(w_1^{E_1}, w_2^{E_2}) \in \Sigma}{\Sigma \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}} \text{ASSUMP}$$

$$\frac{\begin{array}{c} \mathbf{def}(w_1^{E_1}) = d_1 \{ \widetilde{m : w} \}_1^{E_1} \quad \mathbf{def}(w_2^{E_2}) = d_2 \{ \widetilde{m : w} \}_2^{E_2} \\ \forall m':w'_2 \in \{ \widetilde{m : w} \}_2 \ . \ \exists w'_1 \ . \ m':w'_1 \in \{ \widetilde{m : w} \}_1 \ \wedge \ \Sigma, (w_1^{E_1}, w_2^{E_2}) \vdash w'_1^{E_1} \leq_{S_{alg}} w'_2^{E_2} \\ d_2 = \mathbf{drop} \implies d_1 = \mathbf{drop} \end{array}}{\Sigma \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}} \text{INPUT}$$

$$\frac{\begin{array}{c} \mathbf{def}(w_1^{E_1}) = \langle \widetilde{o : u} \rangle_1^{E_1} \quad \mathbf{def}(w_2^{E_2}) = \langle \widetilde{o : u} \rangle_2^{E_2} \\ \forall o':u_1 \in \langle \widetilde{o : u} \rangle_1 \ . \ \exists u_2 \ . \ o':u_2 \in \langle \widetilde{o : u} \rangle_2 \ \wedge \ \Sigma, (w_1^{E_1}, w_2^{E_2}) \vdash u_1^{E_1} \leq_{S_{alg}} u_2^{E_2} \end{array}}{\Sigma \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}} \text{OUTPUT}$$

► **Theorem 8** (Algorithm completeness). *If $w_1^{E_1} \leq_S w_2^{E_2}$ then $\emptyset \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}$.*

► **Theorem 9** (Algorithm soundness). *If $\emptyset \vdash w_1^{E_1} \leq_{S_{alg}} w_2^{E_2}$ then $w_1^{E_1} \leq_S w_2^{E_2}$.*

2.2 Types

To statically track the possible typestates an object might be in, we combine them in union types. We also combine them in intersection types to describe combined behaviour from both typestates in the intersection. Their usefulness will be made clearer when we see the result of upcasting a type. Our type hierarchy is a lattice, thus supporting \top and \perp types. Note that types do not include class information. *Typestate Trees* will be used for that (Section 4).

► **Definition 10** (Types grammar). *We call types, ranged over by meta-variable t , the terms generated by the following grammar. Recall that u refers to typestate terms (Definition 1).*

$$t ::= t \cup t \mid t \cap t \mid u^{\widetilde{E}} \mid \top \mid \perp$$

For example, the union type $\text{COMF_ON}^{E_{\text{SUV}}} \cup \text{SPORT_ON}^{E_{\text{SUV}}}$ describes an object that might be in typestate COMF_ON or SPORT_ON .

Let \mathcal{T} be the set of types produced by rule t . Now we need to define a subtyping notion to apply to types. The setting is inspired in work by Muehlboeck and Tate [27], in particular, their definition of reductive subtyping.

► **Definition 11** (Subtyping on types). *Let $\leq \subseteq \mathcal{T} \times \mathcal{T}$ be the relation defined by the following inductive rules.*

$$\frac{}{t \leq \top} \text{TOP} \quad \frac{}{\perp \leq t} \text{BOT} \quad \frac{u_1^{E_1} \leq_S u_2^{E_2}}{u_1^{E_1} \leq u_2^{E_2}} \text{TYPESTATES}$$

$$\frac{t \leq t_i}{t \leq t_1 \cup t_2} \text{UNION_R} \ (i \in \{1, 2\}) \quad \frac{t_i \leq t}{t_1 \cap t_2 \leq t} \text{INTERSECTION_L} \ (i \in \{1, 2\})$$

$$\frac{t_1 \leq t \quad t_2 \leq t}{t_1 \cup t_2 \leq t} \text{UNION_L} \quad \frac{t \leq t_1 \quad t \leq t_2}{t \leq t_1 \cap t_2} \text{INTERSECTION_R}$$

As a sanity check, we show basic subtyping properties on types: reflexivity and transitivity.

► **Lemma 12** (Reflexivity). *For all t , then $t \leq t$.*

► **Lemma 13** (Transitivity). *For all t, t', t'' , if $t \leq t'$ and $t' \leq t''$, then $t \leq t''$.*

An algorithm to check that two types are in a subtyping relationship (i.e., $t \leq t'$) can be implemented by proof search on the inference rules in Def. 11. For these, one can observe that the combined syntactic height of the two types being tested always decreases [27]. Therefore, every recursive search path is guaranteed to always reach a point in which both types being compared are typestates $u \in \mathcal{U}$. Since the algorithm to test $u_1^{E_1} \leq_S u_2^{E_2}$ terminates, the overall algorithm to check subtyping also terminates. For example, it is easy to check that $\text{COMF_ON}^{E_{\text{SUV}}} \leq \text{COMF_ON}^{E_{\text{SUV}}} \cup \text{SPORT_ON}^{E_{\text{SUV}}}$, using the UNION_R rule in Def. 11.

3 Basic operations on types

In this section, we start by describing some preliminary assumptions on the hierarchy of classes, and then proceed to present the three main operations on types performed during type checking: `upcast` (Section 3.1), `downcast` (Section 3.2), and `evolve` (Section 3.3). To showcase these, we use the code in List. 6 that creates an object of type `SUV`, calls the method `turnOn`, switches mode and finally passes the object to method `setSpeed` (lines 3-6).

► **Listing 6** ClientCode class.

```

1  public class ClientCode {
2      public static void example() {
3          SUV suv = new SUV();
4          while (!suv.turnOn()) { System.out.println("turning on..."); }
5          suv.switchMode();
6          setSpeed(suv);
7      }
8      private static void setSpeed(@jatyc.lib.Requires("ON") Car car) {
9          if (car instanceof SUV && ((SUV) car).switchMode() == Mode.SPORT)
10             ((SUV) car).setFourWheels(true);
11             car.setSpeed(50);
12             car.turnOff();
13     }
14 }
```

The method `setSpeed` takes a `Car` in the `ON` state, enforced by the `@Requires` annotation (line 8). The behaviour provided by the `ON` state is also available in `COMF_ON` and `SPORT_ON`, so the method should be prepared to work with a `Car` in the `ON` state or a `SUV` (in `COMF_ON` or `SPORT_ON`). The method tests if the car is a `SUV` and tries to switch to the sport mode (line 9); if it succeeds, it proceeds to set the four wheels drive (line 10). Then, it sets the speed to a given value (line 11) and finishes the protocol by turning off the car (line 12).

Throughout this paper, \mathcal{C} is the set of class names and c is a meta-variable ranging over its elements. Additionally, assume all classes belong to a single-inheritance hierarchy associated.

► **Definition 14** (Super relation on classes). *Super is a partial function such that, given a class c , $\text{Super}(c)$ is the unique direct super class of c , if there is one.*

► **Definition 15** (Subtyping relation on classes). *The relation $\leq_C \subseteq \mathcal{C} \times \mathcal{C}$ is the reflexive and transitive closure of the Super relation.*

With classes and their `Super` relation, we now need to map classes to their corresponding protocols, containing only useful states (i.e., reachable states from the initial one).

► **Definition 16** (Reachable states). *The immediate state reachability relation is a relation over $\mathcal{W} \times \mathcal{W}$, defined as follows: $w'^{\widetilde{E}}$ is immediately reachable from $w^{\widetilde{E}}$, if:*

1. $w = \widehat{d\{m:w\}}$ and $\exists m'. m':w' \text{ in } \widehat{d\{m:w\}}$;
2. $w = \langle o:u \rangle$ and $\exists o'. o':w' \text{ in } \langle o:u \rangle$;
3. $w = s$ and \widetilde{E} includes the equation $s = w'$.

The state reachability relation is the reflexive and transitive closure of the immediate state reachability relation.

Recall that each class c has an associated protocol $s^{\tilde{E}}$, where s is its initial typestate name. We enforce that for any classes c and c' such that $\text{Super}(c') = c$, the protocols of c and c' are subtypes (i.e., the initial typestate of c' is a subtype of the initial typestate of c).

► **Definition 17** (Protocol input states). $\text{ProtInputs}(c)$ is the set of all input states $d\{\widetilde{m : w}\}$ that are reachable from protocol $s^{\tilde{E}}$ of class c .

By only considering reachable input states from the initial typestate name of the protocol, we perform an optimisation that avoids dealing with useless typestates.

To refer to the typestates occurring in a type, we introduce a dedicated auxiliary function.

► **Definition 18** (Typestates in a type). Function $\text{typestates} : \mathcal{T} \rightarrow \mathcal{P}(U)$ is such that, given a type $t \in \mathcal{T}$, $\text{typestates}(t)$ yields the set of typestates occurring in t . Formally,

$$\text{typestates}(t) = \begin{cases} \text{typestates}(t_1) \cup \text{typestates}(t_2) & \text{if } t = t_1 \cup t_2 \text{ or } t = t_1 \cap t_2 \\ \{t\} & \text{if } t \in \mathcal{U} \\ \{\} & \text{if } t = \top \text{ or } t = \perp \end{cases}$$

3.1 Upcast

To upcast a typestate from class c to class c' , we take all typestates in the protocol of c' that are supertypes of the original typestate, and combine them in an intersection type, combining behaviour from different types. If no supertypes are found, the “empty intersection” yields \top , signalling an error.⁴ Since we take supertypes, upcast builds a new type that is a supertype of the original (guaranteed by Theorem 21); and because we intersect the supertypes, we build the most “precise” type possible with typestates in c' (guaranteed by Theorem 22).

► **Definition 19** (Upcast on types). Function $\text{upcast} : \mathcal{T} \times \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{T}$ is such that, given a type t , a class c whose protocol the typestates in t belong to, and a class c' we want to upcast to; $\text{upcast}(t, c, c')$ yields the type obtained by taking the intersection of all supertypes (in the protocol of class c') of typestates included in t . The domain of upcast only includes triples (t, c, c') such that $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$ and $c \leq_C c'$. Formally,

$$\text{upcast}(t, c, c') = \begin{cases} \text{upcast}(t_1, c, c') \cup \text{upcast}(t_2, c, c') & \text{if } t = t_1 \cup t_2 \\ \text{upcast}(t_1, c, c') \cap \text{upcast}(t_2, c, c') & \text{if } t = t_1 \cap t_2 \\ \bigcap \{u' \in \text{ProtInputs}(c') \mid t \leq u'\} & \text{if } t \in \mathcal{U} \\ t & \text{if } t = \top \text{ or } t = \perp \end{cases}$$

To see how upcast works, consider the `setSpeed` call in List. 6. In line 6, after calling `switchMode`, the type of `suv` is `COMF_ON ∪ SPORT_ON` (since we ignore the output of `switchMode`, we do not know the actual typestate). To compute the type of the object passed as parameter, we use the `upcast` function, using as input: (i) `COMF_ON ∪ SPORT_ON` as the type to be upcast; (ii) `SUV` as the starting class; (iii) `Car` as the target class. Since the given type is a union type composed by two elements, the `upcast` function initially unfolds it and creates one intersection for each element (i.e., `COMF_ON` and `SPORT_ON`) containing all their supertypes. In this case, there is just one supertype for each: `ON`. Thus,

$$\text{upcast}(\text{COMF_ON} \cup \text{SPORT_ON}, \text{SUV}, \text{Car}) = \text{ON} \cup \text{ON} = \text{ON} .$$

⁴ In general, upcast operations are always possible, since they produce a supertype of the original type. The issue here is that no operations are safely allowed on \top , so in practise, even if an error is not immediately reported on upcast, there will be an error when trying to use an object with \top type.

As a sanity check, we show that `upcast` builds a type where the typestates composing it belong to the class we upcast to. Recall that Def. 19 has constraints $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$ and $c \leq_C c'$ (the following results assume them). To improve readability we omit stating the constraints explicitly and simply quantify universally types and classes.

► **Lemma 20** (Upcast preserves protocol membership). *For all t , c and c' , then*

$$\text{typestates}(\text{upcast}(t, c, c')) \subseteq \text{ProtInputs}(c').$$

To ensure `upcast` correctness, we show that the result: (i) is a supertype of the given type (Theorem 21); (ii) is the “closest” type to the original with typestates in the protocol of the target class (Theorem 22); and (iii) preserves the subtyping relation (Theorem 23), i.e., `upcast` on types in a subtyping relation produces types that are still in such relation.

► **Theorem 21** (Upcast Consistency). *For all t , c and c' , we have $t \leq \text{upcast}(t, c, c')$.*

► **Theorem 22** (Upcast Least Upper Bound). *For all t , t' , c and c' , such that $\text{typestates}(t') \subseteq \text{ProtInputs}(c')$ and $t \leq t'$, we have $\text{upcast}(t, c, c') \leq t'$.*

► **Theorem 23** (Upcast Preserves Subtyping). *For all t , t' , c and c' , such that $t \leq t'$, we have $\text{upcast}(t, c, c') \leq \text{upcast}(t', c, c')$.*

3.2 Downcast

To downcast a typestate from class c to c' , we take all typestates in the protocol of c' that are subtypes of the original typestate, and combine them in a union type. We use a union type because we need to account for all possible typestates an object might be in. Since we take the subtypes, downcast builds a new type that is a subtype of the original one (guarantee given by Theorem 26); and because we make the union of them, we build the “closest” type possible with typestates in c' (guarantee given by Theorem 27).

► **Definition 24** (Downcast on types). *Function `downcast` : $\mathcal{T} \times \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{T}$ is such that, given a type t , the class c whose protocol the typestates in t belong to, and the class c' we want to downcast to; $\text{downcast}(t, c, c')$ yields the type obtained by taking the union of all subtypes (in the protocol of class c') of typestates included in t . The domain of `downcast` only includes triples (t, c, c') such that $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$ and $c' \leq_C c$. Formally,*

$$\text{downcast}(t, c, c') = \begin{cases} \text{downcast}(t_1, c, c') \cup \text{downcast}(t_2, c, c') & \text{if } t = t_1 \cup t_2 \\ \text{downcast}(t_1, c, c') \cap \text{downcast}(t_2, c, c') & \text{if } t = t_1 \cap t_2 \\ \bigcup \{u' \in \text{ProtInputs}(c') \mid u' \leq t\} & \text{if } t \in \mathcal{U} \\ t & \text{if } t = \top \text{ or } t = \perp \end{cases}$$

Note that `downcast` only yields \perp if given \perp . Consider the third case of Def. 24. The union only yields \perp if no sub-typestates in the protocol of c' are found. But that is impossible. If we downcast from a typestate t (in c) to a subclass c' , and since the protocol of c' is a subtype of the one of c , there will necessarily be at least one typestate in c' subtype of t . Moreover, Theorem 54 will show that our overall approach is sound.

To see how `downcast` works, consider the downcast performed in line 9 of List. 6. To compute the type of (SUV) `car`, we use `downcast`, defined in Def. 24, passing as parameter: (i) `ON` as the type to be downcast (given the `Requires` annotation); (ii) `Car` as the starting class; (iii) `SUV` as the target class. Since the type passed as parameter is a simple typestate, the `downcast` function just creates a union containing all the subtypes of `ON`. Concretely,

$$\text{downcast}(\text{ON}, \text{Car}, \text{SUV}) = \text{COMF_ON} \cup \text{SPORT_ON} .$$

As a sanity check, we show that `downcast` builds a type where the typestates composing it belong to the class we downcast to. Recall that Def. 24 has constraints $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$ and $c' \leq_C c$. (the following results assume them). To improve readability, the constraints are implicit and we simply quantify universally types and classes.

► **Lemma 25** (Downcast preserves protocol membership). *For all t, c and c' , we have*

$$\text{typestates}(\text{downcast}(t, c, c')) \subseteq \text{ProtInputs}(c').$$

To ensure `downcast` correctness, we show that the result: (i) is a subtype of the given type (Theorem 26); (ii) is the “closest” type to the original with typestates in the protocol of the target class (Theorem 27); and (iii) preserves the subtyping relation i.e., `downcast` on types in a subtyping relation produces types that are still in such relation (Theorem 28).

► **Theorem 26** (Downcast Consistency). *For all t, c and c' , we have $\text{downcast}(t, c, c') \leq t$.*

► **Theorem 27** (Downcast Greatest Lower Bound). *For all t, t', c and c' , such that $\text{typestates}(t') \subseteq \text{ProtInputs}(c')$ and $t' \leq t$, we have $t' \leq \text{downcast}(t, c, c')$.*

► **Theorem 28** (Downcast Preserves Subtyping). *For all t, t', c and c' , such that $t \leq t'$, we have $\text{downcast}(t, c, c') \leq \text{downcast}(t', c, c')$.*

Additionally, we relate the result of upcasting and then downcasting with the original type, as well as, the result of downcasting and then upcasting. The first follows from Theorems 21 and 27, the second from Theorems 22 and 26. These corollaries are also important to ensure the soundness of the approach (Theorem 54).

► **Corollary 29** (Downcast reverses upcast). *For all t, c and c' , we have*

$$t \leq \text{downcast}(\text{upcast}(t, c, c'), c', c).$$

► **Corollary 30** (Upcast reverses downcast). *For all t, c and c' , we have*

$$\text{upcast}(\text{downcast}(t, c, c'), c', c) \leq t.$$

3.3 Evolve

Whenever we perform a method call on an object with a given type, we need to compute the new type representing the typestates the object might be in after the call. To compute such type and rule out misconduct, we define the `evolve` function, which yields \top when a method is not callable in the given type. Ret_m is the set of outputs returnable by method m .

► **Definition 31** (Evolve). *Function $\text{evolve} : \mathcal{T} \times \mathcal{M} \times \mathcal{O} \rightarrow \mathcal{T}$ is such that, given a type t , a method m , and an object $o \in \text{Ret}_m$; $\text{evolve}(t, m, o)$ yields the new type obtained by executing m on any object currently with type t , where o is the value returned by m . Its definition relies on the auxiliary functions $\text{evolveU} : \mathcal{U} \times \mathcal{M} \times \mathcal{O} \rightarrow \mathcal{U}$ and $\text{evolveY} : \mathcal{Y} \times \mathcal{O} \rightarrow \mathcal{U}$. Formally,*

$$\text{evolve}(t, m, o) = \begin{cases} \text{evolve}(t_1, m, o) \cup \text{evolve}(t_2, m, o) & \text{if } t = t_1 \cup t_2 \\ \text{evolve}(t_1, m, o) \cap \text{evolve}(t_2, m, o) & \text{if } t = t_1 \cap t_2 \\ \text{evolveU}(t, m, o) & \text{if } t \in \mathcal{U} \\ t & \text{if } t = \top \text{ or } t = \perp \end{cases}$$

$$\text{evolveU}(u, m, o) = \begin{cases} w & \text{if } \text{def}(u) = {}_d\{m : w, \widetilde{m : w}\} \wedge w \in \mathcal{U} \\ \text{evolveY}(w, o) & \text{if } \text{def}(u) = {}_d\{m : w, \widetilde{m : w}\} \wedge w \in \mathcal{Y} \\ \top & \text{otherwise} \end{cases}$$

$$\text{evolveY}(y, o) = \begin{cases} u & y = \langle o : u, \widetilde{o : u} \rangle \\ \perp & \text{otherwise} \end{cases}$$

Since `evolve` is deterministic, it is defined as a function, not as a labelled transition system.

To see how `evolve` works, consider the `switchMode` call in line 9 of List. 6. To compute the type of `car`, we use `evolve`, defined in Def. 31, passing as parameter: (i) the type `COMF_ON ∪ SPORT_ON` be evolved (given the result of the `downcast` function); (ii) the method `switchMode` to make the type evolve; (iii) the expected output `Mode.SPORT` to enter the `if` branch. Since the type, passed as parameter, is a union type composed by two elements, the `evolve` function is called recursively, and then the auxiliary function `evolveU` is called for `COMF_ON` and `SPORT_ON`. Since the `switchMode` action leads to an output state, for both `COMF_ON` and `SPORT_ON` (see List. 2), the auxiliary function `evolveY` is invoked. Concretely,

$$\text{evolve}(\text{COMF_ON} \cup \text{SPORT_ON}, \text{switchMode}, \text{Mode.SPORT}) = \text{SPORT_ON} \cup \text{SPORT_ON}$$

that can be simplified to `SPORT_ON`. Notice that the evolved type has the same structure of the one before calling the `evolve` function i.e., a union type.

As a sanity check, we show that `evolve` produces a type containing only typestates belonging to the initial class.

► **Lemma 32** (`Evolve preserves protocol membership`). *For all t, m, o, c ,*

$$\text{typestates}(t) \subseteq \text{ProtInputs}(c) \text{ implies } \text{typestates}(\text{evolve}(t, m, o)) \subseteq \text{ProtInputs}(c)$$

To ensure `evolve` correctness, we show that the result preserves the subtyping relation: `evolve` on types in a subtyping relation produces types that still are in such relation.

► **Theorem 33** (`Evolve preserves subtyping`). *For all t and t' such that $t \leq t'$, we have that*

$$\text{evolve}(t, m, o) \leq \text{evolve}(t', m, o).$$

We also relate `evolve` with `upcast` and `downcast` showing that: (i) `upcast` after `evolve` produces a subtype of the inverse sequence of operations (Theorem 34); and (ii) `downcast` after `evolve` produces a supertype of the inverse sequence of operations (Theorem 35). These theorems are key to ensure soundness (Theorem 54). For readability, we omit the constraints on the universally quantified variables needed to use `upcast` and `downcast`.

► **Theorem 34** (`Evolve and upcast`). *For all t, m, o, c and c' , we have that*

$$\text{upcast}(\text{evolve}(t, m, o), c, c') \leq \text{evolve}(\text{upcast}(t, c, c'), m, o).$$

► **Theorem 35** (`Evolve and downcast`). *For all t, m, o, c and c' , we have that*

$$\text{evolve}(\text{downcast}(t, c, c'), m, o) \leq \text{downcast}(\text{evolve}(t, m, o), c, c')$$

4 Typestate Trees

In this section, we describe *Typestate Trees*, the crucial data structure we use to solve the problem of casting in the middle of a protocol. These trees associate classes with types containing only states in the protocol of those classes (i.e., $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$). The tree root indicates the static type of a variable and the corresponding type (in \mathcal{T}) at a given program point. All other nodes describe what should be the type if we downcast to the corresponding class. The type in the root is always a sound approximation of the runtime execution. The types in other nodes are also sound only if the object is an instance of the corresponding class. This will imply that type safety is guaranteed up-to class downcasts being performed to a class of which an object is a subtype of. Hereafter we define well-formed typestate trees and auxiliary functions. Sections 4.1, 4.2, 4.3, and 4.4, describe the main operations on typestate trees: `upcastTT`, `downcastTT`, `evolveTT`, and `mrgTT`, respectively.

► **Definition 36** (Typestate Trees). *Recall that c ranges over classes (\mathcal{C}) and t ranges over types (\mathcal{T}). Let \mathcal{TT} be the smallest set of triples satisfying the following rules:*

$$\frac{n \geq 1 \quad \forall i, 1 \leq i \leq n . \ tt_i \in \mathcal{TT}}{(c, t, \{ \}) \in \mathcal{TT}} \quad \frac{}{(c, t, \{ tt_i \mid 1 \leq i \leq n \}) \in \mathcal{TT}}$$

Notice that triples in \mathcal{TT} represent trees and are composed of: the class c and the type t of the root, and a set of subtrees (again triples in \mathcal{TT}), one for each root child. Such a set is empty if the tree root has no children (i.e., the tree simply represents a leaf). Throughout this paper, tt ranges over elements of \mathcal{TT} and tts ranges over sets of elements of \mathcal{TT} . We need functions to destroy an element of \mathcal{TT} (which is a triple). Let $\text{cl}((c, t, tts)) = c$, $\text{ty}((c, t, tts)) = t$, and $\text{children}((c, t, tts)) = tts$.

► **Definition 37** (No duplicate classes). *The predicate `nodup` over $\mathcal{P}(\mathcal{TT})$ asserts that, given a set $tts \in \mathcal{P}(\mathcal{TT})$, no two typestates trees in tts have the same associated class. Formally, `nodup(tts)` holds if: $\forall tt, tt' \in tts . \ \text{cl}(tt) = \text{cl}(tt') \Rightarrow tt = tt'$.*

► **Definition 38** (Well-formedness Of Typestate Trees). *The predicate `⊤` over \mathcal{TT} asserts that, given a typestate tree (c, t, tts) , it is correctly constructed. Formally,*

$$\frac{\text{typestates}(t) \subseteq \text{ProtInputs}(c) \quad \text{nodup}(tts) \quad \forall tt \in tts . \ \text{Super}(\text{cl}(tt)) = c \wedge \text{upcast}(\text{ty}(tt), \text{cl}(tt), c) \leq t \wedge \vdash tt}{\vdash (c, t, tts)}$$

So, a typestate tree (c, t, tts) is well-formed under the following conditions: (i) all the typestates of type t belong to the protocol of class c ; (ii) there are no two children with the same class; (iii) the classes associated with each child tree are direct subclasses of c ; (iv) if we upcast a type of a child tree, we get a subtype of t ; and (v) each child is also well-formed. Condition (iv) ensures that the type of a child tree is never less “precise” than the type of the parent. From now on, we only consider well-formed typestate trees.

To illustrate the concept, suppose that in line 3 of List. 6, instead of assigning the newly created object to a `SUV` variable, we assign it to a `Car` one, performing an upcast. Since the static and actual type are different, we need a typestate tree to handle future casts. Given Def. 36 and Def. 38, the resulting typestate tree is $(\text{Car}, \text{OFF}, \{(\text{SUV}, \text{OFF}, \{ \})\})$.

4.1 Upcast

Upcasting a typestate tree to class c' ensures that the resulting root class is c' , by recursively following the `Super` relation and building up new tree roots until the root class is c' .

► **Definition 39** (Upcast on typestate trees). Function $\text{upcastTT} : \mathcal{T}\mathcal{T} \times \mathcal{C} \rightarrow \mathcal{T}\mathcal{T}$ is such that $\text{upcastTT}((c, t, tts), c')$ performs an upcast on typestate tree (c, t, tts) to class c' . The domain of upcastTT only includes pairs $((c, t, tts), c')$ such that $c \leq_C c'$. Formally,

$$\text{upcastTT}((c, t, tts), c') = \begin{cases} (c, t, tts) & \text{if } c = c' \\ \text{upcastTT}((\text{Super}(c), \text{upcast}(t, c, \text{Super}(c)), \{(c, t, tts)\}), c') & \text{otherwise} \end{cases}$$

Notice that, under the assumption on the domain of the upcastTT , the function terminates since the distance between c and c' decreases with each recursive step.

► **Theorem 40** (Typestate Trees Well-formedness Preserved By Upcast). For all c'', tt , such that $\vdash tt$ and $\text{cl}(tt) \leq_C c''$, it holds that $\vdash \text{upcastTT}(tt, c'')$.

To see how upcastTT works, consider the `setSpeed` call in List. 6. In line 8, after calling `switchMode`, the object `suv` has the following typestate tree $(\text{SUV}, \text{COMF_ON} \cup \text{SPORT_ON}, \{\})$. When passing `suv` to `setSpeed`, we need to upcast from `SUV` to `Car`. To do that, we use the upcastTT function, defined in Def. 39, passing as parameter: (i) $(\text{SUV}, \text{COMF_ON} \cup \text{SPORT_ON}, \{\})$ as the typestate tree to be upcast; and (ii) `Car` as the target class. Thus,

$$\text{upcastTT}((\text{SUV}, \text{COMF_ON} \cup \text{SPORT_ON}, \{\}), \text{Car}) = (\text{Car}, \text{ON}, \{(\text{SUV}, \text{COMF_ON} \cup \text{SPORT_ON}, \{\})\}).$$

It is crucial to notice that to upcast a typestate tree, we must perform multiple upcasts, incrementally building up new tree roots, not only to preserve the well-formedness property, but also to ensure soundness. For readability sake, we show the problem with an abstract, but simple example. Take classes `A`, `B` and `C`, where $\text{Super}(C) = B$, $\text{Super}(B) = A$, and the protocol equations associated with each class listed below. Recall that `end = drop{}`.

$$\begin{array}{ll} A1 = \{ m1 : end \} & C1 = \{ m1 : end, m2 : end, m3 : C2 \} \\ B1 = \{ m1 : end, m2 : end \} & C2 = \{ m1 : end, m4 : end \} \end{array}$$

Given the protocols above and according to Def. 4 we have:

$$C1 \leq_S B1 \leq_S A1 \text{ and } C2 \leq_S A1, \text{ but } C2 \not\leq_S B1.$$

`C2` not being a subtype of `B1` is not a problem *per se*, but it may be when upcasting, if we define it to go directly to the root instead of going level-by-level, as downcasting after upcasting should lead to the original state.⁵ To see that, consider the code in List. 7, which contains an unsafe method call, but would be accepted. At first, we create an object `c` of class `C` and we call its method `m3`, producing a new typestate, i.e., `C2`. Then, we assign `c` to variable `a` performing an upcast from class `C` to `A` (and from typestate `C2` to `A1`). We finally perform a sequence of downcasts on `a` leading the object to class `C` (and to typestate `C1`).

Listing 7 Direct upcast example.

```

1 C c = new C(); // C1
2 c.m3(); // C2
3 A a = c; // A1: unsound upcast!
4 B b = (B) a; // B1: downcast level-by-level
5 C c = (C) b; // C1: incorrect! the state should be C2 (that of line 2)
6 c.m2(); // unsafe!
```

⁵ Technically, downcasting after upcasting returns an over-approximation of the original state.

In detail (for those interested), notice that the result of upcasting $C2$ directly to class A (line 3, List. 7) is $A1$, since it is the only supertype of $C2$, i.e., $C2 \leq_S A1$. To downcast $A1$ to class B , we check all the typestates in the protocol of B subtypes of $A1$. Since only $B1$ is subtype of $A1$, that is the downcast result (line 4). Similarly, since only $C1$ is a subtype of $B1$, it is the result of downcasting from $B1$ (line 5). Notice how a direct upcast to A , followed by a downcast to B , and then to C , results in a different typestate with respect to the initial one. This is unsound: $C1$ and $C2$ are unrelated. The issue is that a direct upcast to A makes us lose the information about $C1$ not having supertypes among typestates in B . Since we first upcast $C2$ to B , getting \top as result, we find out that $C2$ has no supertypes among typestates in B . Additionally, since we use typestate trees, downcasting to C leads back to $C2$.

4.2 Downcast

When downcasting a given typestate tree tt to class c , we ensure that the root class of the resulting tree is c . If we find a subtree in tt whose class is c , we pick it as the result (by well-formedness, it is unique). Otherwise, we build a new tree downcasting from the most “precise” type information in tt . For this, we use the `closestSubT` function to look for the subtree whose class is hierarchically the “closest” to c .

► **Definition 41** (Closest subtree). *The function `closestSubT` : $\mathcal{TT} \times \mathcal{C} \rightarrow \mathcal{TT}$ is such that $\text{closestSubT}(tt, c)$ yields the subtree associated with the closest superclass of c occurring in tt . The domain of `closestSubT` only includes pairs (tt, c) such that $c \leq_C \text{cl}(tt)$. Formally,*

$$\text{closestSubT}(tt, c) = \begin{cases} \text{closestSubT}(tt', c) & \text{if } c \leq_C \text{cl}(tt') \wedge tt' \in \text{children}(tt) \\ tt & \text{otherwise} \end{cases}$$

To illustrate the use of `closestSubT`, consider classes A , B , and C , where $\text{Super}(B) = A$ and $\text{Super}(C) = B$. Let tt be $(A, t, \{(B, t', \{\})\})$. Then the following equalities hold: $\text{closestSubT}(tt, A) = tt$; $\text{closestSubT}(tt, B) = (B, t', \{\})$; and $\text{closestSubT}(tt, C) = (B, t', \{\})$. The first two cases are easy to understand: the function yields the subtree whose class is precisely the one we are looking for. In the third case, since there is no subtree in tt whose class is C , $\text{closestSubT}(tt, C)$ yields the subtree corresponding to B , which is the “closest” superclass of C present in tt , i.e., $(B, t', \{\})$. Now, suppose instead that $\text{Super}(B) = A$ and $\text{Super}(C) = A$ (i.e., B and C are “siblings”). Then $\text{closestSubT}(tt, C)$ would yield the entire tree tt whose class is A , which is the “closest” superclass of C present in tt . Lemma 42 ensures the correctness of `closestSubT` and is useful for the soundness proof (Theorem 54).

► **Lemma 42** (Closest correctness). *For all tt and c , if $c \leq_C \text{cl}(tt)$ then*

$$c \leq_C \text{cl}(\text{closestSubT}(tt, c)).$$

► **Definition 43** (Downcast on typestate trees). *Function `downcastTT` : $\mathcal{TT} \times \mathcal{C} \rightarrow \mathcal{TT}$ is such that $\text{downcastTT}(tt, c)$ performs a downcast on typestate tree tt to class c . The domain of `downcastTT` only includes pairs (tt, c) such that $c \leq_C \text{cl}(tt)$. Formally,*

$$\text{downcastTT}(tt, c) =$$

$$\begin{cases} tt' & \text{if } tt' = \text{closestSubT}(c, tt) \wedge c = \text{cl}(tt') \\ (c, \text{downcast}(\text{ty}(tt'), \text{cl}(tt'), c), \{\}) & \text{otherwise } tt' = \text{closestSubT}(c, tt) \end{cases}$$

► **Theorem 44** (Typestate Trees Well-formedness Preserved By Downcast). *For all c, tt , such that $\vdash tt$ and $c \leq_C \text{cl}(tt)$, it holds that $\vdash \text{downcastTT}(tt, c)$.*

To see how `downcastTT` works, observe how `(SUV) car` would be checked (in List. 6). To compute its typestate tree, we use `downcastTT`, defined in Def. 43, passing as parameter: (i) `(Car, ON, {})` as the typestate tree to downcast; (ii) `SUV` as the target class. Notice that, in the case the root is also a leaf, we need to replace it with the result of `downcastTT`. Concretely, $\text{downcastTT}((\text{Car}, \text{ON}, \{}), \text{SUV}) = (\text{SUV}, \text{COMF_ON} \cup \text{SPORT_ON}, \{})$.

4.3 Evolve

To compute the typestate tree of an object after a call, we define the `evolveTT` function.

► **Definition 45** (Evolve on typestate trees). *Function `evolveTT : TT × M × O → TT` is such that `evolveTT(tt, m, o)` yields a new typestate tree resulting from applying `evolve(t, m, o)` (Def. 31) to all the nodes of tt . The domain of `evolveTT` only includes triples (tt, m, o) such that $o \in \text{Ret}_m$ (i.e. the set of outputs returnable by method m). Formally,*

$$\text{evolveTT}((c, t, tts), m, o) = (c, \text{evolve}(t, m, o), \bigcup_{tt_i \in tts} \text{evolveTT}(tt_i, m, o)).$$

Notice that, when the set tts is empty, $\text{evolveTT}((c, t, tts), m, o) = (c, \text{evolve}(t, m, o), \{\})$

► **Theorem 46** (Typestate Trees Well-formedness Preserved By Evolve). *For all tt, m, o , such that $\vdash tt$, it holds that $\vdash \text{evolveTT}(tt, m, o)$.*

■ **Listing 8** `EvolveTT` example.

```
1 Car c = new SUV();
2 if (c.turnOn()) c.turnOff();
```

To see how `evolveTT` works, consider the code presented in List. 8 (where the protocols of `Car` and `SUV` are presented in List. 1 and List. 2). The typestate tree of `c` is `(Car, OFF, {(SUV, OFF, {})})`. When the `turnOn` call occurs, we need to “evolve” each node of the typestate tree. To compute the resulting tree, we use `evolveTT`, defined in Def. 45, passing as parameter: (i) the typestate tree of `c`; (ii) `turnOn` as the method called; (iii) `true` as the expected output to enter the `if` branch. Concretely,

$$\text{evolveTT}((\text{Car}, \text{OFF}, \{(SUV, \text{OFF}, \{\})\}), \text{turnOn}, \text{true}) = (\text{Car}, \text{ON}, \{(SUV, \text{ON}, \{\})\}).$$

Notice that every node of the typestate tree is “evolved” using the `evolve` function.

4.4 Merge

In the case of branching code, one has to merge type information coming from all different branches, so that subsequent code can be properly analysed by considering all possibilities (e.g., merging type information coming from both branches of an `if` statement). To this end, we define the `mrgTT` function, which merges two typestate trees. Before presenting `mrgTT`, we define some auxiliary functions, crucial for the formalisation.

► **Definition 47.** *Function `height : P(TT) → N` is such that `height(tt)` yields the greatest number of nodes traversed, in tt , from the root to one of the leaves (both included).*

► **Definition 48.** *Function `clss : P(TT) → P(C)` is such that `clss(tts)` yields the set of classes associated with the typestate trees in tts . Formally, $\text{clss}(tts) = \{\text{cl}(tt) \mid tt \in tts\}$.*

► **Definition 49.** Function $\text{find} : \mathcal{C} \times \mathcal{P}(\mathcal{T}\mathcal{T}) \rightarrow \mathcal{T}\mathcal{T}$ is such that, given a class c and set of typestate trees tts with $c \in \text{clss}(tts)$ and $\text{nodup}(tts)$, $\text{find}(c, tts)$ yields the unique typestate tree in set tts whose class is c .

► **Definition 50 (Merge).** Function $\text{mrgTT} : \mathcal{T}\mathcal{T} \times \mathcal{T}\mathcal{T} \rightarrow \mathcal{T}\mathcal{T}$ is such that, given typestate trees tt and tt' , $\text{mrgTT}(tt, tt')$ yields the typestate tree obtained by merging tt and tt' . The domain of mrgTT only includes pairs (tt, tt') such that $\text{cl}(tt) = \text{cl}(tt')$. Formally,

$$\text{mrgTT}((c, t, tts), (c, t', tts')) = (c, t \cup t', tts_1 \cup tts_2 \cup tts_3)$$

$$\text{where } tts_1 = \bigcup_{c_i \in \text{clss}(tts) \cap \text{clss}(tts')} \text{mrgTT}(\text{find}(c_i, tts), \text{find}(c_i, tts'))$$

$$tts_2 = \bigcup_{c_i \in \text{clss}(tts) \setminus \text{clss}(tts')} \text{mrgTT}(\text{find}(c_i, tts), (c_i, \text{downcast}(t', c, c_i), \{\}))$$

$$tts_3 = \bigcup_{c_i \in \text{clss}(tts') \setminus \text{clss}(tts)} \text{mrgTT}((c_i, \text{downcast}(t, c, c_i), \{\}), \text{find}(c, tts'))$$

Note that mrgTT terminates since $\text{height}(tt) + \text{height}(tt')$ decreases with each recursive step. Moreover, mrgTT is symmetric, i.e., $\text{mrgTT}(tt, tt')$ gives the same result as $\text{mrgTT}(tt', tt)$.

► **Theorem 51 (Typestate Trees Well-formedness Preserved By Merge).** For all tt, tt' , such that $\text{cl}(tt) = \text{cl}(tt')$, $\vdash tt$, and $\vdash tt'$, it holds that $\vdash \text{mrgTT}(tt, tt')$.

To see how mrgTT works, consider the `if` statement in List. 6 (lines 12-14). Notice that, although the `else`-branch is missing, in the process of computing the typestate tree of `car`, we need to consider it to be there (to account for all possible outputs returned by `switchMode`). To compute such typestate tree, we use mrgTT , defined in Def. 50, passing as parameters: (i) `(SUV, SPORT_ON, {})` and (ii) `(SUV, COMF_ON, {})`. Since neither of the parameters have children nodes, it is enough to make the union of the root types. Concretely,

$$\text{mrgTT}((\text{SUV}, \text{SPORT_ON}, \{}), (\text{SUV}, \text{COMF_ON}, \{})) = (\text{SUV}, \text{SPORT_ON} \cup \text{COMF_ON}, \{}).$$

5 Typestate Trees Soundness

In this section, we discuss why we consider type-safe a programming language equipped with our subtypestate mechanism. Such result relies on the key property that given a typestate tree that soundly approximates the current runtime typestate of an object, operations on it result in new typestate trees that still soundly approximate the runtime typestate. This assumes that class downcasts are performed to a class of which the object is a subtype of. So, we do not provide static guarantees that class downcasts will not throw at runtime.

► **Definition 52 (Sequence of upcasts on types).** Function $\text{upcast}^* : \mathcal{T} \times \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{T}$ is such that $\text{upcast}^*(t, c, c')$ performs zero or more upcasts from c to c' step-by-step, following the class hierarchy. The domain of upcast^* only includes triples (t, c, c') such that $\text{typestates}(t) \subseteq \text{ProtInputs}(c)$ and $c \leq_C c'$. Formally,

$$\text{upcast}^*(t, c, c') = \begin{cases} t & \text{if } c = c' \\ \text{upcast}^*(\text{upcast}(t, c, \text{Super}(c)), \text{Super}(c), c') & \text{otherwise} \end{cases}$$

Since the distance between c and c' decreases with each recursive step, upcast^* terminates.

The next relation describes a typestate tree where type information is sound with respect to class c' and type t' . That is, assuming c' and t' represent the exact runtime type of a given object, a sound typestate tree correctly approximates such type. Note that the root has to be necessarily sound with respect to runtime, while the other nodes only need to be sound if the initialising class of the object is a subclass of the class associated with that node. Thus, all non-root nodes describe the type of the object if indeed the object is an instance of the corresponding class. This implies that if we downcast, possibly turning a non-root node into the new root, we preserve soundness only if the runtime downcast succeeds.

► **Definition 53** (Soundness Of Typestate Trees). *The predicate $\vdash_{c',t'}$ over \mathcal{TT} , with $\text{typestates}(t') \subseteq \text{ProtInputs}(c')$, asserts that, given a (well-formed) typestate tree (c, t, tts) , it is sound with respect to class c' and type t' . Formally,*

$$\frac{c' \leq_C c \quad \text{upcast}^*(t', c', c) \leq t \quad \forall tt \in tts . \ c' \leq_C \text{cl}(tt) \Rightarrow \vdash_{c',t'} tt}{\vdash_{c',t'} (c, t, tts)}$$

The next theorem shows that soundness is preserved by typestate tree operations. Note that soundness after downcast is only preserved if at runtime the downcast does not throw an exception (thus the assumption $c \leq_C c' \leq_C \text{cl}(tt)$ on the second item of Theorem 54).

► **Theorem 54** (Typestate Trees Soundness Preservation). *Soundness is preserved by:*

upcast – for all c, t, c', tt , such that $\vdash_{c,t} tt$ and $\text{cl}(tt) \leq_C c'$, it holds that

$$\vdash_{c,t} \text{upcastTT}(tt, c')$$

downcast – for all c, t, c', tt , such that $\vdash_{c,t} tt$ and $c \leq_C c' \leq_C \text{cl}(tt)$, it holds that

$$\vdash_{c,t} \text{downcastTT}(tt, c')$$

evolve – for all c, t, tt, m, o , such that $\vdash_{c,t} tt$, it holds that

$$\vdash_{c,\text{evolve}(t,m,o)} \text{evolveTT}(tt, m, o)$$

merge – for all c, t, tt_1, tt_2 , such that $\vdash_{c,t} tt_1$ or $\vdash_{c,t} tt_2$, and $\text{cl}(tt_1) = \text{cl}(tt_2)$, it holds that $\vdash_{c,t} \text{mrgTT}(tt_1, tt_2)$.

Having shown our approach sound, the following section explains how the functions defined in Section 4 are used during type checking.

6 Application to type checking

We believe the setting presented is quite general and applicable to many object-oriented languages. In this section, we explain, how in detail, assuming a common syntax.⁶ We start by describing how declarations are analysed in JaTyC, followed by expressions, and then statements. We use the Kleene star to denote (possibly empty) sequences.

Class declarations and overriding. First, it is crucial to guarantee that protocols are well-formed and the relation between classes and their protocols makes sense. To this, we ensure that all methods mentioned in the protocol are declared in the class. Similarly, we check that all mentioned outputs are return values of the corresponding methods. Additionally, we check typestate input contravariance and output covariance in overridden methods, since these may include `@Requires` and `@Ensures` annotations in parameters and return types, respectively, which limit the typestates received/returned. Finally, we ensure that the subclass protocol is

⁶ Formalising a type checking system for one particular language, mechanising, and proving it sound is a matter for another paper. Doing that for a core Java-like language is work-in-progress.

a subtype of the superclass one (i.e., the initial state of the former is a subtype of the initial state of the latter according to Def. 4). Thanks to these checks, dynamic dispatch works transparently: if a method is callable on a supertype, it is also callable on its subtypes.

To type check a class, we analyse each method following the sequences of calls allowed by the protocol, similarly to the approach by Bravetti et al. [11], so that method analysis benefits from type information coming from the analyses of methods called before. Type information is stored in a map from locations (local variables, fields of the `this` object, and code expressions) to typestate trees (Def. 36). We also store the typestate trees of expressions since these may evaluate to typestate objects, which must be tracked. Moreover, type information of final states is checked to ensure all fields either correspond to a terminated protocol or are aliased (explained later), to ensure *protocol completion* of references in fields.

Method declarations: `@Ensures(s) type m((@Requires(s) type x)*) {st}`. To check a method, we build a control flow graph [1] with the Checker Framework [30]. Then, we traverse it, visiting each expression or statement, and propagate type information. For each expression, we take the type information obtained from analysing the previous one, and produce new information. Expression or statement analysis is described later.

The initial type information (i.e., the initial input of the graph traversal) is composed by the types of the parameters, expressed via the `@Requires` annotation, combined with information about fields (coming from previous method analysis, as explained before). If a `@Requires` annotation is omitted, it means we expect an aliased reference. Return statements are analysed like assignments, while making sure the returned expression type is a subtype of the one declared via the `@Ensures` annotation. If no annotation is provided, we return an aliased reference. At the end of a method body, we ensure variables and code expressions are either aliased or in a final state, guaranteeing *protocol completion*.

Variable declarations or assignments: `[type] x = exp`. To check a variable declaration or assignment, we call `upcastTT` (Def. 39) on the typestate tree of the right-hand-side, and associate the result with the variable (or field) in the left-hand-side. If `upcastTT` yields a typestate tree with \top as root type, the assignment is not allowed and we report an error. Given how the control flow graph is built, the expression on the right-side was already checked when we reach this point. If we override a typestate tree corresponding to a non-terminated protocol, we also report an error, since the assignment may compromise protocol completion of the overridden reference. Assignments may produce aliasing among variables. Since an object’s state could be modified via multiple aliases, we restrict aliasing to allow us to statically track object states. We enforce a linear discipline: only one variable is “active”, while the others are marked as aliased (and cannot call protocol methods). We also mark the right-hand-side expression as aliased when checking a variable declaration or assignment.

Method call expressions: `exp.m(exp*)`. To check a call, we first ensure the receiver expression is not `null`. We can do this because we distinguish between nullable and non-null types. Then, we analyse each *parameter assignment* applying the same rules explained before. This ensures that calls like `obj.m(x,x)` do not create unintended aliases. We also ensure that the root types of the typestate trees associated with the parameter expressions are subtypes of the expected types in the method signature. Following this, we proceed to check the call itself. We ensure the receiver expression is a non-aliased reference and use `evolveTT` (Def. 45) to compute the typestate tree associated with the receiver after the call, passing the current typestate tree, the method name, and a possibly returned output (if the method call appears in an `if` or `switch` statement). Note that `evolveTT` might be called several times to consider all possible outputs. If `evolveTT` yields a typestate tree where the root type is \top , then the method is not available to be called in that state, so we report an error.

Cast expressions: `(C) exp`. When checking a cast, we know that the inner expression was already checked, similarly to what happens to other expressions. To check it, we must use either `upcastTT` (Def. 39) or `downcastTT` (Def. 43), passing the inner expression typestate tree and the target class. We test if we are upcasting or downcasting by comparing the inner expression static type with the target class. The result is associated with the cast expression and the inner one is marked as aliased. As for assignments, if `upcastTT` yields a typestate tree with \top in the root, we report an error. However, `downcastTT` does not produce errors because we provide type safety up-to downcasts not throwing runtime exceptions.

One key detail about cast expressions is that if a cast expression is the receiver object of a method call, after checking the call, the new type of the receiver object is associated with the most inner expression which is not a cast, not with the cast expression itself. For example, if the receiver is `(A) ((B) x)`, the new type information is associated with `x` directly, not with `(A) ((B) x)`, so that `x` can be used again later (instead of being aliased). This will require an upcast to the class of `x`, but no information is lost, thanks to typestate trees.

New expression: `new C(exp*)`. The initialisation of a new object is analysed similarly to a method call (since we are calling the constructor), except that it returns a new object. So, we associate the expression with a typestate tree with only a root: the class is the object type we are constructing, and the type (from Def. 10) is the initial typestate of the protocol.

If statements: `if (exp) { st } else { st' }`. For simplicity, up until now we omitted an implementation detail crucial to type check `if` statements (and `switch` statements): during the control flow graph traversal, we do not simply propagate a map from locations to typestate trees; we keep track of type information depending on the values of other expressions. For instance, to analyse a method call in a condition of an `if`, we track the type information for when the condition is `true` separately from the one when it is `false`. So, when checking an `if`, we just propagate the former to the first branch, and the latter to the second branch. We also make sure to invalidate such “conditional” type information once it is no longer relevant. Finally, the typestate trees associated with each location after the `if` are the result of merging type information from both branches, using `mrgTT` (Def. 50).

Switch statements: `switch (exp) { (case val : st)* }`. We analyse a `switch` statement similarly to an `if` one. A method call in the expression of a `switch` statement produces type information different for each `case`, but we consider enumeration values that may be returned instead of boolean values. So, to check a `switch` statement, we just need to propagate the information that holds when a given `case` is matched to the related branch. Again, we invalidate this “conditional” type information once it is no longer relevant.

While statements: `while (exp) { st }`. While statements are analysed like `if` ones, except the flow graph is different: after the body is executed, execution returns to the condition. Because of this, we might traverse the same expression or statement in the graph more than once. If that occurs, we merge the new gathered information with the previous one. To ensure that the static analysis terminates, we avoid analysing an expression again if no new type information was gathered. This is guaranteed to occur because the number of all possible typestates is finite. In the worst case, when merging, we might produce a union of all typestates. Typestate trees are also finite because the number of classes is finite.

7 Use Cases

To showcase the applicability and expressiveness of our approach, we start by explaining how the code in List. 6 is type checked in detail. Then, we present a suite of examples with polymorphic code⁷, inspired from **cyber-physical systems**, showing that: (i) JaTyC detects errors the standard Java type checker does not detect; (ii) our setting is flexible and expressive enough to model interesting and intricate scenarios.

Type checking List. 6. To type check the `ClientCode` class (which has no protocol), we analyse the static methods `example` and `setSpeed`, independently (since static methods are not part of a class protocol). The list of steps to type check the `example` method follows:

- Check the expression `new SUV()`, associating it with a leaf typestate tree with class `SUV` and type `OFF` (i.e., `(SUV, OFF, {})`);
- Check the assignment, associating the previous typestate tree with the variable `suv`, and marking the expression on the right as aliased;
- Check the call `suv.turnOn()`, allowed in type `OFF`, generating “conditional” type information: if `true`, `suv` has typestate tree `(SUV, COMF_ON, {})`, otherwise it has `(SUV, OFF, {})`;
- Check the negating expression which “inverts” the conditional information;
- Inside the body of the `while` statement, `suv` is associated with `(SUV, OFF, {})`, and after exiting the `while`, `suv` is associated with `(SUV, COMF_ON, {})`;
- Check the call `suv.switchMode()`, which is allowed in type `COMF_ON`, generating “conditional” type information: `suv` has the typestate tree `(SUV, SPORT_ON, {})` if the call returns `Mode.SPORT`, and if the call returns `Mode.COMFORT`, it has `(SUV, COMF_ON, {})`. Since the returned value is not checked in a `switch` statement, we combine both typestate trees into `(SUV, SPORT_ON ∪ COMF_ON, {})`;
- Check the *parameter assignment* of `suv` by upcasting from `SUV` to `Car`, generating the typestate tree `(Car, ON, {(SUV, SPORT_ON ∪ COMF_ON, {})})`. Since the root type `ON` is a subtype of the required type in the `@Requires` annotation, the *parameter assignment* is allowed. Additionally, variable `suv` is marked as aliased: the `setSpeed` method is now the one responsible to complete the protocol of the given instance;
- No further checks are necessary for the call expression on `setSpeed` since it is a static method and methods are checked in a modular way;
- Type checking the `example` method finishes by checking protocol completion. Since all locations are marked as aliased at the end, no error about completion is reported.

To finish checking the class, we analyse `setSpeed`. The list of steps taken follows:

- We associate `car` with typestate tree `(Car, ON, {})`, according to the `@Requires` annotation;
- Downcast from `Car` to `SUV`, resulting in the typestate tree `(SUV, COMF_ON ∪ SPORT_ON, {})`;
- Check the call `((SUV)car).switchMode()`, which is allowed in type `COMF_ON ∪ SPORT_ON`, generating “conditional” type information: `(SUV)car` has typestate tree `(SUV, SPORT_ON, {})`, if the call returns `Mode.SPORT`, and if the call returns `Mode.COMFORT`, it has `(SUV, COMF_ON, {})`;
- To make `car` usable again, upcast to `Car`, associating `car` with the typestate tree `(Car, ON, (SUV, SPORT_ON, {}))`, if the call returned `Mode.SPORT`; and `(Car, ON, (SUV, COMF_ON, {}))` if the call returned `Mode.COMFORT`;

⁷ The repository of our tool includes an `examples` folder containing such examples.

- Check the `if` statement by propagating the type information corresponding to each branch;
- In the body of the `if` statement, downcast (again) from `Car` to `SUV`, resulting in the typestate tree (`SUV, SPORT_ON, {}`);
- Check the call `((SUV)car).setFourWheels(true)`, which is allowed in type `SPORT_ON`, in a similar fashion as before, associating `car` with `(Car, ON, (SUV, SPORT_ON, {}))`;
- Merge type information from both branches, resulting in `car` being associated with typestate tree `(Car, ON, (SUV, SPORT_ON ∪ COMF_ON, {}))`;
- Check the call `car.setSpeed(50)`, which is allowed in type `ON`, leading to `ON`;
- Check the call `car.turnOff()`, which is allowed in type `ON`, leading to `OFF`;
- Finish by checking protocol completion. Since all locations are marked as aliased or are in a final state (`car` is in the droppable typestate `OFF`), no completion error is reported.

Examples suite. We report the most significant examples of our suite in Table 1: **Directory** indicates the sub-directory; **Features** highlights the key features; **Checks** says if the example is accepted by our tool or not; and, **Runtime** describes the runtime error exhibited, if any.

In *Iterator (1)*, *Alarms* and *Cars (1)*, the examples test how our approach behaves with polymorphic code: as expected, the code compiles and no errors are thrown.

In *Drones (1)* and *Robots (1)*, the examples are more complex: we introduce a typestate data structure to increase the degree of flexibility (storing an arbitrary number of typestate objects, i.e., Drones and Robots). A key feature showcased here is the interaction between typestate objects: every time an object is used, it needs to be extracted from the data structure and put back once it has finished its task. In *Drones (2)*, the interaction between the data structure and the objects is even more articulate: we do not wait for the object to finish its task, but we immediately put it in the data structure and move to the next one, simulating a parallel tasks execution. The *Drones (3)* example is similar to the previous one, but it relies in a test for `null` being incorrectly negated in the return expression of an instance method, which causes a null pointer error in subsequent calls. The tool correctly propagates type information in the order methods may be called and catches this problem.

In *Iterator (2)* and *Cars (2)*, we show two problematic scenarios: index out of bounds and null-pointer exceptions, respectively. The former is caused by getting the next element without checking whether there are remaining elements or not. The latter is caused due to a field usage before initialising it. We are able to statically catch both cases.

Finally, in *Robots (2)*, we have another example of null-pointer error. The exception now is caused by a field being assigned to `null` in the subclass and used in the superclass, after performing an upcast. Thanks to our work, we are able to detect that, after assigning the field to `null`, the object is in a typestate with no supertypes, thus we raise an error.

In short, the provably sound theory presented in this paper is expressive and applicable to a mainstream object-oriented language, dealing with realistic code.

8 Related work

Fugue [13] allows checking typestates (seen as predicates over fields) by annotating methods with contracts and checking invariants. It handles casting and subclassing, where subclasses are allowed to introduce additional states with respect to superclasses. If an object ends up in a state unknown to its supertype, Fugue prohibits upcasting - as in our approach. To handle inheritance, *frame typestates* are introduced. Each frame is a set of fields declared in a particular class. An *object typestate* is the collection of frames. In our approach, our protocols

 **Table 1** Summary of examples.

Name	Directory	Features	Checks	Runtime
Iterator (1)	removable-iterator	Polymorphic safe code	Y	Ok
Iterator (2)	removable-iterator2	Wrong method call order	N	Out Of Bounds
Alarms	alarm-example	Polymorphic safe code	Y	Ok
Cars (1)	car-example	Polymorphic safe code	Y	Ok
Cars (2)	car-example2	Wrong method call order	N	Null-pointer
Drones (1)	drone-example	Typestated data structure	Y	Ok
Drones (2)	drone-example2	Typestated data structure Complex objects interaction	Y	Ok
Drones (3)	drone-example3	Same as Drones (2) and Incorrect test for <code>null</code>	N	Null-pointer
Robots (1)	robot-example	Typestated data structure Simple objects interaction	Y	Ok
Robots (2)	robot-example2	Wrong typestate upcast	N	Null-pointer

are globally defined with automata (e.g., List. 1 and 2), instead of method contracts, which we believe is more natural. Moreover, instead of using frames, we treat each class as a whole. This is enough since we view typestates as defining sequences of calls, not as predicates over fields, which simplifies the approach when dealing with overriding and dynamic dispatch.

Plural [8] statically checks that clients follow usage protocols based on typestates. It is based on earlier work [7] addressing the problem of substitutability of subtypes, while guaranteeing *behavioural subtyping* in an object-oriented language. Subtyping is supported by the programmer explicitly specifying which states “refine” (i.e., are substates of) others in the superclass. In our approach, we do not need to explicitly define subtyping relations: we define protocols in terms of state machines and automatically find all subtyping pairs.

Obsidian [12] is a language for smart contracts with a type system to statically detect bugs. It uses typestates to check state changes and has a permissions system for safe aliasing. It supports parametric polymorphism, but not casting to preserve strong static guarantees.

Gay et al. [18] extend earlier work on session types for object-oriented languages by attaching a protocol in the form of a session type to a class definition, and presenting an unification of communication channels and their session types, distributed object-oriented programming, and a form of typestates supporting non-uniform objects. The formal language includes a subtyping relation on session types [17] but does not include class inheritance (subtyping is just for channel communication). This approach has two implementations: Papaya [23] and Mungo [24]. Papaya considers protocols as in Gay et al. [18], but uses Scala as the target language with the same limitation of not coping with inheritance. Mungo considers protocols along the lines of Gay et al. [18], but uses Java (as we do) as the target object-oriented language. Inheritance is not supported apart from classes without protocols.

Bravetti et al. [11] present a type system for a Java-like language, where objects are annotated with usages, typestate-like specifications stating the allowed sequences of method calls. The type-based analysis ensures protocol compliance and completion, and memory safety (no null pointer dereferencing). However, subtyping (hence casting) is not supported.

Bouma et al. [10] develop a tool called BGJ that takes a global type, modelling the behaviour of processes in a multiparty session typing setting [20], and automatically generates Java classes modelling the APIs of projected local types. The state is encoded with a `state` field and transitions are encoded with methods annotated with preconditions and post-

conditions. To verify the clients of these APIs, the programmer writes Java code annotated with logical formulas. All annotations are statically checked by VerCors [9]. In our approach, one does not need to spread annotations throughout the code to specify or use protocols, we simply associate them with classes and the type system ensures memory-safety, protocol compliance and completion (properties the developer would need to specify for each program).

■ **Table 2** Comparison of related work.

Work	How protocols are defined	Casting approach
Fugue	Typestates are seen as predicates over fields and methods annotated with contracts	Handles casting with frame typestates
Plural	States defined as “refinements” of superclass states and methods annotated with contracts	Explicit specification of sub-typing relations
Obsidian	States defined explicitly and methods annotated with contracts	Casting disallowed for strong safety guarantees
Papaya	Usage types (i.e., automata-like)	Not supported
Mungo	Usage types (i.e., automata-like)	Not supported
BGJ	Scribble notation [28] projected to local types implemented as Java classes with <code>state</code> fields	Not supported
<i>JaTyC (ours)</i>	Usage types (i.e., automata-like)	Fully supported

9 Conclusions and future work

We overcome one of the main obstacles to the adoption of typestates in static analysis of object-oriented programs – the inability of performing cast operations freely at any point of the protocol – by introducing a novel theory based on typestate trees. We equip the theory with a set of functions to manage the typestate tree abstraction, and we mechanise soundness in the Coq proof system. We argue that typestate trees can be applied in various program analysers for object-oriented languages with inheritance, being thus language agnostic, opening the door for acceptance of several programs and features that were rejected until now in this kind of language. To support this claim, we implement a type checker for Java and assess the expressiveness of our approach. The relevance of the theory and of its applications is showcased by typestate-checking realistic Java code of an automotive system with driving dynamics control that allows to customise the drive mode of SUVs.

As future work, we plan to formally establish the runtime soundness of typestate trees by devising a core object-calculus with inheritance, static typestate semantics, and dynamic operational semantics, and by mechanising a type safety result: well-typed programs at runtime comply objects’ protocol with respect to both the order of method calls and its completion, and do not raise null-pointer exceptions. Additionally, we will study how these concepts can be adapted to a setting with multi-inheritance and generics.

A Research Methodology

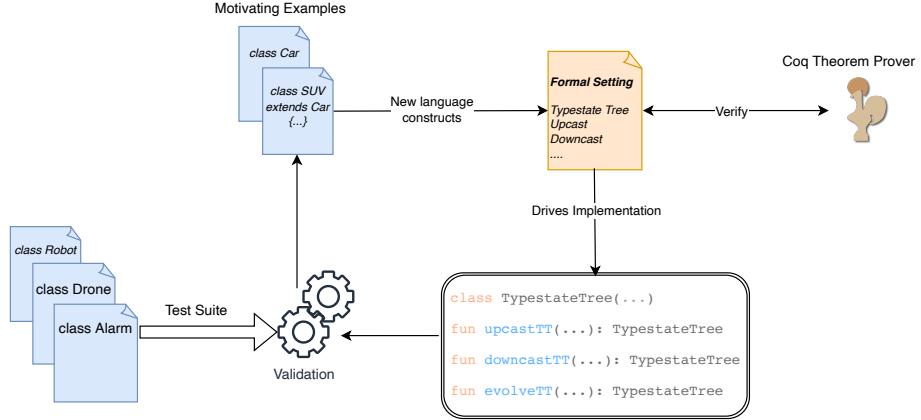

Figure 2 Research methodology behind the behavioural analysis support.

The iterative process in Figure 2 shows our methodology to support behavioural analysis within our type checker: we extract, from motivating examples, the language features to include in the static analysis; we build a formal setting (verified in the Coq theorem prover) to drive the JaTyC implementation; finally, we validate our approach with a suite of examples.

B Glossary

- m A meta-variable ranging over the set of method identifiers **MNames**
- o A meta-variable ranging over the set of output values **ONames**
- s A meta-variable ranging over the set of typestate names **SNames**
- \tilde{A} The wide tilde stands for a sequence of values
- $d\{\tilde{m} : \tilde{w}\}$ An input state (Definition 1)
- $\langle \tilde{o} : \tilde{u} \rangle$ An output state (Definition 1)
- w A meta-variable ranging over input and output states, and typestate names (Definition 1)
- u A meta-variable ranging over input states and typestate names (Definition 1)
- \tilde{E} A set of defining equations
- $w^{\tilde{E}}, u^{\tilde{E}}$ A meta-variable to denote a state w (resp. u) with a set of defining equations
- \mathcal{W}, \mathcal{U} The set of terms $w^{\tilde{E}}$ (resp. $u^{\tilde{E}}$)
- \mathcal{X} A subset of $w^{\tilde{E}}$ containing only input states $d\{\tilde{m} : \tilde{w}\}$
- \mathcal{Y} A subset of $w^{\tilde{E}}$ containing only output states $\langle \tilde{o} : \tilde{u} \rangle$
- \leq_S A subtyping relation between states (Definition 4)
- $\leq_{S_{alg}}$ The algorithmic version of the subtyping relation between states (Definition 7)
- t A meta-variable ranging over the set of types \mathcal{T} (Definition 10)
- \leq A subtyping relation between types (Definition 11)
- c A meta-variable ranging over the set of class names \mathcal{C}
- \leq_C A subtyping relation between classes (Definition 15)
- Ret_m The set of outputs returnable by a method m
- tt A meta-variable ranging over the set of typestate trees \mathcal{TT} (Definition 36)
- tts A meta-variable ranging over $\mathcal{P}(\mathcal{TT})$
- \vdash Well-formedness of typestate trees (Definition 38)
- $\vdash_{c,t}$ Soundness of typestate trees (Definition 53)

Cross Module Quicken – The Curious Case of C Extensions

Felix Berlakovich 

University of the Bundeswehr Munich, Neubiberg, Germany

Stefan Brunthaler 

University of the Bundeswehr Munich, Neubiberg, Germany

Abstract

Dynamic programming languages such as Python offer expressive power and programmer productivity at the expense of performance. Although the topic of optimizing Python has received considerable attention over the years, a key obstacle remains elusive: C extensions. Time and again, optimized run-time environments, such as JIT compilers and optimizing interpreters, fall short of optimizing *across* C extensions, as they cannot reason about the native code hiding underneath.

To bridge this gap, we present an analysis of C extensions for Python. The analysis data indicates that C extensions come in different varieties. One such variety is to merely speed up a single thing, such as reading a file and processing it directly in C. Another variety offers broad access through an API, resulting in a domain-specific language realized by function calls.

While the former variety of C extensions offer little optimization potential for optimizing run-times, we find that the latter variety *does* offer considerable optimization potential. This optimization potential rests on *dynamic locality* that C extensions cannot readily tap. We introduce a new, interpreter-based optimization leveraging this untapped optimization potential called Cross-Module Quicken. The key idea is that C extensions can use an optimization interface to register highly-optimized operations on C extension-specific datatypes. A quickening interpreter uses these information to continuously specialize programs with C extensions.

To quantify the attainable performance potential of going beyond C extensions, we demonstrate a concrete instantiation of Cross-Module Quicken for the CPython interpreter and the popular NumPy C extension. We evaluate our implementation with the NPBench benchmark suite and report performance improvements by a factor of up to 2.84.

1 Motivation

Productivity or performance? Despite the ever-increasing performance of computers, software developers are faced with this conundrum. They can either choose a high-level language like Python to benefit from abstractions like dynamic typing or garbage collection, but sacrifice performance. Alternatively, they can resort to low-level programming languages like C or C++ to gain better performance, but at the cost of developer productivity and safety.

According to the TIOBE index, the popularity of high-level languages such as Python or Ruby is unbroken¹ [36]. At the same time, however, the poor performance of these high-level languages remains an ongoing problem for, e.g., Python or Ruby [2, 39, 31]. Recent efforts address the performance issues of Python and Ruby [16, 38, 37, 40, 10, 9, 11, 12, 15, 14, 34, 35].

Besides the language VMs themselves, Ruby and Python, also have a thriving ecosystem of C extensions. C extensions, however, do not profit from optimizing the language VM. With the ongoing VM optimization efforts and the ensuing increase in performance of the core language, the performance of C extensions could come into focus in the near future.

C extensions also pose an optimization barrier for JIT compilers like PyPy or YJIT [17]. Due to the lack of semantics, JIT compilers cannot reason across the boundary of the core language. As a result, JIT compilers *cannot fully optimize* at the interface to C extensions or even into the extension code. A common workaround is to reimplement the entire extension in the host language (e.g., Python), thus removing the lack of semantics and closing the gap between VM and extension. For example, the PyPy project includes a pure Python implementation of a subset of NumPy to enable more aggressive optimizations. This approach has improved performance substantially in some cases, but requires a full or at least partial rewrite of the extension.

The two approaches of (i) not optimizing extensions at all, or (ii) rewriting them in the host language to make them accessible for JIT compilers, occupy two extremes on the design spectrum. In this paper, we explore an additional way of optimizing the interaction of high-level language code with C extensions.²

We first provide a short analysis of the different C extension varieties, based on popular² C extensions for Python (see Section 3). Our analysis indicates that some C extensions focus on a single, isolated task, which is implemented in optimized C. This variety does not lend itself well to optimization and would also not profit from JIT compilation in many cases. The other variety provides a broader API and custom datatypes, effectively exposing a domain-specific language through an API. This second variety offers a larger optimization potential.

To tap this potential, we introduce a new, interpreter-based optimization technique called *Cross-Module Quickening*, or CMQ for short (see Section 4). CMQ allows the interpreter, in collaboration with the C extension, to extend the interpreter’s optimization effort *into* the extension. The key idea is to provide the C extension with an interface to register specialized, extension-specific interpreter instructions. These specialized derivatives allow extension authors to exploit, for example, type locality within the C extension that would otherwise be invisible to the interpreter. Our technique does not require any changes, such as type annotations, in the Python program. CMQ also does not depend on runtime code-generation and is, thus, suitable for resource-constrained devices.

To demonstrate our idea, we analyze the optimization potential in NumPy, a popular Python C extension (see Section 5.2.5 and Section 6). We provide specialized derivatives for a number of NumPy operations and achieve a speedup of up to 2.84x in NPBench, a collection of compute-intensive NumPy programs (see Section 7).

¹ Python, for example, has continuously gained in popularity since 2018 and even leads the trends for 2024, so far

² The PyPI statistics range back only one month.

Summing up, this paper contributes the following

- We present Cross-Module Quicken, or CMQ for short, a new interpreter-based optimization architecture to optimize *across* C extensions. CMQ introduces a so-called Optimization Interface that allows C extensions to provide optimized instructions, thereby enabling cross-module type feedback via inline caching.
- We classify different use cases of C extensions with respect to their performance potential. We find that it is presently impossible to conduct an extensive quantitative analysis. The key obstacle is due to each C extension requiring varying amounts of domain expertise, usually provided by a human that has experience in using a given C extension. To shed light into the C extension “black box,” we conduct a qualitative analysis on the top ten C extensions instead.
- We describe the relevant details of a concrete CMQ implementation for the CPython interpreter and the NumPy extension. This concrete implementation introduces novel interpreter optimization techniques, such as extension-delimited superinstructions, and per-instruction caches for C extensions.
- We report the results of a comprehensive evaluation that encompasses the following dimensions: dynamic locality, performance, and implementation effort. Specifically, an in-depth analysis of NPBench on NumPy finds:
 - Quantitative dynamic locality of about 99%.
 - Performance improvements by a factor of up to 2.84.
 - Moderate implementation effort of less than 4,000 lines of code in CPython and NumPy.

2 Background

2.1 C Extensions

Most language VMs offer a way to interact with native code, typically called *foreign function interface*. Several language VMs go one step further by allowing *native code extensions*. These extensions are not limited to merely providing functions that can be called from the host language via a foreign function interface. Instead, an extension can define arbitrary host language types and modules, and even manipulate the VMs runtime state through an API. *Extension* means that the language VM loads the code dynamically at *runtime*, as opposed to code that is integrated at build time (e.g., CPython’s `sqlite3` extension). For example, Python, Ruby, and Lua all offer such extension APIs.

In principle, native extensions can be written in *any* language that compiles to native code and can access the VM’s APIs. Since C is the most popular language for native extensions, however, we will refer to native extensions collectively as *C extensions* from now on. Nonetheless, the principles described in this paper apply to native extensions written in any language.

2.2 Type Feedback via Inline Caching

Inline caching, first introduced by Deutsch and Schiffmann in 1984, is a technique for optimizing dynamic languages [18]. The technique is particularly useful for language VMs featuring generic operations. Many language VMs, for example, have a generic `BINARY_ADD` operation that can add two operands with arbitrary types, such as integers or floats.

To deal with the different semantics of, e.g., adding integers compared to adding floats, the language VM needs to resolve the concrete implementation dynamically based on the operand types. Depending on the number of supported types and implementations, this lookup

process can be expensive. The important observation behind inline caching is that even for dynamically typed programs, the operand types for an operation hardly ever change, if at all. Deutsch and Schiffmann called this principle *dynamic locality of type usage* [1, 18, 40].

A language VM can leverage this locality and cache the result of the expensive lookup process. In the example of `BINARY_ADD` above, the language VM could cache a pointer to the concrete implementation of e.g., integer addition. Since this cache typically resides *inline* with the instructions, i.e., no additional redirection is needed to access the cache, it is called an *inline cache*. Next time the language VM encounters this particular occurrence of `BINARY_ADD`, it can use the cached pointer instead of resolving the concrete implementation again. Before using the cache, however, the language VM needs to check that the operand types are equal to the expected types. In the unlikely case that the operand types *have* changed, the runtime would invalidate the inline cache.

2.3 Quicken – Instruction Rewriting to Capture Runtime Knowledge

Another interpreter optimization technique is called *quicken*. Quicken describes a process where an interpreter uses runtime feedback, such as type usage, to rewrite generic instructions to more concrete ones. This principle was originally used for efficiently resolving `classpool` references in the Java virtual machine [29]. The more concrete instructions are sometimes called *optimized derivatives* or just *derivatives*.

An example is a generic `BINARY_OP` instruction, whose operation depends on its operand. `BINARY_OP` with argument 1 performs an addition, whereas with argument 2 it performs a subtraction. If the language VM observes that a particular `BINARY_OP` always performs a subtraction, it can rewrite the instruction to `BINARY_SUBTRACT`. A `BINARY_SUBTRACT` no longer has to consult its argument value, but can perform a subtraction directly.

Quicken is a way for the language VM to encode temporal locality in its instruction set. Depending on the observed information, the encoded state is either permanent or transient, but with a high likelihood. If the state is permanent, the quickened instruction does not need to check any assumptions. If it is only likely, however, the language VM needs to validate the assumptions under which the quickening occurred. If the program invalidates an assumption, the language VM needs to rewrite affected instructions back to their original, generic form. For example, if a quickened instruction depends on specific operand types, and the operand types change, the language VM, needs to revert the instruction to a type-generic instruction. As the language VM speculates on the stability of the observed information, this optimization is typically called *speculative optimization*. This reversal of an optimized instruction back to its original form typically called *deoptimization*.

2.4 Inline Caching and Quicken in Python

Our implementation of CMQ builds on top of CPython and its existing optimization infrastructure. To aid the understanding of our implementation, we give a short overview of the related techniques here. CPython uses a combination of inline caching and quickening. Specifically, CPython uses specialized instructions, some of which also have an inline cache. The instructions with inline cache, such as `LOAD_GLOBAL_MODULE`, store assumption-related data in the cache that allows them to deoptimize if any of the assumptions change. Other instructions, like `BINARY_ADD_INT`, validate the assumptions without an inline cache (e.g., by directly checking the operand types). That is, their assumptions are directly encoded in the instruction set [13].

Extension	Categories

CuPy	extender
PyTorch	extender,optimizer

(a) Python extensions with little room for C extension optimization.

(b) Python extensions with custom datatypes, operator overloading and new surface syntax (extenders).

■ **Figure 1** Overview of the Python C extensions we considered for CMQ. The extensions on the left are binders and/or optimizers. The extensions on the right are extenders.

A peculiarity of CPython is that it uses the inline cache also to store profiling data that controls the quickening process. Specifically, instructions with specialized derivatives, store a counter in the inline cache. Every generic instruction derivative (e.g., LOAD_GLOBAL) decreases the counter upon execution. Once the counter reaches zero, the instruction tries to quicken itself to one of the specialized derivatives (e.g., LOAD_GLOBAL_MODULE). Thus, the counter implements a warmup phase in which the involved operands and types can stabilize. Likewise, when a specialized derivative has to deoptimize due to an invalidated assumption, it increases the counter by a certain *backoff* value. The backoff value ensures that an instruction with varying operand types does not continuously swap between two derivatives.

CPython organizes generic instructions and their specialized derivatives in *instruction families*. Each member of an instruction family has the same inline cache size. The inline cache is located directly after the instruction in the instruction stream. Each instruction is responsible for skipping the cache after instruction execution.

3 C extensions of Dynamic Languages

In this section we describe the results of our investigation of Python’s C extension ecosystem. Although we focus explicitly on Python, we believe that our findings generalize to similar ecosystems, such as Ruby or Lua.

3.1 Domain Specificity of C Extensions

Our initial plan was to conduct a large-scale, quantitative analysis of C extensions. After some experimentation and manual investigation, however, we found this goal to be elusive. This failure is due to C extensions being *domain specific*. They solve a single, well-defined problem, but do so in radically different ways. Ways that do not generalize from one C extension to another, and, therefore, pose a substantial obstacle to automation, the prerequisite for a large-scale analysis and quantitative investigation.

The domain specificity of C extensions not only frustrates generalized analysis attempts. Our performance analysis of C extensions identified a symmetric problem: If one lacks the domain expertise to tell what a “good use case” for a C extension is, it is nigh impossible to perform unbiased experiments.

These initial findings led us to conduct a qualitative analysis using manual investigation instead.

3.2 Of Optimizers, Binders, and Extenders

We analyzed the C extensions for Python in Figure 1 and found that they fall, broadly speaking, into three categories:

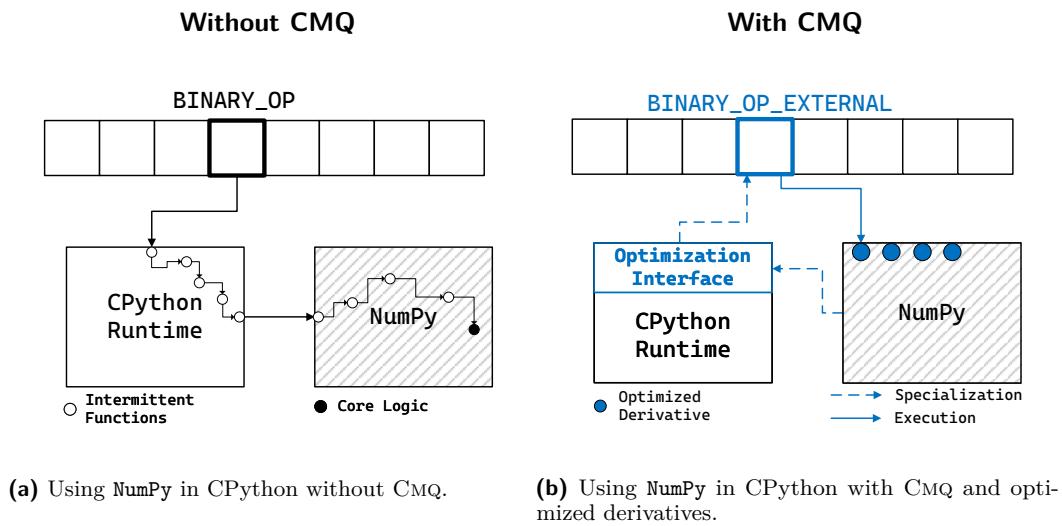

1. *Optimizers*: These C extensions could in principle be written in Python, and some of them probably were initially Python libraries. Due to the proverbial need for speed, however, these libraries are written in C, thereby eliminating a lot of the performance overhead associated with Python. Often, these C extensions offer just a single point of entry, execute efficiently in machine code, and return Python-processable data.
Consider the PyYAML extension as an example: The interface is just one call to the `parse` routine, which performs all the parsing in C, and returns the corresponding configuration data.
2. *Binders*: These C extensions usually cannot be written in Python, because they provide bindings to existing libraries to the Python ecosystem. These libraries are written in another language, such as C and C++, and bindings are the intermediary layer that translates from one world to another. The functionality corresponds to the external library, or a subset thereof that is reasonable to use from within Python.
Consider the lxml extension as an example: The interface corresponds to the libxml library, which implements efficient, feature-rich, and standards-compliant XML parsing.
3. *Extenders*: These C extensions extend Python with functionality not readily present in Python itself. These extensions define custom datatypes, overload and/or misuse operators, and at times resort to a custom embedded-DSL modeled through function calls. Note that extensions in this category are not mutually exclusive to others, as they can also embed existing libraries into their functionality.

Consider the NumPy extension as an example: NumPy defines its own datatype, a multi-dimensional array mapped to contiguous memory . This feature extends Python, as in Python a list or an array behaves similar to Java jagged arrays, i.e., each dimension is just a single array, which maps to another dimension, being a single dimensional array again. In contrast to Python lists, NumPy’s array representation enables high-performance operations on these arrays.

Through the performance optimization lens, the first two categories offer little potential for performance optimization. This lack of potential is due to their inner workings. PyYAML, for example, slurps a YAML file into C, parses the file efficiently using native-machine code, and creates the corresponding Python objects. Since this has been highly optimized already, no optimization opportunity presents itself. Similarly, lxml is just a small layer that invokes libxml to do the heavy lifting. No complex and expensive processing is done within the C extension. Both of these effects are amplified further by the old adage that time spent in libraries is lost w.r.t. optimization [20].

3.3 Exploring Extenders

Extenders, i.e., C extensions enriching the Python programming language do so in various ways. These extensions provide custom data types, such as NumPy providing a multi-dimensional array that is mapped to contiguous memory. Since our target languages are dynamically typed, manipulation of custom data types relies upon *operator overloading*. On top of these data types, C extensions have the possibility to (ab-)use existing functionality to introduce *surface syntax*. NumPy, for example, (ab-)uses Python’s tuples to provide a way to encode multi-dimensional array index access. Where no such surface syntax is available, Extender C extensions resort to using function calls. In combination these properties form a type of embedded DSL.

■ **Figure 2** Without CMQ (left), C extension-calls need to go through a cascade of function calls before reaching the core logic. With CMQ (right), the language VM calls optimized derivatives directly.

In contrast to Optimizers and Binders, programs using Extenders frequently cross the boundary between language VM and C extension. Context such as type locality established by the language VM or the C extension does not cross this boundary, leading to redundant checks and missed optimization potential. In Section 4 we discuss how CMQ lifts this optimization potential. To give concrete examples, we will now focus on the NumPy C extension, which adds high-performance numeric processing to Python.

3.4 Summary of Observations

Let us briefly summarize our findings, which are of vital importance for the following Sections.

- C extensions require domain expertise to analyze and evaluate.
- Only one of three categories offers dormant optimization potential.
- The Extenders category of C extensions form a kind of embedded DSL, by providing custom types, operator overloading, or introducing surface syntax.

4 Design of Cross-Module Quickening

The goal of CMQ is to enable optimizations across extension boundaries. Figure 2 gives an overview of CMQ. Without CMQ (Figure 2a), each operation involving a C extension must go through a cascade of function calls. At present, the interface between language VM and C extension poses an optimization boundary. As a result, the function calls are necessary to reestablish context that was already established previously, or on the other side of the optimization boundary (language VM vs C extension).

To eliminate this overhead, CMQ proceeds as follows (see Figure 2b):

1. CMQ provides a dedicated *Optimization Interface* or OINT for short, which enables C extensions to provide domain-specific optimizations.
2. Based on context information, the C extension can use quickening-based optimization through optimized interpreter instructions.

3. The interpreter provides an interface to replace single generic instructions or entire instruction sequences with optimized ones.
4. Optimized instructions validate that their assumptions hold and deoptimize upon misspeculation.
5. Additional optimization opportunities for C extensions exist, for example, through having per-instruction caches.

The following sections explain the relevant conceptual design details with examples from `CPython` and `NumPy`. Each section also contains forward references to the relevant implementation details in CMQ. Although we discuss implementation details primarily for the `NumPy` C extension, the principles underlying this specific implementation generalize not only to other C extensions, but also to C extension ecosystems of other dynamic programming languages. For brevity, we call our modified `NumPy` CMQ-`NumPy`.

4.1 Optimization Interface

C extensions for language VMs such as Ruby or Python are implemented as dynamically loadable modules. This means that C extensions and the language VM communicate via a predefined interface. Typically, the interface consists of both, public APIs in the language VM and hooks in the C extension called by the language VM. For example, `CPython` automatically calls public `PyInit_*` functions exposed in a loaded C extension. These functions create module objects for each module provided by the C extension. At the same time, `CPython` exposes functions to e.g., query the type of objects or to create new objects such as dictionaries.

We extend this interface between language VM and C extensions with an optional Optimization Interface, or OINT for short. The goal of the OINT is to expand the interpreter’s optimization capabilities with domain-specific optimizations. To that end, the OINT allows a C extension to register an *instruction optimization hook*. One goal of the OINT is to shield the C extension from as many language VM specific implementation details as possible.

Whenever the language VM tries to optimize an instruction, it calls all registered instruction optimization hooks. When exactly an optimization attempt happens, depends on the concrete architecture of the language VM. For example, optimization can happen either as part of an instruction’s execution (as is common for quickening) or in a dedicated optimization phase (as is common in JIT compilation). `CPython` performs instruction quickening as part of the generic instruction’s execution, once an optimization counter reaches zero (see Section 2.4).

The exact contract of the instruction optimization hook depends on the concrete language VM implementation. In general, the language VM needs to provide the C extension with enough information to decide which optimizations are applicable. For example, in CMQ-`NumPy`, the instruction optimization hook receives a pointer to the current instruction and a pointer to the operand stack.

The optimization of an instruction through a C extension is *optional*. Based on the instruction and its operands, a C extension can decide which optimizations are applicable, if any. For example, the C extension can query the operand types to leverage dynamic-type locality. CMQ-`NumPy` uses this principle to optimize certain `BINARY_OP` occurrences. We give a more detailed description of the `BINARY_OP` optimization in Section 6.2. In addition to type checks, the C extension can inspect further properties of the operands to decide whether optimizations are applicable. In Section 6.2 we describe how CMQ-`NumPy` inspects the name of `NumPy` `ufunc` objects to decide whether it can optimize specific `CALL` instructions.

4.1.1 Validating Assumptions and Deoptimization

As discussed in Section 2.3, quickening optimizations can be speculative. To guarantee correctness, the language VM needs a way to detect invalid assumptions and restore the original instructions. One strategy of validating assumptions is as part of the optimized instruction’s execution. For example, our `BINARY_OP` derivatives verify that the operands on the stack have the expected types.

Performing the assumption validation in the operation itself works well for assumptions about operands, such as their types, but is less suited for assumptions concerning global properties. For example, in addition to specific operand types, our `BINARY_OP` derivatives assume NumPy’s default arithmetic implementations for e.g., adding and subtracting arrays. While a user *can* change the implementations by overriding fields in the NumPy module, it happens rarely. Similar to operand types, each optimized derivative could validate this assumption before execution. However, with such an implementation each derivative suffers from a small performance overhead to check for an event that occurs infrequently. To mitigate this cost, the OINT offers an alternative way to validate assumptions. Specifically, the OINT allows C extensions to record deoptimization triggers for optimized instructions. Any code within a C extension that modifies properties previously optimized derivatives depend on, needs to notify the OINT. The OINT then deoptimizes all affected optimized instructions. Code that changes any of NumPy’s default arithmetic implementations, for example, triggers an deoptimization event. In response, CMQ deoptimizes all `BINARY_OP` derivatives. This approach shifts the burden of assumption validation to the infrequent path of changing arithmetic implementations.

A hybrid between the previous two approaches of deoptimization is to combine multiple object properties into a *meta-property*. For example, our `CALL` derivatives optimize calls of NumPy `universal functions`, or `ufunc` for short. The `ufunc` object is a stack operand of the corresponding `CALL` derivative. In addition to validating the `ufunc` operand’s type, the `CALL` derivative needs to verify several additional properties. For example, the `CALL` derivative is only valid for `ufuncs` without custom user loops. Verifying all these properties individually causes a performance overhead and, thus, reduces the profit of the `CALL` derivative optimization. Instead, we change the `ufunc` object to maintain a meta-property in the form of a `specializable` flag. The `specializable` flag represents the state of all individual properties combined. Code that updates any of the individual properties, also updates the `specializable` flag accordingly. Instead of validating all `ufunc` properties individually, the `CALL` derivative now has to validate only the `specializable` flag. Figure 3a illustrates this process graphically. With this approach, the burden of assumption validation is *shared* between code that modifies `ufunc` properties and the `CALL` derivatives.

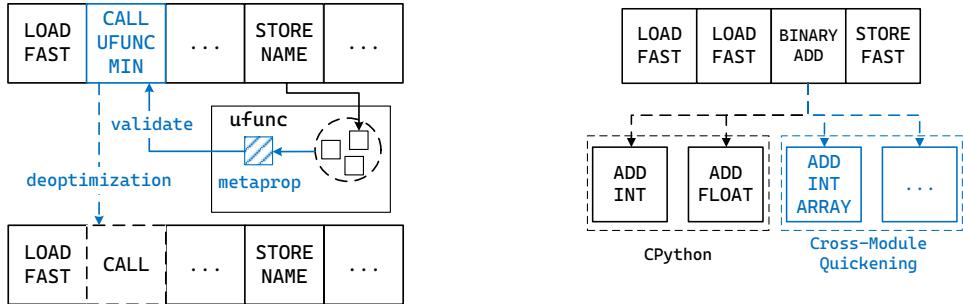

We describe our implementation of the specialization infrastructure for CPython in more detail in Section 5.2.5.

4.2 Cross-Module Optimization Opportunities

4.2.1 Type-specialized Instructions

In Section 2.2 and Section 2.3 we discussed the principle of *locality of type usage*. CPython leverages this principle to quicken type-generic instructions to type-dependent instructions. For example, CPython quickens `BINARY_OP` to `BINARY_OP_ADD_INT`, a derivative that directly adds the two integer operands. Compared to the generic instruction, the derivative’s call stack contains *three* fewer frames when reaching the final `_PyLong_Add` function. In addition, the derivative saves multiple intermediate calls needed to resolve the concrete function that adds Python integers. More specifically, the derivative saves the following steps performed by the generic instruction:

6:10 Cross Module Quickening – The Curious Case of C Extensions

(a) CMQ uses meta-properties to efficiently validate assumptions (see Section 4.1.1).

(b) CMQ allows to quicken instructions with domain-specific derivatives.

Figure 3 Overview of meta-properties (left) and type-specialized instructions (right) in CMQ.

1. Check if any of the operands has an implementation for the + slot.
2. Check if the left operand is a number and has the + slot.
3. Check if the right operand is a number of a different type than the left operand and has a different + slot.
4. Depending on whether the right operand has a different + slot and is a subtype of the left operand, call the left or right operand's + slot.
5. In the slot implementation, ensure that both operands are actually Python Longs.

List 1 Steps for resolving the implementation for adding two integers in CPython.

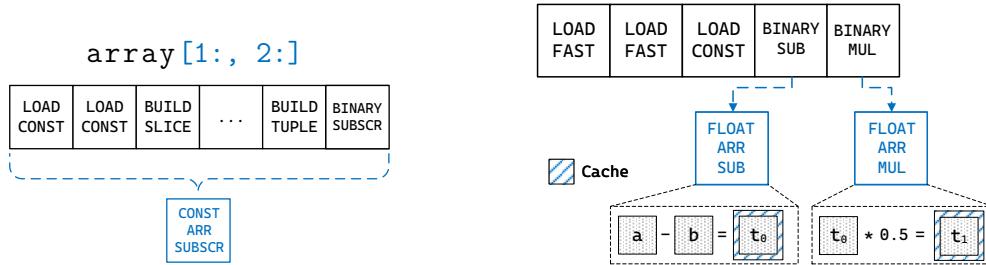

Under the assumption that both operands are Python Longs, the final operation (`_PyLong_Add`) is known immediately and the intermediate steps in List 1 become redundant. However, a language VM can only leverage locality of type usage, if it knows the types and operations involved. For example, the special handling of integer addition in CPython is only possible if both operands are non-subtyped Python Longs. If the language VM cannot reason about a type, such as a type provided by a C extension, quickening is no longer possible.

This issue is exacerbated by C extension types. Depending on the domain and the extension, the C extension has to check additional properties to the ones in List 1. We describe the additional checks that NumPy performs in more detail in Section 6.1. Similarly to the checks in List 1, the additional checks in NumPy are strongly connected to the operands' types. That is, under the assumption of specific operand types, the majority of checks become redundant.

Based on this observation, CMQ enables type-specialized instructions that depend on C extension types. CMQ-NumPy, for example, provides specialized instructions that add two double precision floating point arrays. As a result, starting from the interpreter loop, the call stack for adding two such arrays collapses from 13 frames to 2. In addition, the specialized instructions save several intermediate checks. These checks are subsumed by the fixed number and types of operands involved.

4.2.2 Extension-delimited Superinstructions

Replacing generic instructions with type-specialized instructions renders many of the checks performed by the generic instruction redundant (see Section 4.2.1). With the OINT, a C extension is not limited to replacing a single instruction at a time, however. In certain

(a) CMQ can replace instruction sequences, such as custom array subscripts, with a single optimized instruction (see Section 4.2.2).

(b) Caching data between instruction executions (see Sections 4.2.3 and 6.4).

■ **Figure 4** Illustration of extension-delimited superinstructions (left) and per-instruction caches (right).

cases, a specialized instruction subsumes the result of an entire sequence of instructions. For example, for `BINARY_SUBSCRIPT` instructions with constant indices, such as `array[1:, 2:]`, CMQ-NumPy precomputes the index structure during specialization. With the index structure computed, all the index operands become redundant. As a result, the instructions pushing these operands onto the operand stack are now *dead code* in program analysis terminology. To account for such cases, the OINT allows to replace *entire sequences* of instructions with specialized derivatives, as shown in Figure 4a.

By subsuming multiple unoptimized instructions, the optimized derivative represents a type of *superinstructions*. Unlike conventional superinstructions however, the boundaries of the superinstructions enabled by CMQ are domain-specific and defined by the C extension. Thus, we call this type of superinstruction *extension-delimited superinstruction*.

4.2.3 Caching Between Instruction Executions

Specialized instructions can efficiently encode type membership and similar properties with a low information density (see Section 4.2.1). For example, type membership is representable as a single bit in the instruction encoding. Some optimizations, however, depend on data that is hard to encode in an instruction, but instead need a dedicated cache. NumPy's arithmetic instructions, for example, frequently allocate new arrays, which are deallocated only a few instructions later. At the expense of a little additional memory, optimized derivatives can keep a cached result array to avoid repeated allocations and deallocations. To that end, the OINT provides a mechanism to store data in a cache space specific to an instruction *occurrence*. We call this cache *occurrence cache*. Conceptually, the *occurrence cache* allows an instruction to communicate data between instruction executions or between specialization time and execution. We describe instantiations of both variants in more detail in Section 6.4.

The *occurrence cache* acts like an inline cache, but it is implementation-specific. To the C extension it is opaque whether the language VM actually stores the cache inline. Also, in contrast to the typical usage of an inline cache, i.e., storing function pointers, the *occurrence cache* can store arbitrary data, including data pointers. We describe our implementation of the cache space in more detail in Section 5.2.3 and how we use the cache in Section 6.4.

5 Implementation of Cross-Module Quickening in CPython

In this section, we start with a short overview of CPython’s internal implementation and then describe the integration with CMQ.

5.1 CPython in a Nutshell

The CPython interpreter is a stack machine with instructions that consist of an `opcode` and an `oparg`. The `opcode` specifies what an instruction does and is one byte long. The `oparg` serves different purposes, depending on the instruction, and is also one byte long. For example, in the `LOAD_FAST` instruction, the `oparg` specifies which local-variable slot to push onto the operand stack.

Instructions with inline caches are grouped into families. All members of the same family are specializations of a generic instruction that is also part of the family. Family members have an equally sized inline cache (see Section 2.4 for more details).

The snippets of code that implement an instruction’s semantics are called *opcode handler*. CPython uses *indirect threading*, which means that each `opcode` handler jumps to the next handler through a dispatch table [21]. A compiler feature called `computed gotos` allows an efficient compilation of such dispatch patterns.

5.2 Integration with Cross-Module Quickening

CMQ enables C extensions to replace generic interpreter instructions with optimized derivatives. When integrating CMQ with CPython’s dispatch routine, we faced a number of competing constraints:

1. Specialization should happen as soon as possible to unlock additional performance. However, the language VM should not repeatedly try to specialize an instruction if no specialization is possible or if the instruction deoptimized recently.
2. Considering that specialization happens for *hot code*, the execution of external, optimized derivatives should be as fast as possible.
3. CMQ needs to avoid consuming too much of CPython’s already limited `opcode` space.
4. CPython can load multiple C extensions simultaneously, each of which could potentially register optimized derivatives. In addition, each C extension can register multiple different derivatives for the same generic instruction. Therefore, CMQ must allow the registration of as many derivatives as possible.
5. While specialization and deoptimization happens infrequently compared to an instruction’s execution, the time spent on these tasks must eventually be amortized. Thus, specialization and deoptimization must be reasonably fast, or they defeat the purpose of optimization.

In the following subsections, we describe our design choices for CMQ and how each decision relates to the aforementioned challenges.

5.2.1 Specializing Hot Instructions

For CMQ, we extend CPython’s existing quickening mechanism to consider not only CPython derivatives, but to also call registered instruction optimization hooks (if any). Extending the existing mechanism allows CMQ to leverage CPython’s optimization counter infrastructure. The optimization counter ensures that CMQ (1) only attempts to specialize hot instructions and (2) that each failed optimization attempt delays further attempts by an increasing value. Specifically, if both, CPython’s internal optimizations and the optimization function, fail to optimize an instruction, CPython increases the optimization counter by a backoff value (see Section 2.4).

5.2.2 External opcode handlers

Ideally, C extensions could register `opcode` handlers that resemble internal `opcode` handlers. **Computed gotos**, however, are only possible within a single function. The C standard considers jumps into the middle of a function from outside the function undefined behavior. In **CPython**, therefore, an exact resemblance of internal `opcode` handlers is not possible. Instead, we resort to subroutine-threading for the external `opcode` handlers, i.e., we implement each handler as a function in the C extension.

5.2.3 Dealing with a Limited Opcode Space

CPython's small `opcode` encoding of one byte means that few opcodes remain for specialization through C extensions. Specifically, **CPython** 3.12 has 208 opcodes, leaving 47 opcodes undefined. As new **CPython** releases regularly introduce new `opcodes`, consuming a large number of the undefined `opcodes` for CMQ is undesirable. Thus, we cannot introduce a new `opcode` for each optimized derivative a C extension provides. Instead, we define one additional `opcode` for each *optimizable* generic instruction. In other words, we add one `opcode` for each generic instruction for which a C extension can provide one or many optimized derivatives. For example, we add the `BINARY_OP_EXTERNAL` `opcode` since C extensions can specialize `BINARY_OP`.

One additional `opcode` is not sufficient, however, to differentiate between different derivatives. For example, our modified **NumPy** adds several derivatives for `BINARY_OP`, depending on the operation and the operand types involved. To that end, when C extensions register their specialized derivatives, CMQ assigns each derivative for the same instruction a unique id. CMQ stores the ids in a table to map each id to an external `opcode` handler. During specialization, CMQ repurposes the `oparg` of the corresponding `*_EXTERNAL` instruction to hold the id and, thus, to identify the exact derivative. For example, assume that **NumPy** wants to specialize an occurrence of `BINARY_OP` with a derivative `NP_ADD_FLOAT_FLOAT`. During the initial registration, CMQ assigns the derivative `NP_ADD_FLOAT_FLOAT` the id 5. During specialization, CMQ replaces the generic `BINARY_OP` with `BINARY_OP_EXTERNAL` and its original `oparg` with 5. During execution of the `BINARY_OP_EXTERNAL` occurrence, CMQ looks up the external `opcode` handler with the `oparg` and calls the external handler.

This approach has advantages as well as disadvantages and is specific to **CPython**'s internal implementation. One advantage is that this approach consumes only a small number of `opcodes`. Another advantage is that CMQ has to rewrite only the replaced instruction, as opposed to multiple instructions affected by a layout change. Since the `*_EXTERNAL` instructions have the same inline cache size as their generic counterparts, the layout of the instructions remains the same. If CMQ instead, e.g., changed the inline cache size, all jumps crossing the affected instruction as well as exception-handling tables would have to be rewritten.

A disadvantage of this approach is that it introduces an additional indirection. The `opcode` handlers of the `*_EXTERNAL` instructions have to lookup the external function with the `oparg`. For **CPython** with **NumPy** we found this overhead to be negligible and prioritized the benefit of saving `opcode` space. In language VMs with a larger `opcode` space, or in cases where the indirection negatively affects performance, specialized derivatives can be mapped directly to `opcodes`. A hybrid approach is possible as well. For example, particularly performance-critical derivatives can receive their own `opcode`, whereas other derivatives are grouped according to the scheme above.

5.2.4 Implementing Extension-Delimited Superinstructions

In Section 4.2.2 we discussed the concept of extension-delimited superinstructions. We implemented extension-delimited superinstructions by allowing C extensions to indicate unused arguments during specialization. For example, our modified NumPy specializes `BINARY_SUBSCRIPT` by precomputing its index datastructure and replacing it with a `NP_BINARY_SUBSCRIPT_CONSTANT` derivative (see Section 6.4). As a result, all the index operands required by `BINARY_SUBSCRIPT` become unused. CMQ-NumPy marks the operands as unused via the `OINT` and CMQ automatically takes care of skipping the operand setup during later executions.

In a first step, CMQ determines the instructions responsible for pushing the unused operands onto the stack. We call these instructions `operand originators`. As the `operand originators` are no longer needed, their operands become unused as well. In a second step, CMQ recursively finds the `operand originators` of the now unused operands. This process continues until CMQ has found the first unused instruction in the sequence. CMQ then replaces the first instruction with a `JUMP` that jumps directly to the optimized derivative, e.g., `NP_BINARY_SUBSCRIPT_CONSTANT`. Note, however, that such an optimization is only possible if the skipped instructions are side-effect-free. If, for example, one of the instructions is a `CALL` instruction, CMQ does not optimize the argument setup.

5.2.5 Deoptimization in CPython

As optimization assumptions can become invalid, CMQ needs a way to restore the original instructions in such a case. To that end, CMQ records a `deopt structure` for each instruction optimized. The `deopt structure` contains a pointer to the optimized instruction and the original `opcode` and `oparg`. The approach described in Section 5.2.3 requires CMQ to replace the original `oparg` during specialization. The backup copy in the `deopt structure` enables CMQ to restore the `oparg` upon deoptimization. Once the original instruction is restored, CMQ executes the original instruction instead of the derivative.

For extension-delimited superinstructions (see Section 4.2.2), the `deopt structure` stores the entire list of instructions that were replaced with the superinstruction. When deoptimizing extension-delimited superinstructions it is not enough to restore the original instructions, however. Once the language VM reaches the deoptimizing extension-delimited superinstruction, the instruction pointer is already past the instructions that would have pushed the operands to the stack (see Section 5.2.4). Since the extension-delimited superinstruction does not expect the same number of stack operands as the original instruction, executing the original instruction would fail. Thus, after deoptimizing an extension-delimited superinstruction, CMQ replays all instructions responsible for the stack operands of the restored instruction. Replaying is possible because we limit the related optimization to side-effect-free instructions (see Section 5.2.4).

6 Implementation of Cross-Module Quicken in NumPy

To demonstrate the optimizations enabled by CMQ, we extended NumPy to use the OINT and implemented various optimized derivatives. On module initialization, CMQ-NumPy registers its optimization hook with CPython and later optimizes instructions related to array operations. To understand these optimizations we first give a short overview of NumPy in Section 6.1. In Sections 6.2–6.4 we outline how we implemented the CMQ-NumPy optimizations.

6.1 NumPy in a Nutshell

NumPy is one of the most popular CPython C extensions and consistently among the top 20 downloaded PyPi packages [22]. The NumPy package provides multidimensional arrays, called *ndarrays*, of different data types that optionally can be contiguous, aligned and iterated in different iteration orders. In addition to data representation via arrays, NumPy also contains a variety of mathematical functions operating on those arrays. NumPy is also a cornerstone of several other CPython packages, such as Pandas, SciPy, scikit-learn and PyTorch. To integrate seamlessly with Python, NumPy makes extensive use of operator overloading and, e.g., allows to add, subtract, multiply or divide arrays. Behind the scenes, NumPy takes care of transforming the arrays as necessary to perform the desired operation. For example, through a mechanism called *broadcasting*, NumPy allows to transparently add two arrays with a different number of dimensions:

```
>>> np.array([1, 2, 3]) + np.array([[5, 6, 7], [1, 2, 3]])
array([[6, 8, 10],
       [2, 4, 6]])
```

NumPy implements many of these operations on *ndarrays* as so called *universal functions* or *ufunc* for short. A *ufunc* object represents a mathematical function that operates element-wise on *ndarrays*. Each *ufunc* can have multiple underlying implementations of the mathematical function, called *array methods*. Which array method a *ufunc* uses depends, among other factors, on the input operand types. Internally, NumPy implements array methods as tuned C loops to exploit available hardware features (e.g., vectorization). Before calling any array method, *ufuncs* are responsible for type casting, broadcasting and several other standard NumPy features.

NumPy determines the *ufunc* and subsequently the array method responsible for performing an *ndarray* operation in a multistep process. First, NumPy determines the responsible *ufunc* object. For binary operations with operator overloading, NumPy reads the *ufunc* from a module-wide table. For other operations, such as `minimum` or `maximum`, the *ufunc* object is a callable Python object and pushed onto the operand stack. The subsequent steps are identical for both cases, and we summarize them in List 2.

6.2 Exploiting ufunc Type Stability

NumPy's flexibility and extensibility has allowed it to become a building block in a number of different domains. For example, NumPy allows users to customize almost any step in List 2. This flexibility comes at a cost, however. For every array addition, CPython first performs the steps in List 1 and then the steps in List 2. A crucial observation is that many of the steps in List 2 can be eliminated or simplified by fixating the types and number of inputs to the *ufunc*. For example, when adding exactly two arrays in a `BINARY_OP`, the following simplifications are possible.

If both input arrays are of type *ndarray*, Step 1 and Step 5 become redundant. If, in addition, the array element types are known, Step 3 becomes redundant. Type-specialized instructions described in Section 4.2.1 allow CMQ to efficiently speculate on these properties. By additionally speculating that the user has not changed the default *ufunc* for adding arrays, Step 2 and Step 3 become redundant. CMQ enables this type of speculation with the deoptimization strategies outlined in Section 4.1.1.

1. Check if any of the operands overrides the `ufunc`. NumPy allows any operand participating in a `ufunc` operation to override the responsible `ufunc` object, effectively implementing a form of multi-dispatch;
2. Determine the exact casting rules and perform any necessary casting. For example, in this step NumPy converts scalar values participating in an array operation into arrays;
3. Based on the resulting types from the previous step, resolve the array method;
4. With the array method, resolve the operation types, in particular the result type;
5. Call array preparation functions, if any;
6. Check if a single iteration of the array method loop is possible by analyzing the properties of the participating arrays. Such a simplified case is possible for certain configurations of input arrays. We skip the exact details here for brevity.
7. If a single loop is sufficient, allocate the output array (if necessary) and call the array method loop
8. Otherwise, allocate an iterator and call the array method as many times as dictated by the iterator.

■ List 2 Steps for resolving NumPy `ufunc` and array methods. For more details see the NumPy Enhancement Proposals 13 and 18 [8, 27], the NumPy manual on `ufuncs` [19] and the function `ufunc_generic_fastcall` in `ufunc_object.c` in the NumPy codebase.

To unlock these optimizations, CMQ-NumPy provides specialized `BINARY_OP` derivatives for several array type combinations. For example, CMQ-NumPy specializes `BINARY_OP` occurrences that add or subtract two float arrays, effectively eliminating Step 1–5. While the case distinction in Step 6 and the last step (either Step 7 or Step 8) remain, the specialized derivatives simplify Step 6 to a few comparisons. In the original NumPy, Step 6 is handled by a function that needs to handle several corner cases and deal with potentially more than two input arguments. The added assumptions in the derivatives allow us to partially evaluate the function and to inline the remaining checks directly into the derivatives. As the optimized derivative is represented as `BINARY_OP_EXTERNAL` in CPython (see Section 5.2.3), the optimization also eliminates the `BINARY_OP` dispatching steps (see List 1).

A similar optimization is possible for calls of `ufuncs` objects via `CALL` instructions. As an example, consider a call to the `minimum` function of the NumPy package: `numpy.minimum([1, 2], [3, 4])`. CPython first loads the `minimum` `ufunc` object from the NumPy module and pushes the object to the stack. Next, CPython pushes the argument lists onto the stack. Finally, CPython calls the `ufunc` object via the `Vectorcall` protocol for calling into C extensions. Like for the `BINARY_OP` instructions, CMQ-NumPy provides a derivative that skips many of the steps in List 2 and calls the appropriate array method directly. During specialization, CMQ-NumPy not only validates the operand types, but also ensures that the `ufunc` object represents the expected `minimum` function. Once specialized, the loading of the `ufunc` object becomes redundant (see Section 4.2.2).

6.3 Automatic Generation of Derivatives

During the implementation of `BINARY_OP` derivatives, we noticed that the code of different derivatives differs only at select locations. Specifically, each derivative validates its type-specific assumptions and calls a type-specific array method. All other aspects of the code, such as the simplified Step 6 are identical between the derivatives. For example, all derivatives analyze certain properties of the input arrays, such as dimensions and strides, to decide whether Step 7 or Step 8 is necessary. Similarly, the code to decide whether a derivative is suitable for an instruction occurrence differs only in details.

```

BinOp(
    operation="add",
    left_type="adouble",
    right_type="adouble",
    result_type="NPY_DOUBLE",
    loop_function="DOUBLE_add",
    commutative=True,
)

```

(a) Specification of a derivative that adds two double arrays.

```

if((PyArray_CheckExact(lhs) &&
PyArrayHasType(NPY_DOUBLE) &&
PyFloat_CheckExact(rhs)) ||
// symmetrical commutative case
{
// Specialize for adding
// double arrays
}

```

(b) Automatically generated condition for specializing float array addition. The highlighted parts are taken from the derivative description.

Figure 5 Derivative description (left) and the automatically generated specialization condition (right).

To reduce code duplication, we wrote a code generator in Python that uses Mako templates to generate the various cases and derivatives. The code generator takes a specification of the derivatives produces specialization conditions and derivative implementations. Figure 5a shows an example of the double-array addition derivative specification. The specification defines the required types and the concrete array method to use in the derivative implementation. The code generator automatically generates derivative implementations and their corresponding specialization conditions. Figure 5b shows an example of a generated condition. Since addition is a commutative operation, the code generator automatically generates the symmetric case as well.

The code generator not only reduced the amount of duplicate code, but also allowed us to experiment with different implementation variants. For example, we tested a variant that forcefully inlines all function calls within the derivative implementations and found the performance difference to be negligible.

6.4 Per-Instruction Caches in NumPy

In Section 4.2.3 we described how CMQ enables an instruction-occurrence-specific caching via an `occurrence cache`. CMQ-NumPy uses the `occurrence cache` in optimized `BINARY_OP` and `BINARY_SUBSCRIPT` derivatives. Specifically, the `occurrence cache` we implemented in the OINT in CPython allows CMQ-NumPy to store a pointer for each optimized instruction.

The `BINARY_OP` derivatives use the `occurrence cache` keep a scratch array for results. The idea is based on the observation that `BINARY_OP` instructions often allocate short-lived arrays for the operation result and, thus, cause pressure on the memory subsystem. We gauge the effectiveness of the `occurrence cache` in Section 7.4. Whenever our optimized `BINARY_OP` derivatives allocate a new result array, they store a pointer to the array in the `occurrence cache`. In subsequent executions, the derivatives try to reuse the cached array instead of allocating a new one. Reusing a cached array is possible whenever the cached array has a reference count of 1, meaning that the cache is the only reference to the object. The result cache trades memory for CPU cycles by avoiding the recurring allocation and deallocation of frequently used objects.

In contrast, the `BINARY_SUBSCRIPT` derivatives use the `occurrence cache` to store information precomputed at specialization time. In CPython, a `BINARY_SUBSCRIPT` instruction uses a subscript object to access subscriptable, such as lists or NumPy arrays. NumPy extends

CPython’s subscripting mechanism with the notion of multidimensional subscripts. For example, the expression `array[1:, 2:]` selects all sub-arrays beginning at the second and from each selected subarray all elements beginning at the third. Under the hood, the expression `[1:, 2:]` is a syntactic sugar for `[(slice(1, None, None), slice(2, None, None))]`. In other words, the subscript object is a tuple consisting of two slice objects. While this syntax is highly expressive and makes it easy to navigate nested arrays, the flexibility comes at a cost. For every such subscript access, CPython needs to construct the participating objects, i.e., the slices and the tuple, and then call NumPy to handle the subscript on a NumPy array. The subscript object construction alone constitutes 7 instructions. Next, NumPy needs to deconstruct the subscript object again to compute an index structure that is later used to access the array. Similar to the case of resolving ufuncs (see List 2), the computation in NumPy is generic and needs to handle several corner cases.

An important observation is that all objects participating in the above subscript operation, except the array, are constant. To that end, CMQ-NumPy move the computation of the index structure from instruction execution to specialization time. During specialization of a `BINARY_SUBSCRIPT` instruction, CMQ-NumPy analyzes the instructions constructing the subscript object. If the subscript object is constant, CMQ-NumPy precomputes the index structure and stores a pointer to the structure in the occurrence cache. Instead of recomputing the structure, the specialized `BINARY_SUBSCRIPT` derivatives read the index structure from the cache.

7 Evaluation

7.1 System Configuration

Our changes are based on CPython 3.12.0 and NumPy 1.26.4. To guarantee a fair comparison and equal compilation parameters, we also built the baseline, i.e., CPython 3.12.0 and NumPy 1.26.4, from source.

We perform our evaluation on three different machines, summarized in Table 2. Machine EPYC is equipped with an AMD EPYC Rome 7H12 CPU running at 3.2 GHz, 1TB DDR4 RAM running at 3200 MHz, and Debian 12. Machine i7 is equipped with an Intel Core i7-8559U CPU running at 2.7 GHz, 64GB DDR4 RAM running at 2667 MHz, and Debian 12. Machine M3 is equipped with an Apple 16 core M3 CPU running at 4.05 GHz, 128GB RAM, and macOS 14. On each machine we compiled CPython and NumPy with the bundled GCC (12.2.0) and GNU linker (2.40).

7.2 Experimental Design

CMQ consists of a modified CPython instance that supports the Optimization Interface and a modified NumPy package that leverages the Optimization Interface.

We evaluate the performance improvements of CMQ based on the NPBench benchmark framework [41]. NPBench includes compute-intensive NumPy benchmarks and aims to compare the performance of NumPy-specific optimizing compilers. While our technique is not NumPy-specific, these benchmarks allow us to properly evaluate the afforded performance improvement. In addition to the benchmarks already included with NPBench, we integrated NumPy Phoronix benchmarks from openbenchmarking [33]. Like the included benchmarks, the Phoronix benchmarks consist of scientific kernels that make intensive use of NumPy.

NPBench supports differently sized input presets for the included benchmarks. For our evaluation, we used the `paper` preset, which was also used during the evaluation of NPBench itself [41]. The Phoronix benchmarks have their input sizes hardcoded into the benchmark.

We run all benchmarks with the `NPBench` test runner. The runner starts each benchmark in a new CPython process and repeats the benchmark a given number of times with the CPython `timeit` package. In addition, `NPBench` verifies that the results of an optimized implementation and the NumPy default implementation are equal. We modified `NPBench` to use our customized CPython and NumPy while measuring CMQ’s performance.

To reduce noise, we limit NumPy to a single thread and pin the benchmark run to a single CPU with `cset`. Note that this restriction does not influence CMQ’s relative performance improvement over standard NumPy. Distributing workloads to multiple threads happens in NumPy components unaffected by CMQ. We verified this experimentally by comparing runs with and without threading and found the differences to be within measurement noise (2-3%). Without limiting the number of threads (e.g., to 16) in our experiments, NumPy used *all* available logical CPUs, even for trivial tasks. For the EPYC Rome machine this meant distributing tasks to 256 logical CPUs, effectively overloading the machine synchronization overhead.

We repeat each `NPBench` benchmark 20 times and limit the execution time of a single run to 120s. Since the Phoronix are short-running, we repeat each benchmark run 100 times. We kept the internal iteration count of 40 for the Phoronix benchmarks. With this configuration, one benchmark (`3mm`) timed out in the baseline on all machines.

7.3 Performance

Figure 6 and Figure 7 shows the performance improvement of CMQ over the baseline for the `NPBench` and `Phoronix` benchmarks, respectively. Due to space constraints, we show only benchmarks where CMQ-NumPy could specialize at least one instruction. We give a complete list of benchmark results in Appendix A.

Whereas some `NPBench` benchmarks, such as `adist`, show no improvement, CMQ improves the performance of other benchmarks by a factor of up to 2.84. The improvements are similar on different machines, with the notable differences of `heat3d` and `floydwar`. On these two benchmarks, CMQ achieves no measurable performance improvement on M3. For the `NPBench` benchmarks, we report a geometric mean improvement for the machines EPYC, i7, and M3 of 1.11x, 1.10x and 1.08x, respectively.

For the `Phoronix` benchmarks the situation is similar. Some benchmarks, such as `periodic_dist`, show an improvement of up to 1.94, whereas other benchmarks, such as `eucl_dist` show no improvement. One difference to the `NPBench` benchmarks is that certain benchmarks show a slight decrease in performance, most notably `pairwise` and `rosen`. For the `Phoronix` benchmarks, we report a geometric mean improvement for the machines EPYC, i7, and M3 of 1.10x, 1.08x and 1.06x, respectively.

We discuss these differences in Section 8.1.

7.4 Dynamic Locality Analysis

To analyze type locality and cache stability, we collected various statistics on the EPYC machine over all `NPBench` benchmarks with 20 repetitions. We found the operand types on which the specialized derivatives speculate to be 100% stable except for `resnet`. In `resnet`, 3 operations had to deoptimize due to a changed operand type.

Table 1 shows relevant metrics for the `BINARY_SUBSCRIPT` result cache (see Section 6.4). The other derivatives (e.g., `BINARY_SUBSCRIPT`) cache only static data (e.g., the computed index structure) and, therefore, never need to invalidate the cache. For brevity, Table 1 shows only benchmarks in which cache invalidations occurred. `REFCNT` means the cached array had a reference count greater than one. `SHAPE` means the array did not have the expected shape.

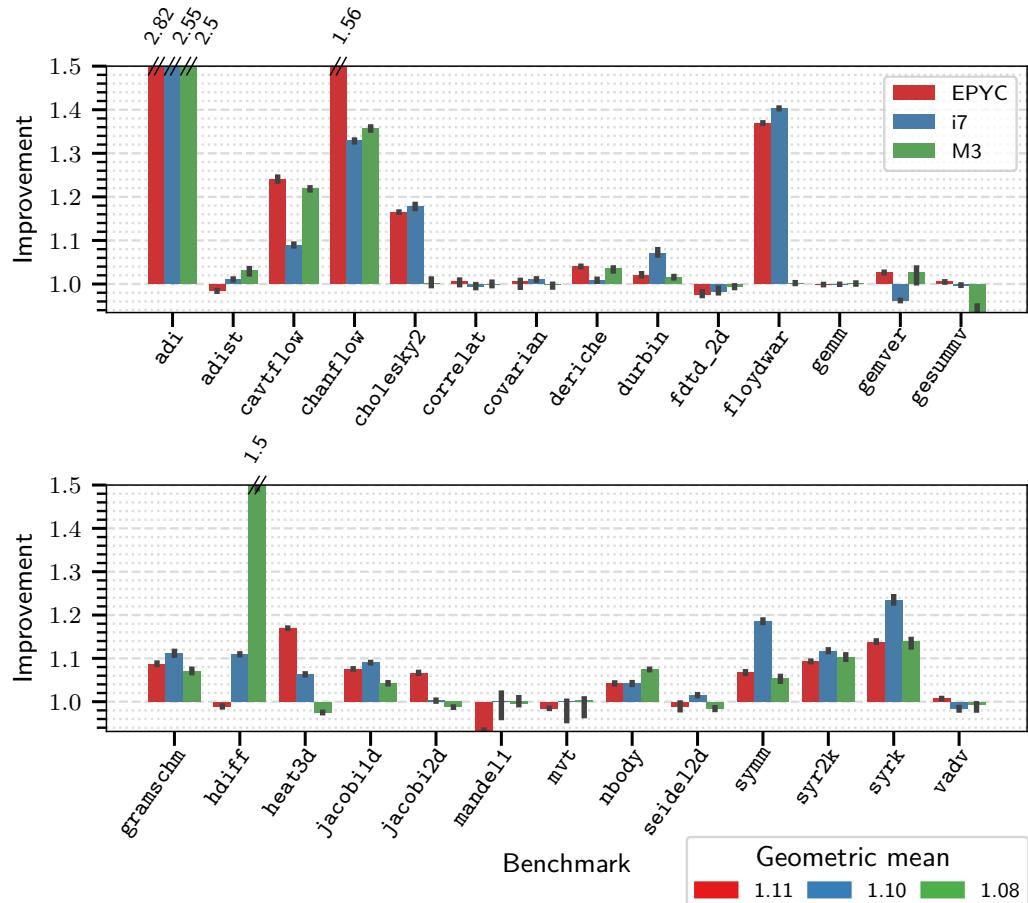

Figure 6 The performance improvement of CMQ-NumPy over the baseline for NPBench benchmarks with at least one specialized instruction. The black lines at the top of the colored bars show the 95% bootstrapping confidence interval with 1000 samples. For the bars that do not fit within the figure, a label on top of the bar shows their value.

In `cavtflow`, `chanflow` and `heat3d` a cached array had a reference count greater than 1, indicating that the array is not in fact temporary. In `syr2k`, the cached array's properties did not match the properties required for the result. CMQ-NumPy keeps a cache counter to detect cases where the cache is invalidated frequently and disables an instruction cache after 100 invalidations. The counter disabled the cache in `syr2k` for one instruction and in `vadv` in 8 instructions. We found this optimization to improve `cavtflow`'s performance by about 10%.

7.5 Implementation Effort

The changes in CPython consist of 1,136 insertions and 51 deletions across 27 files. These changes include the code for statistics, debugging routines, comments and newlines, but exclude files generated by the CPython build. The OINT consists of a hook used by C extensions to register, two callbacks provided by the C extension and three functions the C extension can use to specialize instructions.

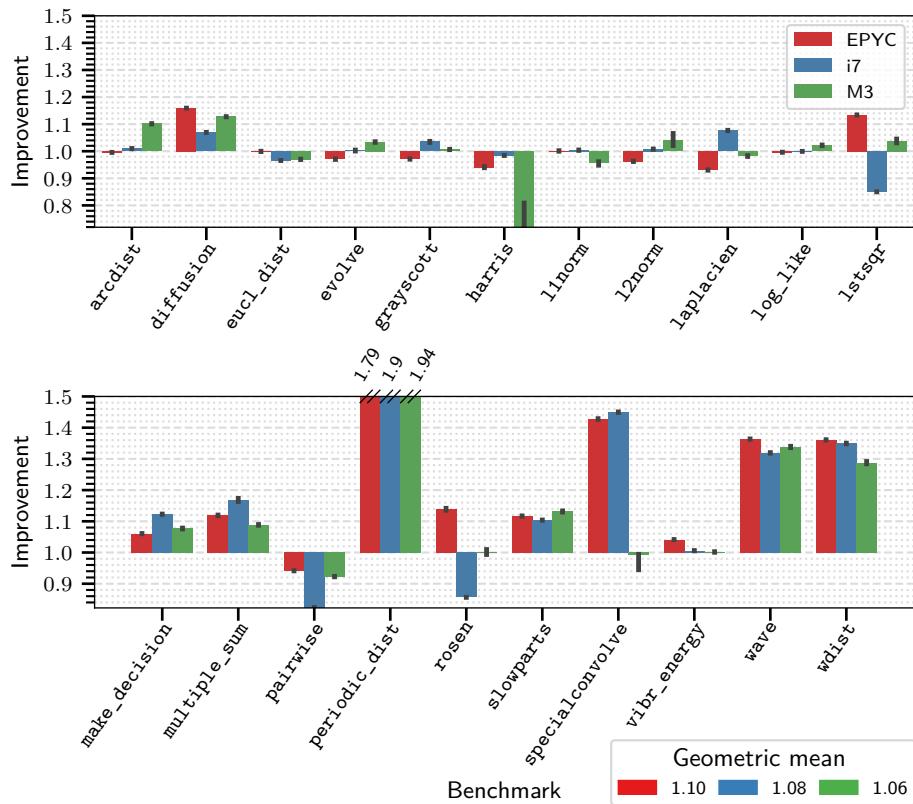

Figure 7 The performance improvement of CMQ-NumPy over the baseline for Phoronix benchmarks with at least one specialized instruction. The black lines at the top of the colored bars show the 95% bootstrapping confidence interval with 1000 samples.

The changes in NumPy consist of roughly 1200 lines of C, 400 lines of Python and 900 lines of template code. These changes include the code for statistics and performance measurements, derivative templates, debugging routines, comments and newlines, but exclude generated files. Implementing these changes took us roughly 3 months, with no prior experience with NumPy. NumPy consists of roughly 163,000 lines of code, which means that our extension (the C and template code) comprise less than 1% of NumPy’s code base. The template code for our optimized derivatives contains primarily rearrangements of existing NumPy code (e.g., applying a `ufunc` to an array with an iterator).

8 Discussion

This section discusses the evaluation results, in particular the varying performance results, as well as what we believe to be relevant threats to validity.

8.1 Performance

Figure 6 and Figure 7 detail the performance results obtained on three different CPU architectures. Although the performance is promising in some cases, it is indistinguishable from measurement noise in other cases. A closer look to what happens under the hood is required to analyze these differences.

Table 1 CMQ-NumPy result cache statistics (see Section 7.4).

Benchmark	Misses	Reason
cavtflow	308	REFCNT
chanflow	308	REFCNT
heat3d	132	REFCNT
syr2k	100	SHAPE
vadv	844	REFCNT

Table 2 Configuration of the benchmarking machines used in Section 7.3.

Machine	CPU	RAM
EPYC	AMD EPYC 7H12	1 TB
i7	Intel Core i7-8559U	64 GB
M3	Apple M3 Max	128 GB

An analysis of the executed interpreter instruction frequencies shows that CMQ-indifferent benchmarks execute *fewer* interpreter instructions. This difference also reduces the impact of CMQ optimizations. The `adi` benchmark, for example, executes most of its instructions in the `kernel` function, with each interpreter instruction executed about 20,000 times, with 20 iterations. In the `fdtd_2d` benchmark, on the other hand, the comparative interpreter execution count is only 500 times. This order-of-magnitude difference provides part of the answer.

The interpreter instruction execution frequency aside, the `fdtd_2d` benchmark provides another part of the answer. With the `paper` preset, `fdtd_2d` operates on large matrices having 1,000 rows of 1,200 columns. With an element size of a double floating point number, such a matrix spans 9,600,000 bytes, which is roughly 9 megabytes. Since this size exceeds the limits of both most operating system page sizes, and CPU data caches, the overall execution time is dominated by these caching effects.

To demonstrate the effect of these two variables on CMQ’s optimization potential, we manually changed the parameters of `fdtd_2d`. Instead of 500 repetitions on 1,000 by 1,200 matrices, we experimented with 10,000 iterations on 200 by 220 matrices. With these parameters, performance improved by about 20%.

On the Phoronix benchmark set (Figure 7), CMQ’s impact is less than on the NPBench benchmarks (Figure 6). The primary reason is that many of the Phoronix benchmarks operate on types for which we have not yet added optimized derivatives, such as 32bit floats and NumPy’s scalar types. In other words, these benchmarks pay the small, but non-zero price of attempted specializations without profiting from CMQ. The futile specialization attempts are also the reason for a slight *decrease* in performance for e.g., the `pairwise` benchmark. Compared to the NumPy benchmarks, the Phoronix benchmarks are short-running. As a result, the overhead of specialization attempts is high compared to the benchmark runtime. We confirmed this theory by increasing the internal iteration count, such that a single benchmark run takes longer. We found that with longer run times, the slowdown for all but one benchmarks approached zero. Only the slowdown of `grouping` remained at roughly 10%. The slowdown remained even when disabling specialization attempts entirely and the exact cause requires further analysis.

8.2 Implementation Effort

8.2.1 CPython

Integrating an CMQ into a language VM consists of two tasks. First, allowing C extensions to register and subsequently calling the C extension to attempt the specialization of hot instructions (see Section 5.2). Second, providing functionality to the C extension via the OINT to analyze, specialize and deoptimize instructions.

In the case of `CPython`, we could reuse much of `C`Python’s optimization-counter infrastructure to trigger the optimization of hot instructions Section 5.2.1. As a result, the first task, amounted to only about 200 lines of code. The OINT functionality for the second task consists of analyses (e.g., for finding the originator of an argument, see Section 5.2.4) and code for handling the optimization and deoptimization. The implementation of the OINT made up the majority of the implementation effort in `C`Python and amounts to roughly 800 lines of code.

8.2.2 NumPy

In general, the implementation effort for implementing optimizations depends largely on the C extension in question. As non-experts in NumPy, we spent the majority of the implementation time (see Section 7.5) with understanding NumPy’s architecture as well as debugging our implementation errors. We believe that domain experts (e.g., NumPy core developers) could implement the optimizations not only in substantially less time, but also with less code. For our research prototype we explicitly specified each derivative (see Section 6.3), leading to a larger amount of boilerplate code. Instead, developers with an intimate understanding of NumPy could generate the specifications from the `ufunc` operation specifications already present in NumPy. Future research could focus on automating parts of the optimization implementation, and thus reducing burden on C extension authors.

8.3 Threats to Validity

Although we spent a great deal of effort on making sure that both design/implementation and evaluation are unbiased and representative of the general principle explored and demonstrated by CMQ, the following threats to validity apply.

8.3.1 Generalization Beyond Python

Our analysis and findings focus on the `C`Python ecosystem. Although we believe that these findings hold equally well for similar ecosystems, such as Lua, Ruby, or even WASM, only a comparative investigation will be able to close this gap. Note that neither our analysis, nor our implementation, rely on specifics of the Python interpreter. Python, for example, uses a stack-based virtual machine interpreter architecture. Our extension-delimited superinstructions observation and optimization (cf. Section 4.2.2) hold equally well for register-based architectures.

The standard³ Ruby interpreter YARV is architecturally similar to Python. Both are written in C, both have bytecode interpreters, and although the YARV does not currently perform runtime specialization, a prototype for a specializing interpreter exists [30]. We thus believe that porting CMQ to Ruby would be relatively straightforward.

Another language VM with C extension support is the Lua VM and its optimized variant LuaJIT. The LuaJIT VM has both a profiling interpreter and a JIT compiler and retains compatibility with Lua C extensions. Unlike Python and Ruby, however, the LuaJIT VM is register-based and the interpreter is written in assembly. While certainly possible, the different architecture and low-level nature of the LuaJIT interpreter would pose an obstacle to porting CMQ to Lua.

³ As with Python, many different Ruby implementations exist. With “standard” we are referring to the interpreter that is part of the official Ruby distribution.

8.3.2 Generalization Beyond NumPy

Based on the domain-specificity of C extensions (cf. Section 3.1), our findings cannot translate to other C extensions *verbatim*. The qualitative analysis results apply in general (cf. Section 3.2), and also to other C extension ecosystems. The corresponding optimization techniques explored and demonstrated for the extenders-category also translate to other C extensions.

Our analysis for `lxml` Python extension indicates, for example, that `lxml` would benefit from extension-delimited superinstructions that operate on native types. Note in this context that our OINT design and implementation is not *closed*, but can be extended for other use cases, and indeed we expect future work, also by other researchers, to uncover more optimization features.

8.3.3 Performance Bias Through NPBench

We evaluate CMQ with NPBench that consists of a suite of compute-intensive scientific kernels. These benchmarks cannot be representative of other workloads for different C extensions. No claim to the expected speedup potential can be made on a sound scientific basis.

8.3.4 Performance Result Interpretation

The authors are not experts in optimization of mathematical kernels. The reported results are, thus, merely indicative. An expert possessing the relevant domain expertise may see, and actually uncover, more optimization potential.

9 Related Work

In the Python ecosystem, `Numba` is one way to speed up scientific Python programs, in particular programs using `NumPy`. `Numba` is a Python JIT compiler based on the LLVM JIT compiler framework [28]. As shown by Ziogas et al., `Numba`'s JIT-approach enables impressive performance improvements for some benchmarks [41]. However, `Numba` supports only a subset of Python and cannot optimize functions with incomplete type information. `Cython` is a compiler that compiles a superset of Python to optimized C code and aims to narrow the gap between writing Python code and C extensions [3]. In addition to lowering the burden of writing C extensions, an extension to `Cython` could help to automatically generate optimized derivatives for CMQ.

Grimmer et al. take a different approach to dealing with C extensions [25]. Their Truffle Multi-Language Runtime runs both, the host language and the C extension, on the same language VM, on top of the Truffle framework. Running the C extension is possible through a C interpreter implemented in Truffle [23]. In lack of a benchmark suite for C extensions, the authors evaluate the peak performance of the Multi-Language Runtime with two Ruby programs. A later paper suggests that the performance depends on the exact language combination and benchmark [24]. The approach of running C extensions with a Truffle C-Interpreter was later generalized with `Sulong` [32].

The work closest to ours is “Dr Wenowdis”, a system to communicate function type information from C extensions to PyPy [7]. In their paper, the authors focus primarily on boxing and unboxing overhead, but the principles are similar to our type-specialized instructions (see Section 4.2.1). We believe that our work is mutually beneficial with “Dr Wenowdis” and that the principles of CMQ could be extended to JIT compilers as well.

The WebAssembly Garbage Collector (WASM GC) proposal is similar in spirit to CMQ [26]. With WASM GC, a language implementation running on a WASM engine can communicate information about its object layout to the WASM host engine. This additional communication enables the WASM garbage collector to reason about and to collect guest objects. Thus, the guest language implementation is no longer a black box to the WASM host engine. While WASM does not have C extensions, the proposed WASM System Interface (WASI) fulfills a similar purpose. We believe, therefore, that CMQ’s principles could benefit WASI as well.

10 Conclusions

We present the first analysis and exploration of C extensions for dynamic languages, exemplified by the Python ecosystem. Based on this analysis, we find that the key obstacle of a large-scale quantitative analysis is that many C extensions require their own *domain expertise*. This domain specificity of C extensions makes them both difficult to compare and difficult to evaluate performance against, since the domain specificity also implies a lack of generalizable benchmark suites.

Due to this negative result, we instead focus on a qualitative analysis of Python’s C extension ecosystem. We find that C extensions fall into three categories: (i) optimizers, (ii) binders, and (iii) extenders. Optimizers are C extensions that could be written in Python, but are written in C to speed up the processing. Binders are C extensions that essentially bind Python to existing C libraries. Extenders add functionality to Python that does not readily exist.

From a performance perspective, we find that the first two categories provide few optimization opportunities. This lack of opportunities is rooted in the fact that most time is spent in the C extensions themselves. The third category, however, offers optimization potential as evidenced by the speedups demonstrated by CMQ. Based on the example of NumPy, we illustrate a total of three orthogonal optimization techniques.

Since our work represents, to the best of our knowledge, the first foray into optimization across module boundaries, we expect future work efforts that extend and generalize the ideas presented herein. We believe that a natural step would be to try integrating our findings into just-in-time compilers. A generalization, on the other hand, would try to apply our ideas to another dynamic language ecosystem, such as Ruby, Lua, PHP, or Perl. We furthermore expect that the presented system will be adapted and extended by performance-conscious extension authors, leading to new optimization opportunities down the road. Finally, even a closed ecosystem such as JavaScript may benefit from our ideas: the runtime system and the browser represent a form of C extension for the JavaScript virtual machine. Through similar APIs, JavaScript engines could, thus, benefit from optimizations.

Abstract

C vulnerabilities usually hold verbatim for C++ programs. The *counterfeit-object-oriented programming* attack demonstrated that this relation is asymmetric, i.e., it only applies to C++. The problem pinpointed by this COOP attack is that C++ does not validate the integrity of its objects. By injecting malicious objects with manipulated virtual function table pointers, attackers can hijack control-flow of programs. The software security community addressed the COOP-problem in the years following its discovery, but together with the emergence of transient-execution attacks, such as Spectre, researchers also shifted their attention.

We present HOBBIT, a software-only solution to prevent COOP attacks by validating object integrity for virtual function pointer tables. HOBBIT does not require any hardware specific features, scales to multi-million lines of C++ source code, and our LLVM-based implementation offers a configurable performance impact between 121.63% and 2.80% on compute-intensive SPEC CPU C++ benchmarks. HOBBIT’s security analysis indicates strong resistance to brute forcing attacks and demonstrates additional benefits of using execute-only memory.

Funding The research reported in this paper has been funded by the Federal Ministry for Climate Action, Environment, Energy, Mobility, Innovation and Technology (BMK), the Federal Ministry for Labour and Economy (BMAW), and the State of Upper Austria in the frame of the COMET Module Dependable Production Environments with Software Security (DEPS) [(FFG grant no. 888338)] within the COMET - Competence Centers for Excellent Technologies Programme managed by Austrian Research Promotion Agency FFG.

1 Motivation

Among the myriad of security exploits, control-flow hijacking is the most severe problem, as it allows the attacker to execute arbitrary code. A buffer overflow, for example, allows an attacker to overwrite the return address stored in a function’s stack frame, and thus divert control-flow to a location of her choice. Many other similar vulnerabilities exist and have been both explored and exploited over the past two decades. Most of these vulnerabilities affect both C and C++ alike.

The feasibility of an attack focusing exclusively on the C++ superset was demonstrated by Schuster et al. in 2015 [45]. By injecting malicious objects into a C++ application the attack hijacks control-flow and allows Turing-complete, arbitrary computation. In analogy to other similar attacks, such as return-oriented programming, this attack is known as *counterfeit-object-oriented programming*, COOP for short.

Due to the prevalence of C++ in systems and application software, researchers focused on devising mitigations against COOP. To prevent control-flow hijacking, prior defenses apply principles from effective C defenses. The principle of W^X limits attacker capabilities to inject code through new hardware features, such as Intel’s NX bits [52]. CFIxx, for example, uses the MPX extension to secure a bookkeeping table it relies upon [12]. By applying cryptography to encode and decode control-flow data, adversaries cannot know *a priori* how target addresses are encoded. CCFI, for example, uses Intel’s AES-NI instructions to cryptographically secure program addresses, such as return addresses, function-, and `vtable` pointers [31].

Although both of these defenses thwart COOP attacks, they, too, have drawbacks. Reliance on Intel’s MPX is problematic for three reasons. First, MPX may not be available in a system’s target environment, such as in embedded systems or IoT contexts. Second, Intel could decide to abandon the MPX instruction set extensions. Consider the MPK instruction set extension, which was discontinued rather abruptly, rendering defenses relying on it incapacitated. Third, MPX is non-compositional: A defense cannot protect an application that already relies on MPX for its business logic, as the MPX registers are already taken.

Cryptographic protection of pointers is desirable due to strong security guarantees, but suffers from prohibitive performance penalties. CCFI’s use of AES-NI reserves x86-64’s vector registers, i.e., SSE, AVX, AVX2, or AVX512, blocking their use for other purposes. Unavailability affects video processing, cryptographic operations, and a variety of other tasks.

HOBBIT neither requires specific hardware extensions nor blocks vector registers and, thus, addresses both of these challenges. Instead, HOBBIT modifies the C++ object layout to embed an integrity signature when an object is constructed. This signature is validated *before* executing each virtual method’s body.

A Clang/LLVM-based implementation of HOBBIT compiles large programs, such as the WebKit browser, and allows parameterization to balance security with performance. The key factor affecting performance is the choice of hashing technique to create an object’s signature. Our evaluation shows that choosing strong hashing techniques can lead to substantial overheads. To eliminate this overhead, HOBBIT implements two different optimizations. First, HOBBIT applies a class-sensitive optimization to restrict its protection to classes that are essential to the COOP attack. Second, HOBBIT applies the idea of MAC algorithm parameter randomization, thereby increasing overall security. For many application contexts, HOBBIT is thus the only viable defense against COOP.

Our contributions are as follows:

- We present HOBBIT, a software-only defense that thwarts counterfeit-object-oriented programming (COOP, for short).
- We describe the implementation of a fully-fledged Clang/LLVM-based prototype that supports all C++ features, such as multiple inheritance (see Sections 5 and 6).
- We discuss two new HOBBIT optimization techniques that enable users to balance their security needs with the available performance budget. We introduce Gadget-directed optimization (see Sections 5.5 and 7.5), to apply protections specifically to COOP gadgets, and Class-Hierarchy-driven Seed Randomization (see Sections 5.3 and 6.4).
- We evaluate HOBBIT w.r.t. performance, scalability, and security (see Section 7). Specifically, we report:
 - *Performance*: A configurable performance impact between 121.63% and 2.80%.
 - *Scalability*: HOBBIT compiles complex real-world software, such as the WebKit web browser.
 - *Security*: HOBBIT provides comprehensive security through either strong hashing techniques or randomizing parameters of weaker hashing techniques.

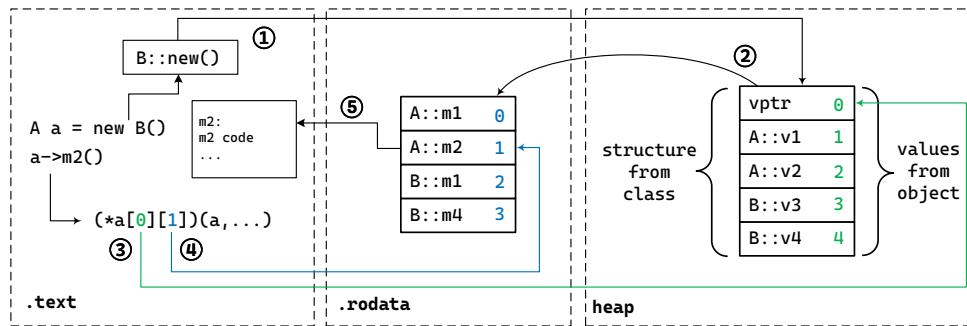

Figure 1 Overview of polymorphism and dynamic binding in C++. (1) constructors allocate objects and set `vptr` and field values, (2). Method calls require resolving of the `vtable`, (3), and then the corresponding fixed method id, (4), before being able to call the method, (5).

2 Background

In this section, we will introduce the background needed to understand the Counterfeit Object-Oriented Programming (COOP) attack. Since COOP is a high-level attack targeting specific C++ semantics, we will briefly explain the C++ object layout, polymorphism, and dynamic dispatch mechanism. Finally, we need to cover some preliminary concepts used in HOBBIT.

2.1 C++ Polymorphism and Dynamic Binding

In object-oriented programming languages, such as C++, programs are organized around classes and objects. *Classes* in C++ define the fields of objects and the *methods* operating upon them. A concrete instance of a class is called *object* and consists of values for the defined data fields residing in a contiguous memory region. To create and initialize newly created objects, programmers call special methods, so-called *constructors*.

Figure 1 illustrates these concepts. Instantiating a new B object triggers a call to its constructor (1), which allocates a contiguous memory region and sets the `vptr` due to the concrete dynamic type (2). The class determines the structure of each object, while the object holds values specific to the instance.

To dynamically bind a method call, C++ uses so-called `vtable`-based method dispatch (see Figure 1). For each class, C++ generates a corresponding `vtable` that holds the addresses of each callable method on it. If a class inherits a method, its address will merely be copied into the corresponding method slot. If a class overrides a method, a new address will be written into the corresponding method slot. A method call, then, consists of two steps: (i) resolving the `vtable` by dereferencing an object and accessing the first entry, which holds the `vtable` reference (3), and (ii) resolving the method by dereferencing the proper method through a callsite-fixed method identifier (4).

2.2 Counterfeit-Object-Oriented Programming (COOP)

Over the past four decades, the memory unsafe nature of C and C++ lead to an “Eternal War in Memory” [51]. In the beginning, attackers were able to insert instructions as data in writable memory. By facilitating a buffer overflow to overwrite the return address,

attackers could hijack the control-flow of a program to execute injected code, resulting in Arbitrary Code Execution (ACE). Simple defenses, such as Write exclusive-or Execute (W^X) – marking memory as either writable or executable, but not both – render such code injection attacks impossible. Therefore, attackers adapted and began reusing existing code, residing in executable memory. Attackers either reused whole functions (e.g., return-into-libc [21, 35]) or performed arbitrary computations by chaining together small pieces of code, called *gadgets*, as in Return-Oriented Programming (ROP) [46, 42, 49] and its variations [10, 19, 15, 44]. Many defenses targeting mentioned Code Reuse Attacks (CRAs) exist [28, 37, 1, 2, 11]. A more recent CRA targeting high-level C++ semantics is COOP [45].

COOP exploits the dynamic dispatch mechanism and escapes mentioned defenses above. Instead of introducing new invalid control-flows like in ROP or return-into-libc, COOP misuses existing callsites. To illustrate this point, consider the example from the previous section, but from the perspective of the CPU. A callsite merely fixes the method identifier, but accepts *any vtable* and will, thus, invoke *any* method identified by the fixed method identifier (see Figure 1, ⑤.)

COOP abuses this property of *vtable*-based method dispatch, by injecting malicious objects, so-called *counterfeit objects*. These objects use invalid *vtable* entries, to abuse method invocation. Instead of abusing gadgets as in return-oriented programming, COOP abuses whole functions. Since the notion of code-reuse attacks is tied to the nomenclature of *gadgets*, COOP, too, defines whole-function reuse gadgets.

These COOP gadgets are methods that can be abused for a specific malicious purpose. Not all COOP gadgets are equally important, though. The most important gadget is the so-called *main-loop gadget*, or ML-G for short. Consider the following C++ method:

```

1  virtual void removeElement(Element x) {
2      for (int i= 0; i < this.N; i++) {
3          this.L[i].remove(x);
4      }
5  }
```

 **Listing 1** Example of a COOP main-loop gadget (ML-G).

As shown in Listing 1, the `removeElement` method will loop over an array, namely the field `L` and invoke the virtual method `remove` on every object stored in the field `L`. From an adversarial COOP perspective, this means that the attacker can inject arbitrary malicious objects and store them in the corresponding `L` field. Once she can invoke the `removeElement` method, the attack will be launched.

More advanced variants of COOP relax this requirement for a container object holding references to other objects. Crane et al., for example, describe *Recursive-* and *Unrolled COOP* variants that allow different patterns of repetition [20]. By applying control-flow integrity, valid control-flow transfers can be restricted to the program’s call-graph. Chen et al. demonstrates that COOP can still succeed despite this constrain [16]

2.3 Execute-Only Memory (XOM)

Machine code in the `text` section of a program usually possesses read *and* execute privileges. The read privilege is required to process inlined data, such as jump tables for `switch` statements. But the read privilege requirement is not *strict*. The only essential privilege for code is the ability to execute. Inlined data must then move to another section with read privileges.

The principle of least privilege – a core tenet of computer security policies – prescribes that reducing privileges improves security. Thus, in the 60s the Multics project already supported execute-only memory [18]. Over the past decade, the idea of execute-only memory saw a revival [4, 47, 19, 20, 24, 6]. The revival was due to advanced, sophisticated multi-stage attacks that used memory leaks to (i) read a processes code layout, and then to (ii) relocate a generic attack to the specific code layout used by a program. These specific code layouts were derived from an active research area called “software diversity,” and complementing existing methods with execute-only memory begot the new class of defenses called *leakage-resilient diversity*.

2.4 Message Integrity Through MACs

To verify the authenticity and integrity of a message sent over an untrusted medium, people use so-called *message-authentication codes*, MACs for short. Both sender and receiver agree on a message authentication code (MAC) algorithm, based on a shared secret key k . Then, the sender computes the MAC checksum, also known as tag t , for every message m : $t = MAC(m, k)$ and sends this tag t along with the message. At the receiving end, we recompute the tag t' for the received message m' : $t' = MAC(m', k)$. Then, by comparing both tags t and t' for equality, we verify the message m 's integrity. Since the MAC algorithm is based on a secret key k , only shared between sender and receiver, third-parties cannot compute valid tags. Typically, secure MAC algorithms are based on cryptographic keyed-hash functions.

Counterfeit-object-oriented programming exploits the fact that control data, such as `vptrs` are mixed with non-control data. Similar to buffer overflows, mixing both types of data proves to be a security problem when adversaries inject malicious objects.

3 Related Work

Due to the severity of counterfeit-object-oriented programming as an attack vector, a variety of defenses [26, 20, 40, 57, 5, 16] has been proposed. Prior work, thus, considers multiple different design criteria. These design criteria include: software-only [20, 5] vs hardware-based [31, 54], hardening applied to binaries [41, 56, 23, 22] vs software-only, differences w.r.t. protected program parts (such as, protecting `vtables`, `vtable`-pointers, or dynamic dispatch). Due to these differences, giving an exhaustive treatment is in direct conflict within traditional scope restrictions. We therefore focus on the most directly related work, and skip, e.g., prior work dealing with securing C++ programs without source code access.

Most closely related to HOBBIT is CFIXX, which uses Intel's discontinued MPX extension to protect `vptrs` [12]. At its core, CFIXX separates `vptrs` from `vtables` and stores them into a dedicated memory area protected by MPX. In 2022, Xie et al. demonstrated a CFIXX version building on Intel's Control-Flow Enforcement Technology (CET) [54]. Recently, many defenses proposed the use of Intel's MPK extension. Unfortunately, using MPK is not compositional: If an application uses MPK itself, it cannot share its MPK use with any other component, such as a defense.

Compared to HOBBIT, CFIXX highlights the need for a software-only approach that does not require specific hardware extensions beyond extended-page table support to enable execute-only memory.

CCFI, short for cryptographically-secured control-flow integrity, is another closely related defense – not specifically aimed at preventing COOP attacks, but providing comprehensive protection against essentially all forms of control-flow hijacking [31]. CCFI pioneers the use of MACs to protect code pointers. Unfortunately, to secure the keys from leaking, the system proposed to reserve vector registers (i.e., SSE’s `xmm` registers), thus slowing down application relying on their use, such as media en- or decoders.

Compared to HOBBIT, CCFI highlights the need to preserve performance characteristics of programs, primarily by finding alternatives to protect secret keys that do not result in prohibitive performance impacts.

Hardware-based approaches are inextricably bound to the hardware mechanism and thus prone to sun-setting, as in the case of Intel’s MPX instructions, or lack of compositionality, as in the case of MPK extensions.

Defenses based on cryptographic primitives often suffer from poor performance, e.g., by effectively blocking vector registers, and the security-prerequisite of having cryptographic primitives not spill data onto the stack.

4 Threat Model

COOP is a rather sophisticated attack and will, thus, often be a last resort for attackers. We assume, consequently, that proper defenses against simpler attacks, such as code injection, ROP [46, 42], and return-into-libc [21] are in place. Since HOBBIT aims to prevent COOP attacks, we assume a strong threat model in line with previous work [45, 20, 31, 12].

In general, launching a COOP attack requires an attacker to hijack an initial object, including its virtual table pointers (`vptrs`) and data, and inject new counterfeit objects. To that end, an attacker needs to read or infer addresses of Virtual Tables (`vtables`) and write object-like data, including `vptrs` and other data, to specific memory regions. A variety of vulnerabilities provide such capabilities, including buffer overflows [38] and use-after-free vulnerabilities [51]. Although a restricted read- and write capability might suffice, we assume an attacker capable of reading arbitrary readable memory and writing to arbitrary writable memory.

Our system relies on `W^X`, marking memory either as writable or executable, but not both at the same time. Writing to code residing in executable memory or execute written data is not possible. Therefore, injecting new code or modifying existing code is not possible.

The attacker’s arbitrary read capability renders defenses relying on secrets in readable memory ineffective. For example, protecting against overflowing into control data, such as return addresses or `vptrs` with (stack) canaries, is not effective. An attacker can easily read these values and embed them in her payload, or – assuming an arbitrary write capability – skip canaries at all. To mitigate this issue, we assume Execute-Only Memory (XOM), therefore, we consider values or functions in XOM as secret.

Finally, we assume an attacker with specific knowledge about the target program and system. First, he has access to the target program’s source code. Second, she is able to infer the base address of the initial object, and the addresses of virtual function gadgets (`vfgadgets`) located in C++ modules. Although COOP relies primarily on high-level C++ semantics, some `vfgadgets` rely on specific instructions or registers, e.g., `vfgadgets` for loading argument registers to pass arguments to other `vfgadgets`. An attacker requires at least partial knowledge of the binary layout to use some `vfgadgets`. Third, the attacker knows about the system’s configuration, including deployed defenses, software versions, and hardware features.

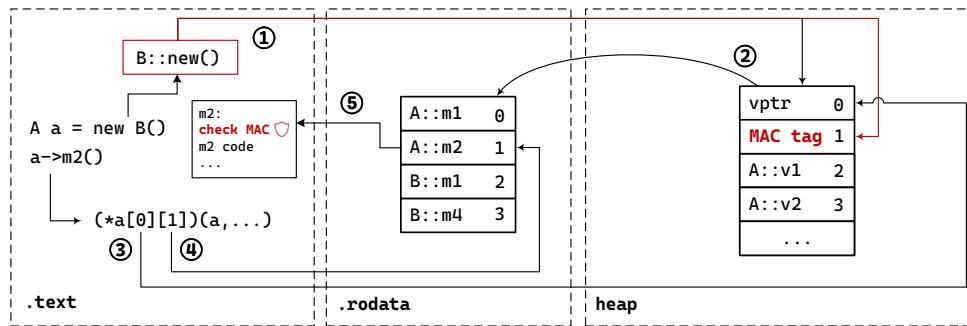

Figure 2 HOBBIT changes to C++. (1) constructors allocate objects, set `vptr` and field values and compute a MAC value, (2). Method calls are resolved as before, see Figure 1, but all method prologs now validate the MAC value, (5).

5 Design Aspects of Hobbit

HOBBIT is, broadly speaking, a defense that monitors and validates integrity. Whenever this integrity is violated by an adversary, we know that the program is under attack. A direct consequence of any integrity-protection mechanism also holds for HOBBIT: we protect neither the injection, nor the modification of objects; subsequent method calls trying to *act* on maliciously-modified objects will detect integrity violations.

The integrity monitored by HOBBIT is the object to `vptr` binding. One could just add a random value into an object and repeatedly validate its value. Since our threat model includes a powerful attacker with memory read capabilities, choosing a simple random value is insecure. Instead, HOBBIT considers objects, more specifically `vptrs`, between constructors and methods as messages, and secures them by applying message-authentication codes.

The following sections provide an in-depth discussion of the relevant design aspects of HOBBIT. Section 5.1 discusses C++ relevant aspects of object lifetime and changing the object layout to add the MAC tag. Sections 5.2 and 5.3 describe the benefits of using execute-only memory, and MAC-algorithm diversification. Section 5.4 lists possible locations for verifying signatures. Finally, we introduce the concept of gadget-directed optimization in Section 5.5.

5.1 C++ Object Lifetime and Layout

Objects in C++ live between construction and destruction, i.e., by constructors and destructors, respectively. Constructors instantiate an object by initializing, or assigning concrete values to its fields, which themselves are prescribed by their corresponding class definitions. Since a `vptr` is merely a field itself, at least from a run-time perspective, the constructor assigns the `vptr` of the called dynamic type. Destructors clean up object instances and, finally, free the allocated memory.

HOBBIT changes the C++ object layout by adding a machine-word per `vptr` that holds the computed MAC tag (see Figure 2 (1)). Besides requiring an extra word per `vptr`, such a change breaks the application binary interface (ABI), and we discuss the implications thereof in Section 6.

5.2 Message-Authentication Codes and Execute-Only Memory

In HOBBIT, we consider vptrs as messages sent from constructors (see Figure 2 (1)) and received by virtual methods (see Figure 2 (5)). The key security aspect of MAC functions is the shared-secret key between senders and receivers. If an attacker retrieves this secret key, she can craft valid signatures for malicious messages, thus violating the authenticity property of sent messages. To prevent leakage of this shared-secret key, HOBBIT piggybacks on execute-only memory’s leakage-resilience property.

Execute-only memory means that the adversary is precluded from reading code memory. As a result, we can hide privileged information directly in code memory. HOBBIT hides two privileged pieces of information there: (i) keys as intermediate constants, and (ii) MAC algorithm implementations. Hiding implementations from adversaries forces them to guess, thus further frustrating attacks.

MAC algorithm parameters, too, are important for security. Consider the following parameterization to compute object-vptr tags:

$$t = \text{MAC}(\text{vptr} \oplus r) \quad (1)$$

Although we include a random parameter r to the MAC computation, our attacker can use their memory-read primitive to read an object – including its `vptr` and the corresponding tags – and, use it later on during an attack at a different location. Such a staged attack is called a “replay” attack. To counter these replay attacks, we need to add the `vptr` location to the computation:

$$t = \text{MAC}(\text{vptr} \oplus \&\text{vptr} \oplus r) \quad (2)$$

By making MAC tags location-dependent, the attacker cannot trivially replay the object layout she read at a different location.

Prior defenses reserve registers to hold the key and exclude them from register allocation [31, 39]. Since the compiler then never allocates these registers, the key stored therein is considered safe from attackers. Although simple, this solution suffers from two drawbacks. First, reserving registers increases register pressure, which is particularly problematic on architectures with few registers, such as x86. Second, whether a key stored in registers is actually safe, depends on additional measures and precautions for context switches. Through its use of execute-only memory, HOBBIT bypasses these shortcomings.

5.3 Class-Hierarchy-Driven Seed Randomization

By using just a single random parameter r in our MAC tag computation, the adversary can bypass HOBBIT, once he identifies both the secret MAC algorithm and the value of r . HOBBIT counters this problem by using as many random parameters r as possible. In theory, different random parameters r can be randomly assigned across an application. In practice, however, we need to preserve C++ semantics across type-compatible call-sites. A conservative way to ensure semantics preservation is to map a single random parameter r to a subgraph in the class hierarchy graph (see Section 6.4). A more aggressive way would be to factor in run-time information, e.g., through profiling.

Due to this additional security mechanism, we can also loosen the strength requirements for our MAC algorithm. By choosing small, but efficient pseudo hash functions, such as `moremurmur-hash` [32], HOBBIT users favor performance over security, and vice versa. Since MAC algorithm implementations are protected by execute-only memory (see Section 2.3), the perceptible loss of security is minimal.

HOBBIT supports a wide variety of MAC hashing algorithms, such as `blake3`, `highwayhash`, `xxhashct`, `moremurmur`, and `moremurmur-random`.

5.4 Validating MAC Tags

HOBBIT recomputes and validates tags stored in objects in function prologs of virtual functions (see Figure 2, (5)). Although an attacker can inject malicious objects, HOBBIT will detect tampering with a tag *after* resolving the dynamic type, but *before* executing the actual method body. Alternatively, HOBBIT can also validate tags already at virtual call sites, but this implies embedding MAC hash computation into every call site, thus increasing the amount of machine instructions for each call site. Depending on the chosen MAC function implementation (e.g., inlined), these additional machine instructions might result in a considerable binary size increase.

In C++, most compilers use `vptrs` for other run-time related features besides dynamic dispatch. The use of run-time type information (RTTI), for example, requires loading the `rtti` pointer from the `vtable`. Similarly, dynamic casts use information stored in `vtables`, such as offsets to access/identify sub-objects for multiple inheritance. Although HOBBIT could validate tags in these cases, too, we choose to focus protection on dynamic dispatch, which is the key objective for COOP attacks.

5.5 Gadget-Directed Optimization

For performance-critical systems, such as real-time applications, HOBBIT can relax security and optimize for speed. Since COOP relies on special gadgets for dispatching other gadgets, we can embed integrity checks only in methods acting as such gadgets. To prevent attackers from executing Main Loop Virtual Function Gadgets (ML-Gs), HOBBIT can perform static analysis on source code to identify methods iterating over a collection of objects and calling virtual functions on them (see Section 6.5.)

HOBBIT could also analyze binaries to identify gadgets relying on binary instructions. Muntean et al., for example, created a tool for identifying gadgets and automating a COOP attack [34]. In general, identifying all gadgets is difficult and since variants of COOP exist, the resulting defense may not be complete [20, 16].

6 Hobbit Implementation

We implemented our prototype of HOBBIT as compile-time transformations on top of LLVM/Clang 17.0.3 [17] for the `x86_64` Linux platform and Itanium ABI [25]. Most researchers implement their prototypes as passes in LLVM that operate on and modify the LLVM specific intermediate representation, short LLVM IR. However, we implemented most parts of HOBBIT in Clang, since compilation is a lossy transformation and high-level C++ information, e.g., virtual methods and their callsites, are not – at least without complex analysis – available in LLVM IR.

First, HOBBIT extends the object layout to reserve space for the newly introduced MAC tag fields. After reserving space for MAC tags, we add instructions for computing and storing MAC tags in objects to constructors. For the final part of the `vptr` validation, we implement MAC tag checks in virtual methods. In Section 6.3 we describe our different MAC function implementations, Section 6.4 shows HOBBIT’s diversification implementation, and Section 6.5 demonstrates a prototype of our Gadget-directed Optimization. Section 6.6 lists the limitations of our prototype implementation of HOBBIT.

6.1 Extending Object Layouts

Extending the object layout requires us to change the size of objects in a special data structure called `RecordLayouts`. Clang uses the type `CXXRecordDecl` to represent C++ structs, unions, and classes. `RecordLayouts` store information about fields, their offsets, paddings, and lengths, (virtual) bases, and other layout-related information. Since HOBBIT introduces a new MAC tag field, we have to increase the size of the layout accordingly. On `x64` systems, pointers are eight byte long. Therefore, we add eight bytes to the (data-) layout size for dynamic `CXXRecordDecls` that do not inherit `vptr` (and consequently the MAC tag field) from a parent class in `AST/RecordLayoutBuilder` (`ItaniumRecordLayoutBuilder::LayoutNonVirtualBases`). Later, during the lowering of records, we add the field information for our MAC tag field, right after the `vptr` (see Listing 2).

```

1 void CGRecordLowering::accumulateVPtrs() {
2     if (Layout.hasOwnVFPtr()) {
3         auto vfptra = ...;
4         Members.push_back(vfptra);
5         auto HobbitMACField = MemberInfo(getSize(vfptra.Data),
6                                         MemberInfo::Field,
7                                         getIntNTType(64));
8         Members.push_back(HobbitMACField);
9     }
10    ...
11 }
```

Listing 2 Add MAC tag field while lowering records.

Extending the object layout breaks the C++ ABI compatibility. By recompiling the entire toolchain, including a standard C++ library, we still can compile and run programs with our C++ ABI modifications. We encountered one error in the `libunwind` library regarding macro definitions for the size of `libunwind::UnwindCursor`. `libunwind::UnwindCursor` is a dynamic class, therefore, consists of a `vptr` and with HOBBIT also a MAC tag field. To fix this error we have to account for the new tag field and thus add one to all macro definitions defining the constant `_LIBUNWIND_CURSOR_SIZE` in `__libunwind_config.h`. With this simple fix, HOBBIT can compile even the largest C++ programs.

6.2 Computing and Validating MAC Tags

C++ programs adhering to the C++ standard create objects solely by calling constructors. Therefore, we decided to implement the MAC tag computation and storing of the results in constructors. Constructors already perform the `vptr` initialization in a function called `CodeGenFunction::InitializeVTablePointer`. Likewise, HOBBIT initializes the MAC tags right after `vptr` initialization. Listing 3 shows the resulting assembly code of a constructor compiled with HOBBIT. A standard `clang` compiler emits the three assembly instructions (lines 3–5) initializing the `vptr` of an object of a class `B`. Since `_ZTV1B` points to the beginning of the `vtable` – the first two entries in the `vtable` are the offset-to-top and the RTTI pointer – the compiler adds 16 bytes to the `vtable` such that the `vptr` points to the first virtual function and finally saves the `vptr` in the designated field at the beginning of the given object. The remaining instructions (lines 7–12) are emitted by HOBBIT and responsible for loading

```

1 _ZN1BC2Ev:
2 ...
3 leaq    _ZTV1B(%rip), %rcx # load address of vtable
4 addq    $16, %rcx          # add 2 qwords for 1st virt. function = vptr
5 movq    %rcx, (%rax)      # store vptr at beginning of object
6 # HOBBIT START #
7 movq    (%rax), %rdx      # load vptr into rdx register
8 movq    %rax, %rcx         # load this into rdx register
9 xorq    %rdx, %rcx         # vptr xor this
10 movabsq $random, %rdx     # load secret value r to rdx
11 xorq    %rdx, %rcx         # xor secret value r = mac tag
12 movq    %rcx, 8(%rax)      # save mac tag to designated field
13 # Possible inlined hashing or call to compiler-rt hash function
14 # HOBBIT END #
15 ...

```

Listing 3 x86_64 assembly for an exemplary constructor of a dynamic class B emitted by HOBBIT.

```

1 _ZN1A2m2Ev:
2 # start function prolog:
3   # save callee-saved registers
4   # set up stack for local variables
5   #
6 # HOBBIT START #
7 movq    (%rcx), %rdx      # load vptr to rdx
8 movq    %rcx, %rax         # load this ptr to rax
9 xorq    %rdx, %rax         # vptr xor this
10 movabsq $random, %rdx     # load secret value r to rdx
11 xorq    %rdx, %rax         # xor secret value r = mac tag'
12 movq    8(%rcx), %rcx      # load saved mac tag
13 cmpq    %rcx, %rax         # check if tag' = tag
14 jne     .LBB4_2            # on mismatch jump to trap
15 ... # actual function      # actual function body
16 .LBB4_2: # %MACMismatchBlock # block with trap for mac tag mismatch
17 movl    $147, %edi          # store result code 147 to edi
18 callq   exit@PLT           # exit(147) on mac tag mismatch
19 # HOBBIT END #

```

Listing 4 x86_64 assembly for an exemplary virtual method of a dynamic class B emitted by HOBBIT.

both `vptr` and `this` in registers, followed by the `xor` instruction. The `movabsq` instruction loads an immediate – the random secret r – to a register and `xor` it to the previous result. Finally, the `xor` result is written to the MAC tag field, 8 bytes after the `vptr`.

HOBBIT inserts MAC tag validation checks in virtual functions (see Listing 4). These validation checks protect against attackers calling virtual functions on objects with fake or altered `vptrs`, therefore mitigating COOP attacks. If HOBBIT should protect dynamic

■ **Table 1** Details of implemented MAC functions used for benchmarking.

Name	MAC Function	Implementation
baseline	—	—
no-hash	none; only <code>xor(vptr, &vptr, random_secret)</code>	—
blake3	C implementation of BLAKE3	static lib
highwayhash	highwayhash	shared lib
xxhashct	compile-time implementation of xxhash	static lib
moremur	pseudo hash function based on moremur	inlined
moremur-random	diversified version (random parameter) of moremur	inlined

casts or RTTI access, we could insert MAC validation checks at those locations as well. To prevent the execution from virtual function bodies HOBBIT inserts the following instructions in `CodeGenFunction::StartFunction`:

1. We retrieve all `vptrs` for the current object.
2. For each `vptr`, we compute the MAC tag again.
3. For each `vptr`, we load the stored MAC tag value.
4. Then, we compare the computed and loaded MAC tag values.
5. If these tags match, we start executing the function body.
6. Otherwise, we detect an ongoing COOP attack and can launch counter-measures. In our prototype implementation, we simply exit the program with status 147.

Listings 3 and 4 show the resulting assembly code for both constructors and virtual methods of a class with 1 `vptr` without any hashing (`no-hash`).

6.3 MAC Function Implementations

We implemented different MAC functions in HOBBIT and extended the `baseline`, an unmodified Clang/LLVM 17.0.3. Table 1 shows the different hash implementations for the MAC function. The simplest approach is `no-hash` (as shown in Listings 3 and 4) that uses the identity function as MAC in Equation (2). Therefore, tag t is the unhashed result of the `xor` operations.

In contrast, `moremur` [32] implements a pseudo-hash function as MAC. These pseudo hash functions should be small, such that HOBBIT inlines these hash functions in both constructors and virtual functions. With XOM, immediate values used in such hash functions are resistant to leakage and can thus be considered secret. Section 6.4 describe `moremur-random`, a diversified implementation variant of `moremur`.

```

1   ...                                # preceding instructions from Listing 3
2   movabsq $random, %rax             # load random value to rax
3   xorq    %rax, %rdi               # xor random value = mac tag
4   callq   coop_hash@PLT            # call to compiler-rt hash function
5   movq    %rax, %rcx               # store result of coop_hash to rcx
6   movq    -16(%rbp), %rax          # reload this pointer
7   movq    %rcx, 8(%rax)            # save mac tag to designated field
8   ...

```

■ **Listing 5** Constructor calling a hash function in `rt-lib`.

We implemented the remaining MAC functions, all including larger and more complex hash functions, as compiler run-time libraries, short `compiler-rt`. LLVM provides and links these libraries for run-time support in compiled binaries. We implemented different versions of such a `compiler-rt` for the remaining MAC variants `blake3` [9], `highwayhash` [3], and `xxhashct` [55]. HOBBIT links the `compiler-rt` libraries for `blake3` and `xxhashct` statically to the program under compilation. `Highwayhash`, in contrast, is dynamically linked as a shared library.

With run-time hashing support enabled, HOBBIT simply inserts a call to the hash function located in the run-time library, according to Equation (2). Listing 5 shows the resulting instructions. After the initial `xor` instructions, the result is passed as an argument to the `coop_hash` function. The function `coop_hash` computes a hash according to the chosen hash function (Table 1), namely `blake3`, `highwayhash`, or `xxhashct`. Finally, after loading the `this` pointer again, the returned result is stored in the designed MAC tag field.

6.4 Class-Hierarchy-Driven Seed Randomization

In its current implementation, the random parameter r of Equation (2) is fixed over the whole program. We implemented a naive diversification approach diversifying this random parameter. Ideally, we would choose a different parameter for each class, however, due to the polymorphic nature of C++, the diversification degree is limited. We create MAC tags in constructors and validate them in virtual functions, therefore, both MAC functions must use the same random parameter. With subtyping, methods must be callable for different classes, according to the inheritance graph. Therefore, our diversified implementation chooses a random parameter for each weakly connected subcomponent of the inheritance graph. The inheritance graph is, in fact, a directed acyclic graph¹, since C++ has the concept of multi-inheritance, hence the famous *diamond problem*.

We implemented `moremurmur-random` in the following steps:

1. In an initial compilation step, HOBBIT outputs all classnames with the corresponding (virtual-) bases.
2. We implemented a Python script that constructs the inheritance DAG.
3. Our script assigns each weak component² a different random parameter r .
4. HOBBIT then use this class assignment to diversify the MAC tag computation.

By enabling `link-time optimization`, we could implement the inheritance graph analysis and the diversification assignment in Clang/LLVM.

6.5 Gadget-Directed Optimization

We implemented a simple gadget-directed optimization that identifies simple main-loop gadgets. With this optimization enabled, HOBBIT performs a static analysis to identify potential main-loop gadgets. Our naive analysis checks whether a virtual method belongs to a class declaring any fields of C++ standard container type [13], either directly or indirectly, by inheriting from classes with such fields. This prototype gadget-directed optimization only identifies simple main-loop gadgets, but fails to identify other forms of dispatcher gadgets, serving as a main-loop gadget [45, 20]. Other dispatcher gadgets include `recursive gadgets`, `unrolled COOP`, or iterators over linked lists. HOBBIT could use COOP exploit automation frameworks, such as `iTOP`, to identify additional gadgets and feed them into our gadget-directed optimization [34].

¹ Not a tree, as one would expect.

² All connected subgraphs, also called *components*, ignoring the direction of edges.

 **Table 2** Benchmark system configuration.

	EPYC 7H12	i7-8559U	Ryzen 9 5900X
Processor	AMD EPYC 7H12	Intel 8559U	AMD Ryzen 9 5900X

OS	Debian 12	Debian 12	Ubuntu 22.04.4 LTS
Kernel	6.1.0-16-amd64	6.1.0-16-amd64	6.5.0-27-generic
gcc	12.2.0	12.2.0	11.4.0
glibc	2.36	2.36	2.35
linker	gold (2.38)	gold (2.38)	GNU ld (2.38)

6.6 Limitations

HOBBIT does not protect RTTI objects. RTTI objects are dynamic types, but not created by calling constructors at run-time. Instead, Clang initializes RTTI objects during compilation, therefore, HOBBIT does not compute and store MAC tags for such objects. At load-time, vtables and RTTI objects alike are loaded into `.rodata`. However, protecting RTTI objects is still possible but requires extra effort. We could, for example, create initialization code similar to our MAC tag initialization in constructors and call this RTTI object initializer when the address of both vtables and RTTI objects is known, at load-time. Since HOBBIT does not create MAC tags for RTTI objects, we do not emit integrity checks in virtual functions belonging to RTTI classes.

7 Evaluation

We present the evaluation of our prototype implementation of HOBBIT. In Section 7.1, we describe the machines used for our evaluation. Sections 7.2–7.4 show the performance evaluation, including measurements of run-time, memory-usage, and code-size. We evaluate our implemented prototype of gadget-directed optimization in Section 7.5. In Section 7.6, we evaluate the scalability of HOBBIT by compiling real-world applications with HOBBIT. Finally, Section 7.7 shows the evaluation of the class-hierarchy-driven seed randomization.

7.1 System Configuration

We perform our evaluation of HOBBIT on three different machines listed in Table 2.

We used machines EPYC 7H12 and i7-8559U for the performance evaluation in Section 7.2 and the gadget-directed optimization evaluation in Section 7.5. The scalability evaluation in Section 7.6 and the evaluation of the diversification statistics in Section 7.7 were done on Ryzen 9 5900X.

Our prototype of HOBBIT is based on the LLVM/Clang version 17.0.3 (see Section 6), which we call **baseline** in the following evaluation. Since HOBBIT breaks the C++ ABI, we have to build and use a custom-built version of the LLVM C++ standard library `libc++` [29] (same as LLVM/Clang: 17.0.3). To improve comparability – although not strictly necessary – we build and use a custom-built `libc++` for the baseline as well.

7.2 Performance

As common in performance evaluations, we evaluate the performance of HOBBIT by building the SPEC CPU 2017 benchmark with our compiler modifications. In particular, since HOBBIT only applies changes to C++ programs, we run the four C++ benchmarks of the SPECSpeed™

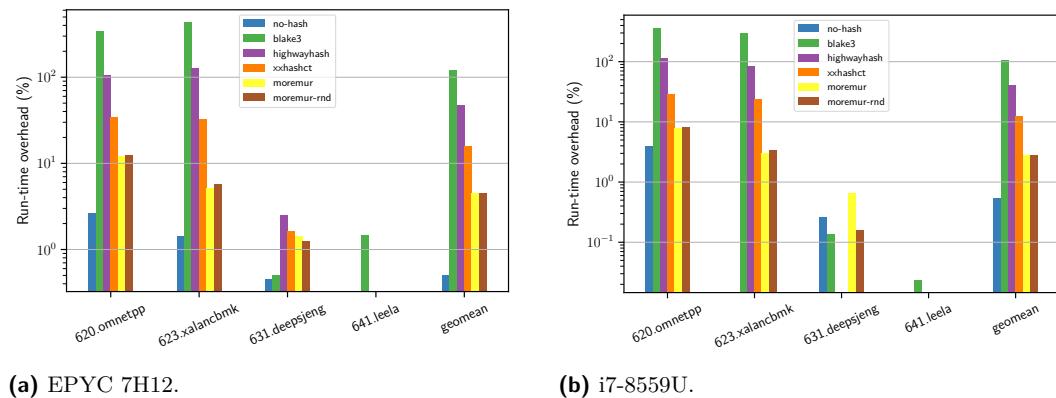

Figure 3 Run-time overhead introduced by HOBBIT for C++ benchmarks of the SPECspeed™ 2017 Integer test suite, relative to baseline on log-scale.

2017 Integer test suite, namely 620.omnetpp, 623.xalancbmk, 631.deepsjeng, and 641.leela. The remaining non-C++ benchmarks showed – as expected – no measurable overhead. As mentioned in Section 7.1, we use the custom-built libc++ instead of the bundled version of the Linux distribution. Each experiment compiles all relevant benchmarks and runs the compiled benchmark afterwards. We repeated each experiment 10× on EPYC 7H12 and 6× on i7-8559U and calculated the geometric mean over those repetitions.

Run-time, a key metric within SPEC, quantifies the time in seconds required for a benchmark to execute. Figure 3 shows the results for all evaluated MAC functions (see Table 1).

For the i7-8559U machine, the geometric mean overhead over all benchmarks, are 107.62% (**blake3**), 40.40% (**highwayhash**), 12.21% (**xxhashct**), 2.83% (**moremur**), and 2.80% (**moremur-random**). In comparison, on EPYC 7H12, the benchmarks show a higher performance impact over all benchmarks, namely 121.63% (**blake3**), 47.81% (**highwayhash**), 16.02% (**xxhashct**), 4.49% (**moremur**), and 4.54% (**moremur-random**). Both, 620.omnetpp and 623.xalancbmk, show the most performance impact on both machines. On i7-8559U, 620.omnetpp shows the highest run-time increase consistently for all benchmarked MAC functions. In contrast, on EPYC 7H12, we see a significantly higher run-time overhead on 623.xalancbmk for **blake3** and **highwayhash** compared to 620.omnetpp. The remaining hash functions (**xxhashct**, **moremur**, and **moremur-random**) on EPYC 7H12 show the same trend as on i7-8559U, namely, a higher performance overhead for 620.omnetpp rather than 623.xalancbmk.

We also evaluated a stripped down version that does not compute MAC tags to measure the minimum overhead (**no-hash** in Figure 3). On i7-8559U **no-hash** introduces a geometric mean overhead of 0.55%, with a maximum performance impact of 4.00% (620.omnetpp). In contrast to “correct” hash functions, the implementation of **no-hash** is 7.27% faster on EPYC 7H12 (overall 0.51%; 620.omnetpp 2.66%) when compared to i7-8559U.

7.3 Memory

Since HOBBIT extends object layouts, therefore, increases the size of objects, we are interested in the maximum **resident set size** (RSS). RSS is a metric indicating the memory usage of a process in RAM. Swapped memory does not count to RSS. By querying the **rusage** counters [43], our benchmarking environment measures the maximum RSS **maxrss**.

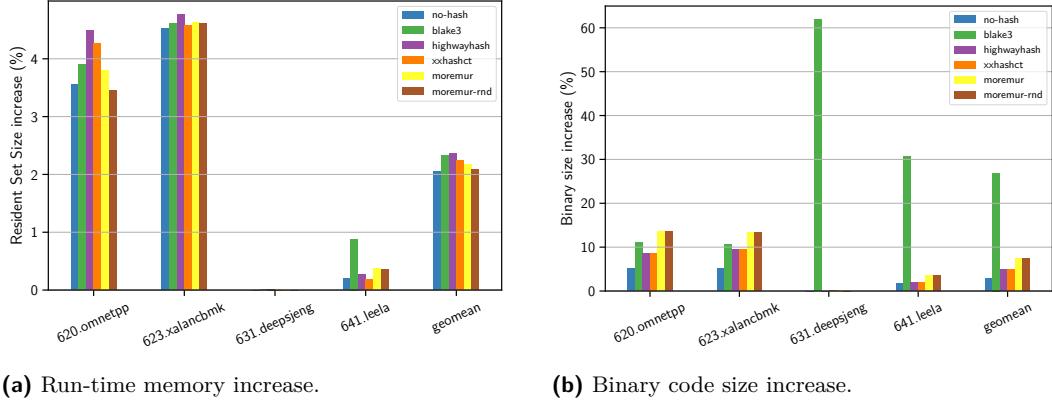

Figure 4 Memory effects of HOBBIT for C++ benchmarks of the SPECspeed™ 2017 Integer suite, relative to baseline (EPYC 7H12).

Table 3 Binary sizes of benchmarks and run-time libraries for both machines EPYC 7H12 and i7-8559U.

(a) Binary sizes of baseline benchmarks.

Name	Size in Bytes
620.omnetpp	2,915,320
623.xalancbmk	7,362,408
631.deepsjeng	118,120
641.leela	254,936

(b) Binary sizes of hashing run-time libraries.

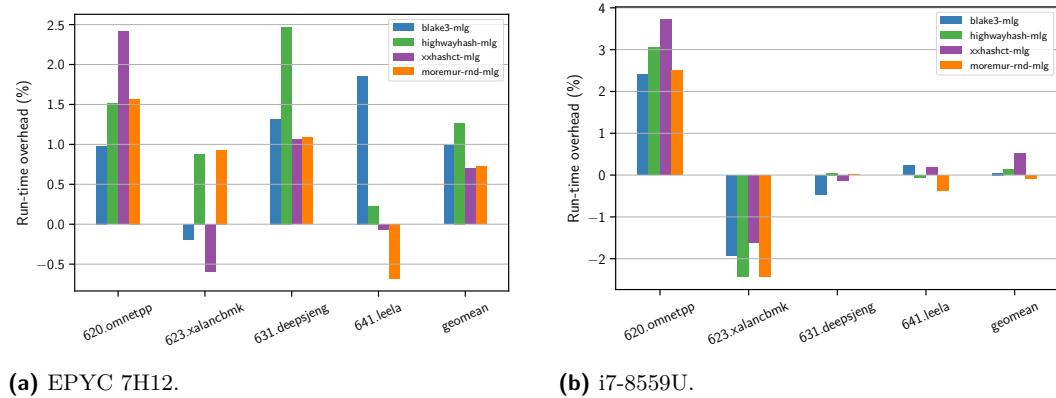

Name	Size in Bytes
blake3	90,618
highwayhash	15,816
xxhashct	1,874

Figure 4 shows the benchmarking results for machines EPYC 7H12 and i7-8559U. On both machines, our benchmarks show an overall geometric `maxrss` overhead of 2.2% and 2.18%, respectively. We see the highest `maxrss` overhead for 623.xalancbmk (EPYC 7H12 4.64%, i7-8559U 4.65%). 620.omnetpp has a similar `maxrss` overhead (EPYC 7H12 3.99%, i7-8559U 3.88%), whereas HOBBIT has a low `maxrss` impact on 641.leela (EPYC 7H12 0.41%, i7-8559U 0.32%). For 631.deepsjeng, our defense does not increase the `maxrss` on neither machine at all.

7.4 Code Size

HOBBIT inserts instructions for creating and validating MAC tags and, for some MAC functions, links run-time libraries and creates function calls to these libraries. These additional instructions (and libraries) increase the binary size of compiled programs. To that end, we evaluate the binary size of each benchmark. Table 3 shows the binary sizes of the baseline benchmarks (see Table 3a) and the run-time hashing libraries (see Table 3b).

The binary size increase on both machines is identical and shown in Figure 4b. HOBBIT, in its `blake3` variant, introduces the highest geometric mean increase in binary size of 26.90% over all benchmarks, ranging from 10.50% for 623.xalancbmk up to 61.87% for 631.deepsjeng. `Blake3` is a big hashing library (see Table 3b). Since HOBBIT links `blake3` statically to the compiled program, the big library size, compared to small benchmarks as in 631.deepsjeng and 641.leela, contributes to the significant increase in the resulting hardened binary. On the other hand, for `highwayhash`, nearly 8.5× bigger than `xxhashct`, accounts for roughly

(a) EPYC 7H12.

(b) i7-8559U.

Figure 5 Reduction of performance impact through gadget-directed optimization.

the same binary size increase as `xxhashct`. The reason for this similar increase in binary size – despite a different library size itself – results from a different linkage. `Highwayhash` is dynamically linked, whereas `blake3` and `xxhashct` are statically linked, therefore, embedded in the binary. HOBBIT variants that inline MAC functions in constructors and virtual functions, namely `mormeur` and `moremurm-random`, introduce the highest increase in binary size for 620.omnetpp (13.54%) and 623.xalancbmk (13.36%).

7.5 Gadget-Directed Optimization

We evaluated our naive implementation for the main-loop gadget analysis optimization (see Section 6.5), that only creates and validates MAC tags for classes having a standard C++ container field.

Although our gadget-directed optimization finds no main-loop gadgets for benchmarks 623.xalancbmk, 631.deepsjeng, and 641.leela, it finds 12 instances of classes having – directly or indirectly – at least one container-type field. HOBBIT inserts MAC tag integrity validation logic in 137 methods of these 12 classes.

Figure 5 shows the run-time overhead introduced by HOBBIT with gadget-directed optimization enabled.

7.6 Scalability

To evaluate the scalability of HOBBIT, we compiled WebKit, a web browser engine consisting of millions of lines of C and C++ code (see Table 5). Specifically, we built the GTK version of Webkit, `WebKitGTK` [53], a full-featured port of WebKit for GTK-based Linux desktop systems. Although HOBBIT breaks the C++ ABI through its object-layout extension, we only needed a single change to successfully compile WebKit, shown in Listing 6. Since `ScrollableArea` is a dynamic class, HOBBIT inserts a field for the MAC tag, thus we have to add 8 to this `static_assert` to account for the increased object size.

After the compilation, we evaluated the run-time overhead introduced by our defenses with the following browser benchmarks: (i) Kraken, (ii) MotionMark, (iii) Octane, and (iv) Speedometer.

As this evaluation requires a GUI, we performed the experiments on Ryzen 9 5900X. With only a terminal window opened, we started the `MiniBrowser`, a minimal browser based on `WebKitGTK`. After each benchmark execution, we closed the `MiniBrowser`, waited for ten

```

1  #if CPU(ADDRESS64)
2  -static_assert(sizeof(ScrollableArea) == sizeof(
3      SameSizeAsScrollableArea),
4      "ScrollableArea should stay small");
5  +static_assert(sizeof(ScrollableArea) == sizeof(
6      SameSizeAsScrollableArea) + 8,
7      "ScrollableArea should stay small");
8  #endif

```

■ Listing 6 Fix required to compile WebKitGTK.

■ Table 4 Performance impact on browser benchmarks.

Benchmark	blake3	highwayhash	xxhashct	moremurmur-random
Kraken 1.1 [27]	2.72%	0.70%	0.77%	-2.05%
MotionMark 1.3 [33]	14.64%	1.67%	1.87%	3.03%
Octane 2.0 [36]	53.54%	17.32%	2.83%	1.34%
Speedometer 2.1 [50]	161.74%	43.24%	7.85%	2.54%

seconds and repeated the experiment. In total, we executed each benchmark three times. Table 4 shows the geometric mean performance impact of our evaluation. Kraken measures the time needed to finish the benchmark, therefore, an induced overhead means an *increase* in run-time. In contrast, the other benchmarks measure *score points*, meaning that an induced overhead *decreases* the achieved score.

These real-world benchmark results confirm the results obtained from compute-intensive programs. HOBBIT allows balancing security and performance, and we did not notice perceptible delays in daily browsing activities.

To further show that HOBBIT scales to other real-world programs, we successfully compiled the following programs listed in Table 5. We included the version of the compiled programs as well as their C++ source lines of code (SLOC). The selected programs range from small web frameworks to fully fledged web browsers and compiler. For measuring SLOCs we used the tool `sloccount` [48].

■ Table 5 Source lines of code (SLOC) of real-world programs compiled with HOBBIT.

Program	Description	Version	SLOC (C++)
crow	C++ Web framework	1.2.0	25,203
json	JSON library for C++	3.11.3	102,977
llvm	Collection of compiler tools	17.0.6	2,201,374
webkitgtk	GTK port of WebKit	2.41.1	4,444,590
620.omnetpp	SPECspeed@2017 Integer suite	SPEC CPU 2017	63,100
623.xalancbmk	SPECspeed@2017 Integer suite	SPEC CPU 2017	243,046
631.deepsjeng	SPECspeed@2017 Integer suite	SPEC CPU 2017	7,284
641.leela	SPECspeed@2017 Integer suite	SPEC CPU 2017	30,473

 **Table 6** Top-5 and overall weakly connected component set size for libc++, C++ benchmarks of SPECspeed™ 2017 Integer, and WebKitGTK.

Top 5	libc++	omnetpp	xalanc	deepsjeng	leela	WebKitGTK
1.	78	193	442	78	78	3,916
2.	45	78	93	45	45	1,962
3.	27	52	78	27	27	1,541
4.	13	45	62	13	14	1,066
5.	12	34	49	12	13	427
Overall	197	379	539	197	252	30,438

7.7 Class-Hierarchy-Driven Seed Randomization

We evaluated the number of diversified random parameters for our implementation from Section 6.4. Table 6 shows the Top-5 weakly connected components, that constitute the diversification unit. Each of these units is a set of classes for whom we must choose the same random parameter. All C++ benchmarks of SPECspeed™ 2017 Integer and WebKitGTK depend on libc++ and, thus, include and extends libc++’s inheritance graph. 631.deepsjeng does not introduce any new dynamic classes to the inheritance graph, whereas WebKitGTK adds 30,241 new weakly connected components.

8 Discussion

We discuss and interpret the relevant findings of our evaluation.

8.1 Performance

Our performance evaluation shows that the performance impact depends primarily on the choice of the MAC algorithm. Although `blake3` offers the highest security, its performance impact, too, is the highest. To improve performance, HOBBIT offers two complementary options. First, users can opt to use simpler MAC algorithms, such as `moremur`, which is more performance friendly. Second, users can apply our gadget-directed optimization to reduce performance impact of even the most expensive MAC algorithms.

Since we did not find any impact on large, real-world software, such as the WebKit browser, we argue that HOBBIT can be used in a wide variety of contexts.

8.2 Security

We compiled the `CFIxx-Suite` [14] with our HOBBIT compiler. This exploit coverage test suite, created by Burow et al., demonstrates several scenarios for attacks on the dynamic dispatch mechanism [12]. Our security evaluation of HOBBIT is shown in Table 7. HOBBIT, in its initial version, only protects against scenarios 3–5 (namely `VTxchg`, `VTxchg-hier`, `COOP`), but fails to detect scenarios 1–2 (namely `FakeVT`, `FakeVT-sig`).

The initial HOBBIT implementation prevents malicious execution of virtual function bodies by validating the integrity of `vptrs` in the function prologue. Since scenarios 1–2 insert fake `vtables` that contain pointers to non-virtual functions, therefore unprotected by our defense, our prototype implementation does not prevent this form of attacks.

Table 7 Results of testing different `vtable` related attack building blocks against LLVM, LLVM CFI, and different configurations of HOBBIT.

Exploit	LLVM	LLVM-CFI	Hobbit	Hobbit+LLVM-CFI	Hobbit-VFCS
FakeVT	✗	✓	✗	✓	✓
FakeVT-sig	✗	✓	✗	✓	✓
VTxchg	✗	✓	✓	✓	✓
VTxchg-hier	✗	✗	✓	✓	✓
COOP	✗	✗	✓	✓	✓

However, HOBBIT is compatible and composable with other defenses such as LLVM CFI [30]. We compiled the exploit coverage test suite with HOBBIT again, this time with `vcall sanitizer` enabled. To enable LLVM CFI, we provided the following compiler flags:

```
-fsanitize=cfi-vcall -fno-sanitize-recover=vcall -fno-sanitize=vptr
```

LLVM CFI succeeds in defending against fake `vtable` attacks and limits successful virtual calls to valid subtypes of the dispatched object’s static type. Still, LLVM CFI fails to prevent an attacker from maliciously changing `vptrs` adhering to the type hierarchy or inserting fake objects without calling the appropriate constructor – the core principle of COOP. Combining HOBBIT with LLVM CFI protects against all five exploit types evaluated in the exploit coverage test suite.

To account for situations where CFI cannot be used, we implemented an extension of HOBBIT, namely HOBBIT-VFCS. This HOBBIT extension moves validation code from the function prologue of virtual functions to their call sites. HOBBIT-VFCS validates `vptrs` *after* loading the `vptr` (Figure 2 ③), but *before* invoking the method call (Figure 2 ④). Emitting validation checks at each call site increases the binary size, but mitigates all five exploits. In future work, we can apply the same principle – checking the validity of `vptrs` immediately after loading – to protect other `vtable` related mechanisms, such as dynamic casts, too.

8.2.1 Balancing Performance and Security

HOBBIT has, essentially, two orthogonal compile-time parameters: (i) hash function algorithm selection, and (ii) validation code granularity. By selecting a strong hash function, such as `blake3`, the overall security improves at the cost of performance. Conversely, selecting a more efficient hash function, such as `moremurmur`, decreases security and increases performance.

To offset the performance penalties, HOBBIT offers users to parameterize the granularity of validation code insertion. Either all virtual functions or only COOP-relevant call sites are protected. By protecting all call sites, HOBBIT achieves the highest security at the potentially highest performance impact (i.e., by selecting an “expensive” hash function). Conversely, by selecting only the COOP-relevant call sites, HOBBIT reduces performance impact to a negligible level.

Although four different levels can be specified, we recommend the following settings in practice. A strong hash function, such as `blake3`, should be combined with COOP-relevant gadget granularity. A weak hash function, such as `moremurmur`, can be used to protect all virtual functions.

8.2.2 Uniformly Distributed Vtables

A method to perform cryptanalysis is to correlate input with output characteristics. Known-plaintext attacks are a form where the attacker knows the plaintext and infers a model from the outputs. In our model both inputs and outputs are either known or can be read directly through a memory-read primitive. The MAC algorithm used is hidden away effectively through execute-only memory. Yet, some of the input characteristics may allow attackers to launch a known-plaintext attack.

Consider, for example, that the attacker knows the addresses of `vtables` v_1 , v_2 , and v_3 . Let's assume that although the addresses of these `vtables` v_i are different, their distances may remain constant. An adversary could, therefore, rely on such constant inter-table differences to infer properties about the concrete hash MAC algorithm used by HOBBIT.

Although our present implementation does *not* address this issue, we can achieve uniform distribution of inter-table differences by way of randomizing the order of emitting `vtables`. If this randomization proves to be insufficient, padding entries can be added in between emitted `vtables` to increase the entropy of `vtable` addresses.

9 Conclusions

HOBBIT presents an integrity-protection mechanism to thwart counterfeit-object-oriented programming attacks. At its core, this attack shares a symmetry to classical buffer overflows, in the sense that the underlying problem is the mixing of control with non-control data. For buffer overflows, this mix consists of keeping return addresses among stack frame data. For COOP attacks, this mix consists of keeping the `vptr` among object field data. By injecting malicious objects, the adversary can thus hijack control-flow and initiate illegitimate method calls.

To stop this type of whole-function code-reuse attack, HOBBIT changes the object layout to embed a tag value. This tag is computed by MAC functions that encode `vptr` information, `vptr` location, and a random secret. By leveraging execute-only memory, HOBBIT provides additional security. Due to complementary optimizations, users gain the ability to balance performance and security.

A comprehensive analysis provides evidence of both (i) configurable performance impact between 121.63% and 2.80% and (ii) scalability to multi-million lines of C and C++ code. At the same time, HOBBIT does not depend on MPX and does not inhibit performance by reserving registers. Without any hardware requirements, HOBBIT is applicable to embedded- and IOT devices.

Abstract

Kotlin language has recently become prominent for developing both Android and server-side applications. These programs are typically designed to be fast and responsive, with asynchrony and concurrency at their core. To enable developers to write asynchronous and concurrent code safely and concisely, Kotlin provides built-in *coroutines* support. However, developers unfamiliar with the coroutines concept may write programs with subtle concurrency bugs and face unexpected program behaviors. Besides the traditional concurrency bug patterns, such as data races and deadlocks, these bugs may exhibit patterns related to the coroutine semantics. Understanding these coroutine-specific bug patterns in real-world Kotlin applications is essential in avoiding common mistakes and writing correct programs.

In this paper, we present the first study of real-world concurrency bugs related to Kotlin coroutines. We examined 55 concurrency bug cases selected from 7 popular open-source repositories that use Kotlin coroutines, including IntelliJ IDEA, Firefox, and Ktor, and analyzed their bug characteristics and root causes. We identified common bug patterns related to asynchrony and Kotlin's coroutine semantics, presenting them with their root causes, misconceptions that led to the bugs, and strategies for their automated detection. Overall, this study provides insight into programming with Kotlin coroutines concurrency and its pitfalls, aiming to shed light on common bug patterns and foster further research and development of concurrency analysis tools for Kotlin programs.

1 Introduction

Kotlin is a cutting-edge programming language that has recently become a primary language for Android development. Its modern syntax, seamless interoperability with Java, and enhanced features have positioned Kotlin as the preferred language for creating mobile and server-side applications for many developers. A standout feature amongst Kotlin's diverse functionalities is the built-in *coroutines* [14] support, which significantly simplifies asynchronous programming. Coroutines offers developers a streamlined approach to handling background tasks, thus enabling more intuitive and readable code.

Kotlin coroutines enables writing asynchronous code in a sequential style, thus avoiding the complexity of multithreaded programs. One may think of coroutines as lightweight threads. Following the notion of coroutines in the literature [12], Kotlin coroutines can

suspend and resume their execution, and they do that through the *suspending* functions. Suspending functions (marked with the `suspend` keyword in Kotlin) are similar to *async* functions in other asynchronous languages and frameworks [37, 33], which encapsulate asynchronous computations but look like synchronous code, and calling them looks similar to calling regular functions. A suspending function indicates that it can be suspended in the middle of computation and resumed later. By suspending and resuming at predefined points, they yield computing resources to other coroutines and coordinate their execution. For example, when a suspending function encounters a long-running task and suspends, the underlying thread does not block but takes another coroutine to execute.

While coroutines simplify writing asynchronous programs and increase performance by asynchronously running long-running tasks, asynchronous programming comes with additional challenges. Besides the inherent concurrency non-determinism of multithreading, which causes traditional classes of concurrency bugs (such as data races, deadlocks, order violations, and atomicity violations), utilizing coroutine requires developers to reason about the asynchronous interactions between the concurrent components due to coroutine semantics, synchronous/asynchronous execution contexts, suspension and resumption of coroutines. Developers unfamiliar with the Kotlin coroutine semantics can use coroutines and suspending functions improperly, resulting in subtle concurrency bugs.

Kotlin is a relatively new language, so we know little about common misconceptions and bug patterns in programs with Kotlin coroutines. This work aims to shed light on them.

Our contribution. In this study, we explored real-world concurrency bugs in programs that use Kotlin coroutines. We collected concurrency bugs from popular open-source code repositories and identified common patterns in these bugs, their root causes, and misconceptions that might cause them. The results are available in the following GitHub repository [6].

Our analysis shows that some concurrency bugs are related to *bridging synchronous and asynchronous executions*. While asynchronous functions can only be called on a coroutine and the syntax of suspendable functions helps *function coloring* by marking asynchronous functions, composing synchronous parts of the program with asynchronous functions remains a challenge to programmers inexperienced in asynchronous programming. As a quick remedy for calling asynchronous functions from synchronous functions, they may call these functions in blocking coroutines, which in turn may affect the program's performance or even introduce deadlocks in case of *nested blocking calls*. On the other hand, when calling synchronous functions from asynchronous functions, they should be aware that the called function may run in an asynchronous context. Calling asynchronous functions from such functions can demand manual bookkeeping of coroutine scopes or omitting one of Kotlin's core concurrency principles: structured concurrency [34, 9]. In addition to *nested blocking calls*, we identified classes of bug patterns where the developers may violate structured concurrency by improper *scope passing*, *querying asynchronous objects*, *synchronization with asynchronous objects*, and improper *coroutine exception handling*.

In summary, our work makes the following contributions:

- We present the first (to the best of our knowledge) comprehensive study of real-world concurrency bugs in programs that use Kotlin coroutines, examining 55 concurrency bugs selected from 7 popular open-source repositories that use Kotlin coroutines.
- We identify common bug patterns related to Kotlin coroutines, presenting real-world examples and possible corrections for each, providing root causes and misconceptions that lead to these bugs, and discussing strategies for their automated detection.

Moreover, we communicated our findings to Kotlin developers. Our initial discussions show that our findings align with some of their observations, e.g. [29, 27]. We are in contact with them to develop inspection tools for identified bug patterns and have already contributed to IntelliJ IDEA with an inspection that detects one of the identified bug patterns [7].

Impact. We envision our findings contributing to developing reliable Kotlin programs targeting multiple audiences. They can help (i) Kotlin programmers better understand concurrency bugs and write correct programs, (ii) increase the awareness of programmers using Kotlin libraries about the potential asynchrony in the functions they use, (iii) provide insights to the Kotlin language team about possible misconceptions of programmers and (iv) researchers develop suitable concurrency analysis and testing tools for Kotlin programs.

2 Background on Kotlin Coroutines

Essentially, coroutines are lightweight threads that are relatively cheap to suspend and resume. They also support efficient cancellation, which, in sum, makes them very powerful for asynchronous programming. This section briefly introduces coroutines in Kotlin, discussing important differences compared to traditional threads and the features necessary to understand the bug patterns we present in our study.

Launching a coroutine. A coroutine is a computation unit not bound to any particular thread. Instead, coroutines run on threads and reuse them. When a coroutine gets suspended (pauses in the middle of computation), the underlying thread does not park but takes another coroutine and executes it, utilizing resources more efficiently. In this essence, coroutines can be considered a framework for managing expensive threads.

When launching a new coroutine, we can specify a coroutine dispatcher, which determines how to schedule the coroutine. The default dispatcher (`Dispatchers.Default`) is essentially a thread pool, where the number of threads is bound to the number of CPUs. It is also possible to launch coroutines on the `Main` dispatcher, ensuring that they are executed on the Main (UI) thread, or the `IO` dispatcher when the code does not compute something but blocks the running thread with an I/O operation.

Listing 1 shows an example with one coroutine launching another and printing “Hello”, and the second suspending for one second and printing “World!”. The `main()` function starts with a `runBlocking` call, which bridges the non-coroutine and coroutine worlds, blocking the current thread for the duration of the coroutine it runs. The `launch` call starts a new coroutine concurrently with the rest of the code on `Dispatchers.Default` coroutine dispatcher, which means this coroutine will run on a shared pool of threads. The `delay` call in the launched coroutine suspends it for one second. As result, this code prints “Hello” followed by “World!”.

Listing 1 Launching a new coroutine in Kotlin.

```

1 fun main() = runBlocking { // launches a coroutine on this thread
2     launch(Dispatchers.Default) { // launch a new coroutine
3         printWorldWithDelay()
4     }
5     println("Hello")
6 }
7

```

```

8 suspend fun printWorldWithDelay() {
9     delay(1000L) // non-blocking delay for 1 second
10    println("World!")
11 }

```

Suspending functions. To utilize coroutines, Kotlin provides the *suspending function* concept. Suspending functions, marked with `suspend` modifier, can be paused and resumed later without blocking the underlying thread. In Listing 1, `printWorldWithDelay()` and `delay(..)` are suspending functions, which might pause (in this case, the underlying thread switches to executing another coroutine). A suspending function can only be called from another suspending function, providing a structured way to write asynchronous and non-blocking code.

To summarize, the `suspend` keyword in Kotlin is used to mark a function that can be asynchronously completed – it can suspend its execution at some point, being resumed where it left off later, without blocking the underlying execution thread.

Structured concurrency. Coroutines follow a principle of structured concurrency, which means that new coroutines can only be launched in a specific scope, delimiting the lifetime of the coroutine. Structured concurrency ensures that they are not lost and do not leak. An outer scope cannot be completed until all its children's coroutines are complete, while cancellation of one of the coroutines in a scope instantly aborts the others within the scope.

In Listing 1, `runBlocking` launches a new coroutine and establishes a coroutine scope (accessible by `this` in the code block), so any coroutine launched within this block will cause this `runBlocking` call to wait until the launched coroutine finishes. This is why the `runBlocking` call does not complete until the second coroutine that prints “World!” finishes.

One may also specify a custom `CoroutineScope` to ensure that launched coroutines do not get lost and do not leak. Specifically, the scope finishes when all the coroutines launched within it are completed, while canceling the scope results in the cancellation of all the coroutines within it. Listing 2 contains the `printHelloWorld()` suspending function that, similarly to the code in Listing 1, launches a new coroutine and prints “Hello”, while the launched coroutine suspends for one second and prints “World!”. The coroutine scope here ensures that `printHelloWorld()` finishes only when the launched coroutine finishes. At the same time, in case the launched coroutine gets canceled, the whole scope gets canceled, resulting in `printHelloWorld()` cancellation.

■ Listing 2 Creating a custom `CoroutineScope` in Kotlin.

```

1 suspend fun printHelloWorld() = coroutineScope {
2     launch {
3         delay(1000L)
4         println("World!")
5     }
6     println("Hello")
7 }

```

Cancellation. Kotlin coroutines provide a built-in cancellation mechanism, which is especially useful for long-running applications. For example, a user might have closed the page that launched a coroutine, so its result is no longer needed, and the coroutine can be canceled. If a coroutine gets canceled while suspending, the respective `suspend` function throws `CancellationException` – the user code must not catch and always propagate it.

■ Listing 3 Coroutine communication via channel.

```

1 fun main() = runBlocking {
2     val channel = Channel<Int>(capacity = 1)
3     launch {
4         for (x in 1..5) channel.send(x * x) // sends to channel
5     }
6     repeat(5) {
7         println(channel.receive()) // receives from channel
8     }
9 }
```

With structured concurrency, when a coroutine is canceled, all the coroutines operating within the scope get canceled, too, thus ensuring that all the related computations are safely canceled and do not leak.

Channels. When programming with coroutines, developers typically use channels for implicit synchronization and communication instead of manipulating shared memory. A channel is a blocking queue of bounded capacity with `receive` operation suspending if the channel is empty and `send` suspending when the channel is full. Listing 3 illustrates an inter-coroutine communication via channel. One coroutine sends square numbers to the channel, and the main coroutine reads these numbers from the same channel and prints them.

Coroutines and threads. Coroutines do not introduce a new concurrency model but enable cooperative concurrency and efficient and safe thread management, with the structured concurrency feature and explicit communication primitives in particular. However, one may still program with coroutines in a way similar to programming with threads, sharing a mutable state (e.g., a concurrent cache) and using the same synchronization primitives (e.g., mutex).

Discussion. Programming with coroutines varies significantly from traditional thread-based programming. These differences might give rise to unique bugs distinct from those typically encountered when manipulating threads and shared memory. This work sheds light on popular concurrency bug patterns discovered in real-world applications with Kotlin coroutines.

3 Bug Study Methodology

Our bug study targets seven open-source repositories listed in Table 1 together with the numbers of Kotlin code lines, commits, and GitHub stars. The repositories are selected based on three criteria: (i) the repository mainly contains Kotlin code, (ii) the project depends on the Kotlin coroutines library, and (iii) the repository has a high number of commits, indicating its active development and high number of stars indicating its popularity and the interest of the community.

As Kotlin is the primary language for Android development, we started with identifying top-starred Android projects on GitHub and eliminated the projects that have less than 1,000 commits and lack descriptive commit messages. As a result, we obtained two repositories: the `Shadowsocks` proxy client [31] and the `Tachiyomi` comic reader [35]. Next, we determined the Android repositories with the highest commit count. After elimination, the

 **Table 1** The selected GitHub repositories for the bug analysis.

Repository	Commits	Stars	Kotlin LOC	Total LOC
JetBrains/intellij-community	427.4 K	16.1 K	1 603.4 K	9 805.0 K

jshaw29/tachiyomi-backup ¹	6.2 K	25.8 K	66.1 K	114.1 K
ktorio/ktor	5.1 K	11.8 K	152.5 K	152.6 K
shadowsocks/shadowsocks-android	3.6 K	34.3 K	7.8 K	12.2 K

following three were selected: the `WordPress` website builder [3], the `WooCommerce` webshop manager [2], and the `Firefox` web browser [25]. Additionally, we selected the `Ktor` [18] framework for building asynchronous server-side and client-side applications and `IntelliJ IDEA` Community Edition [17], both developed by JetBrains – the main maintainers of Kotlin coroutines.

To collect concurrency bugs related to Kotlin coroutines, we analyzed all commits in the selected repositories. Specifically, (1) we filtered the commits based on whether the commit messages contained specific concurrency-related keywords, and (2) manually reviewed the sifted commits. Finally, (3) we categorized the identified bugs by the root causes of the errors.

Filtering the commits based on the commit messages. Following prior research on concurrency bug studies [38, 40, 23], we selected the commits that include at least one of the following keywords: `race`, `deadlock`, `synchronization`, `concurrency`, `lock`, `mutex`, `atomic`, `compete`, or `semaphore`. With our work focusing on Kotlin coroutines, we expanded the filter with the coroutine-related keywords: `runBlocking`, `Dispatcher`, `CoroutineScope`, `cancel`, and `CancellationException`. For the feasibility of the manual analysis, we limited the number of selected commits associated with each keyword to the most recent 30 commits.

Manual analysis of the selected commits. After filtering the commits in the repositories, we had 1353 commits to analyze. We manually reviewed them, examining their commit messages and code changes. We selected the commits that fixed a concurrency bug involving Kotlin coroutine primitives, with the change being comprehensible without in-depth knowledge of the codebase. Thus, we also filtered out the classic concurrent bugs unrelated to coroutines. We ended up with 55 bugs that involve Kotlin coroutine constructs.

Manual analysis and categorization of the bugs. Finally, we categorized the filtered 55 bugs by their root causes, analyzing the programming patterns that led to the errors. The source code links to the studied bugs are available in our GitHub repository [6].

Classic concurrency bugs. As the goal of this work is to analyze concurrency bugs that are related to Kotlin coroutines, the study does not cover traditional multithreaded concurrency bug patterns [23] such as data races, order violations, or atomicity violations. Rather, we focus on the bug patterns related to and introduced by using Kotlin coroutines constructs.

¹ The Tachiyomi repository has been taken down since January 2024: <https://tachiyomi.org/news/2024-01-13-goodbye>, so we reference a backup repository instead.

Table 2 Collected bugs and their categorization into bug patterns of nested `runBlocking`, scope passing, querying asynchronous objects, synchronizing with cancellation, and `CancellationException` bugs. All observed bugs that did not fall into one of these categories are listed under “Uncategorized”.

Repository	Nested <code>runBlocking</code>	Scope Passing	Querying Async	Sync Cancel	Cancellation Exception	Uncategorized
IntelliJ	6	0	1	1	10	5
Firefox	2	2	2	2	0	4
Tachiyomi	2	0	0	0	3	1
Ktor	0	0	1	0	0	3
Shadowsocks	0	0	1	0	1	1
Wordpress	1	0	0	0	0	0
Woocommerce	0	2	0	1	0	3
Total	11	4	5	4	14	17

4 Categorization of Bugs

In this section, we analyze the bug patterns and root causes of the concurrency bugs and categorize them based on their characteristics. We discuss possible developer misunderstandings that lead to these mistakes, offer insight into possible remedial steps to rectify these errors and suggest methods for their automatic detection.

Table 2 lists the number of bugs in the repositories that fall into each of the bug categories. Based on our analysis of the Kotlin-specific concurrency primitives that are commonly involved in bugs and their root causes, we categorized the concurrency bugs in Kotlin programs into the classes of bugs due to (1) nested `runBlocking` calls (Section 4.1), (2) coroutine scope passing (Section 4.2), (3) querying asynchronous objects (Section 4.3), and (4) synchronizing with cancellation (Section 4.4). A special class of bugs occurs when a `CancellationException` is accidentally caught or incorrectly rethrown (Section 4.5). While it is not strictly a concurrency bug, it is caused by the Kotlin coroutines machinery, so we included it in our analysis.

Lastly, not all bugs found in the collection phase can be categorized into one of the categories. These bugs are displayed in Table 2 in the “Uncategorized” column. We omit these bugs in our analysis.

4.1 Calling `runBlocking` in a Coroutine

A common concurrency bug in Kotlin manifests when `runBlocking` coroutine builder is called from a coroutine and blocks the underlying coroutine dispatcher thread. Such a pattern can lead to a deadlock. We observed 11 bugs caused by this.

Root cause. The root cause of this bug is an improper use of the `runBlocking` coroutine builder designed to bridge non-coroutine and coroutine worlds and not expected to be called from another coroutine. Such an improper use can block the underlying scheduler thread, which might lead to a deadlock. Figure 1 and Listing 4 provide program examples with this bug pattern.

Figure 1 provides the code and the deadlock illustration. The program launches Coroutine *A* on the `Dispatcher.Main` dispatcher (line 2), dispatching the coroutine onto the UI thread. Then, coroutine *A* calls `nonSuspendingFunction()`. In turn, this function calls

`runBlocking` (line 8) which launches a coroutine *B* scheduled on `Dispatcher.Main` (line 9). The `runBlocking` builder blocks the UI thread and, due to structured concurrency, waits for coroutine *B* to finish. However, coroutine *B* cannot be dispatched until the UI thread is free. In other words, coroutine *A* blocks the thread that needs to execute coroutine *B*, while coroutine *A* also waits for coroutine *B* completion, which results in a deadlock.

The same deadlock might also occur in a multi-thread scenario. Listing 4 provides such an example, using the `Default` multi-threaded dispatcher to schedule coroutines. Similarly to the code in Figure 1, the program gets into a deadlock when all threads are executing the coroutines launched in `main()`, schedule new coroutines in `nonSuspendingFunction()` calls. However, these new coroutines cannot be executed – all the scheduler threads are occupied with the coroutines launched in `main()` and wait for the completion of these coroutines launched in `nonSuspendingFunction()`.

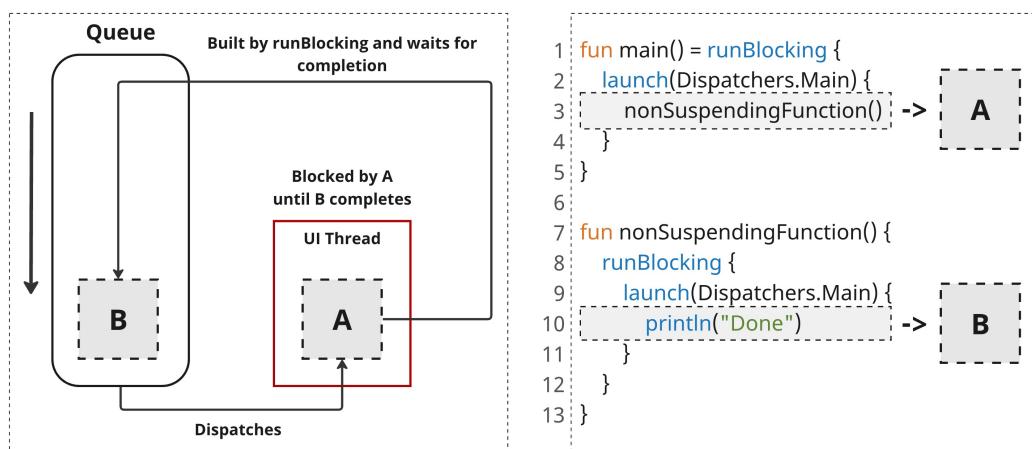

Figure 1 A program with a deadlock due to a `runBlocking` call from a coroutine on a single-threaded dispatcher.

Misconceptions. A common misconception is that the `runBlocking` builder can safely be used in non-suspending functions. However, a non-suspending function can be called from an asynchronous context; there is no guarantee that it runs outside a coroutine. Even if developers know they are working inside a coroutine, they might be unaware that the function they call contains a `runBlocking` builder. It is not always trivial to determine whether a piece of code runs inside a coroutine or whether a function call reaches a `runBlocking`, especially when the call stack is large.

When developers need to call a suspending function from a non-suspending function, they tend to call `runBlocking`, especially when the developer is unaware that this synchronous function actually runs in a coroutine. The right course of action, however, is not always clear and requires careful consideration by the developer. In the example program, turning `nonSuspendingFunction` into a `suspendingFunction` by adding the `suspend` keyword does the trick, as given as a potential solution in Listing 5. By turning the function into a suspend function, the developer can call `coroutineScope`, which allows for a normal `launch`. Note that this requires all functions calling `suspendingFunction` also to be suspending. In other cases, one might prefer to acquire a coroutine scope created elsewhere. This scope, however, comes with its own set of challenges, which we explain in Section 4.2.

Listing 4 A program with a deadlock due to a `runBlocking` call from a coroutine on a multithreaded dispatcher.

```

1 fun main() = runBlocking {
2     for(i in 1..1000) { // 1000 > max number of scheduler threads
3         launch(Dispatchers.Default) {
4             nonSuspendingFunction()
5         }
6     }
7 }
8
9 fun nonSuspendingFunction() {
10    runBlocking {
11        launch (Dispatchers.Default) {
12            println("Done")
13        }
14    }
15 }
```

Listing 5 A potential solution to the bug with nested `runBlocking` calls.

```

1 fun main() = runBlocking {
2     launch(Dispatchers.Main) { // launch coroutine A
3         suspendingFunction() // safe to call
4     }
5 }
6
7 suspend fun suspendingFunction() {
8     coroutineScope { // suspends execution until coroutine B is done
9         launch(Dispatchers.Main) { // launch coroutine B
10            println("Done")
11        }
12    }
13 }
```

Ultimately, both `runBlocking` and `coroutineScope` will pause the execution of the function calling it. The difference is that `runBlocking` does this by blocking the underlying thread and `coroutineScope` by suspending the coroutine, which releases the thread in the meantime.

A situation where it is nontrivial to identify parts of the codebase that run in coroutines and they may introduce unintended nested `runBlocking` calls might occur when the codebase is gradually migrated to use coroutines [10].

Possible automated detection. A static analysis can inspect the program's call graph and detect situations when `runBlocking` is called from a `suspend` function. This analysis could also be implemented as an IDE inspection, and we have successfully added one into IntelliJ IDEA [7].

4.2 Scope Passing

Scope passing is a coding pattern in which a function launches a coroutine in a coroutine scope created outside the function. This situation can lead to an unexpected execution order of program statements, which may violate their intended order. While passing the coroutine scope is not incorrect and sometimes might be necessary, it makes it difficult to reason about the execution order.

Root cause. The root cause is the nondeterminism in the completion time of the coroutines launched on an external scope. Listing 6 provides a program example for the bug pattern. Consider the function `loadTopPerformers` (line 4), which is responsible for loading some data and storing it in the `lastUpdateTopPerformers` variable (line 2). The developer expects the data to be available in the `lastUpdateTopPerformers` variable once the `loadTopPerformers` function returns. However, this is not necessarily the case: the coroutine scope used to launch the coroutine on line 5 is not bound by the function `loadTopPerformers`; it is inherited from the `DashboardViewModel` class.

As illustrated in Figure 2, the `this` object in the `loadTopPerformers` function refers to class `DashboardViewModel`, which extends `CoroutineScope`. This results in the coroutine unexpectedly outliving the function it was created in.

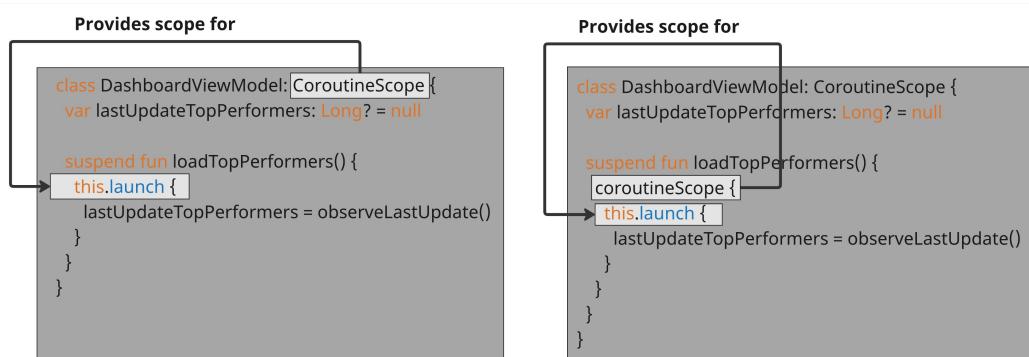

Figure 2 Visual clarification of coroutine scope origin and usage for Listing 6. Left shows the situation where the spawned coroutine can outlive the function it was created in. Right shows how this can be solved by creating a scope in the same function.

The problem can be fixed by ensuring that `loadTopPerformers` returns after the `lastUpdateTopPerformers` variable is set. As given in Listing 7, the example bug can be fixed by starting a `coroutineScope` call wrapping the function body (line 5). Then, the scope

Listing 6 An example scope passing bug, which is a simplified version of the bug in [32].

```

1 class DashboardViewModel: CoroutineScope {
2     var lastUpdateTopPerformers: Long? = null
3
4     suspend fun loadTopPerformers() {
5         launch {
6             lastUpdateTopPerformers = observeLastUpdate()
7         }
8     }
9 }

```

■ **Listing 7** A potential solution to example scope passing bug in Listing 6.

```

1 class DashboardViewModel: CoroutineScope {
2     var lastUpdateTopPerformers: Long? = null
3
4     suspend fun loadTopPerformers() {
5         coroutineScope {
6             launch {
7                 lastUpdateTopPerformers = observeLastUpdate()
8             }
9         }
10    }
11 }
```

■ **Listing 8** An example for a scope passing bug, which is a simplified version of the bug in [28].

```

1 class ProductShippingClassViewModel(): CoroutineScope {
2     private var loadJob: Job? = null
3
4     fun load() {
5         waitForCurrentLoadJob()
6         loadJob = launch { /* loading logic */ }
7     }
8
9     fun waitForCurrentLoadJob() {
10        launch { // launch since join cannot be called from normal fun
11            loadJob?.join() // join suspends until load job is done
12        }
13    }
14 }
```

suspends the function `loadTopPerformersStats` until all its children are completed. Note that this solution would not have been an option if `loadTopPerformers` was a non-suspending function since the `coroutineScope` can only be called from a suspending function.

Another example of a coroutine unexpectedly outliving its calling function due to launching on an external scope is provided in Listing 8. The function `load` starts an expensive load operation by spawning a coroutine (line 6). To ensure this operation only runs once at a time, the developer keeps a reference to its `Job` (line 2). Next, he creates a function `waitForCurrentLoadJob` that performs a `join` operation. Then, at line 5, this waiting function is called before the expensive load operation is started. However, since `waitForCurrentLoadJob` is a normal function, it cannot call the suspending `join` method. In order to access this `join` operation, a coroutine is launched (line 10). However, this coroutine is launched on a scope that is defined outside the `waitForCurrentJob` function. The wait function will, therefore, return immediately, allowing a new load job to be started before the old one is completed.

Misconceptions. A developer might expect a function that launches a coroutine to wait for the coroutine to finish since that is often the case due to structured concurrency. This, however, only holds when the coroutine scope is created in that same function. In the example of Listing 6, the `loadTopPerformersStats` sits in between scope creation and

coroutine launch. Listing 8 shows that a normal function `waitForCurrentLoadJob` calls a `join` operation by spawning a coroutine. As discussed in Section 4.1, a problem arises when a suspend function needs to be called from a non-suspending function that runs in a coroutine. The developer needs to choose between calling `runBlocking`, passing scope, or refactoring all depending code to suspend functions.

Automated detection. Detecting this bug pattern is challenging since there can be valid reasons for passing the scope. However, the problem is that the developer might be unaware that, in some cases, a launched coroutine outlives the function that launched it. A simple analysis can be made that checks whether the scope used to launch a coroutine is created in the same function or not. A simple and non-intrusive visual indication might aid the developer in understanding the lifetime and scope of the launched coroutine.

4.3 Querying Asynchronous Objects

A race condition that commonly occurs with many languages is the result of querying the state of an object in shared memory and, based on that, deciding how to act on it. Listing 9 provides such an example where the developer checks if the channel is closed and sends a message if it is not closed.

Root cause. The root cause for this bug is simple and similar to race conditions in classical multithreaded programs. When an object is shared among threads, its state might change between checking its state and acting on it depending on the accesses to the object. In the example of Figure 9, the channel can be closed between the check `isClosedForSend` (line 1) and sending the message (line 2). A visual representation of this particular example is provided in Figure 3.

Misconceptions. The misconception is that the state of such an object will not change between the query and the action, disregarding the possibility of interleavings from other threads. The fix for the bug is to avoid sending if the channel is closed. As locking is undesired in Kotlin coroutines, the bug fix does not introduce explicit synchronization but wraps the `send` call in a `try/catch` block. A call on a closed channel should throw a `ClosedSendChannelException`, which allows the developer to handle it gracefully.

Automated detection. As the bug occurs in the case of a race condition on the channels, detecting this pattern can benefit from existing data race detectors.

4.4 Synchronizing with Cancellation

Synchronization with Cancellation is an attempt to ensure that a certain coroutine only runs once at a time by canceling the previous coroutine before the next is launched.

Root cause. The `cancel` method of a coroutine returns before the coroutine actually cancels or stops. In other words, `cancel` cannot be used to synchronize executions. In the example of Listing 11 there is a coroutine launched on line 7. The desired behavior is that this coroutine runs only once at a time. Otherwise, there exists a possible data race between the `read` (line 8) and `write` (line 11) actions. The `refresh` function (line 3) might be called again before the coroutine on line 7 is finished. To prevent a second coroutine from running in parallel, the developer keeps a reference to the `Job` of that coroutine and cancels it before a new

Listing 9 Race condition on channel status, taken from the bug fix in [24].

```
1 if (!channel.isClosedForSend) {
2     channel.send(message)
3 }
```

Listing 10 Potential solution to Listing 9.

```
1 try {
2     channel.send(message)
3 } catch (e: ClosedSendChannelException) {
4     // handle closed channel if needed
5 }
```

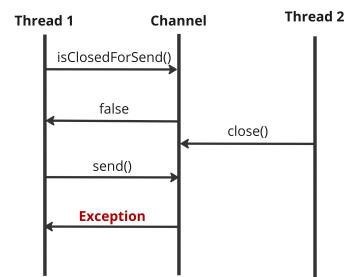

Figure 3 Visual representation of the execution order that could lead to a send operation over an unexpected closed channel.

Listing 11 Missed synchronization with `Job.cancel`, a simplified version of the bug in [5].

```
1 var pendingJob: Job? = null
2
3 suspend fun refresh() {
4     pendingJob?.cancel() // does not wait for the coroutine to stop
5     coroutineScope {
6
7         pendingJob = launch(Dispatchers.IO) {
8             val result = read(someVar)
9
10            launch(Dispatchers.Main) {
11                write(someVar, result)
12            }
13        }
14    }
15 }
```

coroutine is started. This should ensure that the coroutine only runs once at a time. However, cancellation does not guarantee that execution will stop immediately, and the `cancel()` call does return immediately. Therefore, this coroutine can exist in parallel. Primitives that allow for synchronization are mutexes, joins, and channels. In this case, a potential solution is provided in Listing 12, a mutex that wraps the scope of the launched coroutine will make sure this coroutine can only be launched once the previous one is finished.

Misconceptions. A developer might be unaware that canceling of coroutines is cooperative, meaning that they can only cancel and stop when they reach a suspension point or manually check their cancellation status. Therefore, canceling the coroutine never guarantees that it actually stops. Additionally, the `cancel` method does not wait for the coroutine to be stopped.

4.5 Swallowing CancellationException

Incorrect handling of `CancellationExceptions` can introduce bugs manifesting in the executions with exceptions. While these bugs are not strictly concurrency bugs, they are specific to Kotlin coroutines. Therefore, we cover them in this section.

 **Listing 12** A potential solution to the synchronizing with cancel example in Listing 11.

```

1 val mutex = Mutex()
2 var pendingJob: Job? = null
3
4 suspend fun refresh() {
5     pendingJob?.cancel() // optional
6     mutex.withLock { // waits for coroutine to stop
7         coroutineScope {
8
9             pendingJob = launch(Dispatchers.IO) {
10                 val result = read(someVar)
11
12                 launch(Dispatchers.Main) {
13                     write(someVar, result)
14                 }
15             }
16         }
17     }
18 }
```

Root cause. A `CancellationException` is thrown to signal that a coroutine is canceled. When this exception is caught, it interferes with the canceling mechanism of the coroutines. In Listing 13, a call to `suspendingFunction` is wrapped in a try/catch block to log any occurred errors. However, when the coroutine gets canceled while executing `suspendingFunction` a `CancellationException` is thrown which is then caught and logged. While logging a cancellation might be unfortunate, a bigger problem is that the cancellation is swallowed, since for it to work the exception needs to be propagated. A solution is given in Listing 14. The `CancellationException` is specifically caught and rethrown. We observed 14 bugs caused by accidentally swallowing `CancellationException`. This is also one of the most discussed issues in the Kotlin Coroutines issue tracker [29].

A bug that we did not observe but can occur involving `CancellationException` is when older Java frameworks throw these exceptions that could potentially run in a coroutine, making it stop silently when it shouldn't. In the example of Listing 15, a coroutine is launched on line 2. This coroutine calls a function `libraryCall` (line 3), which in this example is part of the same file but, in practice, can be any java library that throws a `CancellationException`. When this code example is executed, it will never reach the `println` statement on line 4. However, the program does finish gracefully (exit code 0). This is discussed in greater detail in the article "The Silent Killer That's Crashing Your Coroutines" [11].

 **Listing 13** Swallowed `CancellationException`.

```

1 suspend fun foo() {
2     try {
3         suspendingFunction()
4     } catch (e: Exception) {
5         Log.error(e)
6     }
7 }
```

Listing 14 A potential solution to swallowed `CancellationException` in Listing 13.

```

1 suspend fun foo() {
2     try {
3         suspendingFunction()
4     } catch (e: CancellationException) {
5         throw e
6     } catch (e: Exception) {
7         Log.error(e)
8     }
9 }
```

Listing 15 A library call throws a `CancellationException` and incorrectly cancels the coroutine.

```

1 fun main() = runBlocking {
2     launch {
3         libraryCall()
4         println("Unreachable")
5     }
6 }
7
8 fun libraryCall() { // Anything that throws CancellationException
9     throw CancellationException() // Exception unrelated to coroutines
10 }
```

Misconceptions. The developer might forget or not be aware of the canceling mechanism of coroutines. Accidentally catching a `CancellationException` is the result of that.

Possible automated detection. One may implement a static analysis that inspects the call graph and searches for `try-catch` blocks that can call a `suspend` in the `try` block and catch `CancellationException` (or a more generic one, e.g., `Exception` or `Throwable`) without propagating it by rethrowing outside the `catch` block. However, one should be careful when other constructs from the standard Java library that may throw `CancellationException` are used in the `try` block.

5 Threats to Validity

Potential threats to the validity include the representativeness of the studied concurrency bugs and our study methodology. Similar to other bug studies, our work analyzes a limited set of project repositories and a limited set of their commits.

We studied the Kotlin repositories based on our selection criteria for well-maintenance and popularity, which are based on the lines of code, number of commits, and stars. However, these criteria can potentially miss some Kotlin repositories with concurrency bugs. Similarly, we study a subset of commits in the selected repositories filtered by some keywords. We do not include some Kotlin framework keywords in our repository search, such as “channel” and “suspend”, which are frequently used during development with coroutines, appear in many of the commits, and introduce noise in the search results. Hence, the search results may potentially miss some bugs. Moreover, some bugs may not be explicitly discussed in the repositories’ commit messages or may not even have been diagnosed or fixed; therefore, they

may be missed by a repository search. Finally, our methodology involves a manual analysis of the commit source codes. While we aimed the analysis to be comprehensive, it may have missed some concurrency bugs studied or fixed in the commits.

While the study has limitations, some of which are inherent to real-world bug studies, we believe the studied bugs provide a useful sample of real-world concurrency bugs to shed light on misunderstandings and bug patterns in Kotlin programs with coroutines.

6 Key Takeaways and Discussion

While Kotlin coroutines provide a robust and straightforward mechanism for writing asynchronous programs, our study shows that developers can introduce specific concurrency bugs if they need to correctly use the asynchrony features.

Key takeaways. Our main observation is that developers may find it hard to identify *function coloring*, i.e., distinguishing which parts of their code run in asynchronous contexts, *bridging asynchronous and synchronous parts of their code*, and they may be unaware of or disregard the *semantics and mechanisms of some coroutine features* (e.g., the coroutine cancellation mechanism).

- While the Kotlin Coroutines framework helps developers identify asynchrony in their code by marking suspendable functions, programmers should be aware of regular functions that are called by asynchronous functions. Such functions, in turn, can run in an asynchronous context, and it can be hard to follow if they run in synchronous or asynchronous context, especially in large programs with deep execution call stacks.
- Developers should be careful when bridging the synchronous and asynchronous parts of their programs. Our analysis shows that when they need to call a suspend function from a synchronous context, they may tend to use *runBlocking* calls as a quick solution. This mistake is understandable since a suspend function calling a synchronous one is unaware that it might reach a *runBlocking*, while the synchronous function is unaware it is called from a coroutine. However, this unawareness can lead to dangerous *runBlocking* calls, which can result in serious concurrency errors such as deadlocks.
- When developers are aware of the asynchronous execution context but still need to call a suspend function from a normal one, they might choose to pass a coroutine scope. This solution, however, can introduce unexpected executions: the suspend function can outlive the synchronous function that called it. Incorrect reasoning about the function scopes and making incorrect assumptions about the completion of functions can result in unexpected execution orders of the program's statements.
- Similarly, the developers should be aware of the asynchronous objects and use the correct library structures to access or run operations on them. Incorrect assumptions (e.g., on the synchronization with channels) and ignorance of possible interference from other threads result in concurrency errors.
- Finally, developers should be aware of the semantics and guarantees of the programming abstractions and features they use. For example, we observed that there is common confusion about the canceling behavior of coroutines. Canceling a coroutine is cooperative and, therefore, does not guarantee it will be canceled. Similarly, the developers unaware of the cancellation exception handling mechanism of coroutines can introduce serious problems as incorrectly catching for these exceptions potentially silences critical exceptions in their programs.

Discussion. Besides increasing developers' awareness of common misconceptions, understanding common bug patterns can lead to the development of suitable program analysis tools for Kotlin programs. We communicated our findings to the Kotlin and IntelliJ teams at JetBrains. Our findings have led to the development of an inspection tool for detecting problematic `runBlocking` calls, which is currently part of the IntelliJ source code [7].

7 Related Work

7.1 Studies of Real-world Concurrency Bugs

Similar studies have been conducted that collect and categorize concurrency bugs in different programming languages and frameworks. Earlier work analyses of C/C++ concurrency bugs from server and client applications [23, 15], and report that most non-deadlock concurrency bugs are caused by atomicity and order violations. Focusing on misuse of asynchronous constructs in C# programs, the work in [26] identifies problems due to misuse or unnecessary use of asynchronous methods, invocation of long-running tasks in asynchronous methods and some anti-patterns specific to C#'s `async` and `await` model. Another study on real-world concurrency bugs [40] targets asynchronous and event-driven Node.js programs. The work identifies the concurrency bug patterns in Node.js programs as atomicity violations, order violations, and starvation in the execution of event handlers.

For Golang, the studies in [8] and [38] collect and analyze real-world concurrency bugs. The bug study in [8] focuses on data races in Go programs, and [38] focuses on the inter-thread communication mechanisms, i.e., whether message passing or shared memory concurrency is less error-prone. The findings of these works successfully led to the research and development of multiple concurrency bug analysis techniques for Go [39, 21, 13, 20, 36].

Targeting the actor model of concurrency, bug studies in [16, 22, 4] focus on actor programs, where a program consists of a set of actors that concurrently operate on their local states and communicate by exchanging asynchronous messages. The work in [16] categorizes the bugs in actor programs into communication bugs (problems in handling messages or due to delivery orderings of messages) and coordination bugs (e.g., ungraceful shutdown or recovery of actors). Following the categorization of classical shared-memory concurrency bugs, the work in [22] categorizes the actor program bugs into lack of progress and message protocol violations and defines specific subclasses of each category for actor programs. The study of actor concurrency bugs in [4] focuses on real-world Akka actor programs and analyzes their symptoms, root causes, and API usage. The bug characteristics in actor programs differ from classical shared memory programs and coroutine programs we study in this work since actors provide a high-level concurrency model without a shared state, and the concurrency nondeterminism is in the order of asynchronous events.

Different from these works, which identify the classical bug patterns of atomicity and order violations in the shared memory accesses [23, 15, 1], atomicity and order violations in the handling of events [40], message protocol violations in actor programs [16, 22, 4], or misuses and bugs in asynchronous programming in C# [26] or Go [8, 38], in this work, we focus on concurrency bugs in Kotlin programs and identify new bug patterns specifically related to Kotlin coroutines.

7.2 Analysis of Kotlin Programs

Kotlin is a relatively new programming language and only some recent research addresses the analysis of Kotlin programs. A related work targeting channel-based concurrent programs [30], which tests channel-based systems through fuzzing, has found and led to the resolution of a

bug in the Kotlin coroutine implementation. Another related work, Lincheck [19], provides a testing framework for concurrent algorithms that run on the JVM, which has been adopted in Java and Kotlin communities.

The bug patterns we discovered in this work can be useful for designing and developing program concurrency analysis tools for Kotlin programs.

8 Conclusion

This paper introduces the first real-world concurrency bug study for Kotlin coroutines, shedding light on the typical patterns of concurrency bugs. Having examined 55 concurrency bugs selected from 7 popular open-source repositories that use Kotlin coroutines, we identified common bug patterns related to Kotlin coroutine semantics. We distilled suggestions for Kotlin developers to avoid these programming errors and discussed possible techniques to detect such issues automatically. We reported our findings to the Kotlin and IntelliJ teams at JetBrains, and we believe our findings will help future research and development of concurrency analysis tools for Kotlin.

A Language-Based Version Control System for Python

Luís Carvalho

Abstract

We extend prior work on a language-based approach to versioned software development to support versioned programs with mutable state and evolving method interfaces. Unlike the traditional approach of mainstream version control systems, where a textual diff represents each evolution step, we treat versions as programming elements. Each evolution step, merge operation, and version relationship is represented explicitly in a multifaceted code representation. This provides static guarantees for safe code reuse from previous versions and forward and backwards compatibility between versions, allowing clients to use newly introduced code without needing to refactor their program manually. By lifting versioning to the language level, we pave the way for tools that interact with software repositories to have more insight into a system’s behavior evolution. We instantiate our work in the Python programming language and demonstrate its applicability regarding common evolution and refactoring patterns found in different versions of popular Python packages.

1 Introduction

The evolution of software systems is an essential aspect of software development and its life-cycle. As requirements from stakeholders change, software systems must evolve to conform to such changes. These changes may include bug fixing, implementing new features, porting code to new hardware, updating business requirements, and other tasks that represent activities in the life-cycle of a software system. As the release cycles in the software development process become shorter [20] the overhead of managing multiple versions increases. On the one hand, software maintainers have to reason more frequently about what changes to backport and whether the changes they introduced break existing client code. On the other hand, the stakeholders of a product will need to consider more frequently whether or not to upgrade. Integrating a release with breaking changes leads to runtime errors and requires manual intervention, while missing a critical update may lead to software vulnerabilities.

Given the manual effort required for semantic software versioning, which is largely rooted in the fact that version control systems (VCS, e.g. `git`, `svn`, `mercurial`) operate on *text* rather than *programs*, we extend prior work on a language-based VCS for a core functional language, Versioned Featherweight Java [5], by adding support for programs with mutable state and side effects, and versioning of class methods.

9:2 A Language-Based Version Control System for Python

The current industry practices for software evolution advocate the use of version control systems. However, while very good at managing *changes* to information, VCS give no semantic meaning to each program delta (*diff*). Each evolution step is typically defined by 1) the new code it introduces and 2) an accompanying natural language message describing the change. To issue a new version of the software, the developer includes one or more of these steps and generates a *changelog*, naming the version according to some convention.

A widely adopted convention is Semantic Versioning [26], where the increment of each version identifier denotes the nature of the introduced changes. Clients can then define their update policy according to this convention. There is no guarantee that the code effectively follows the versioning policy (e.g. the developer unknowingly introduced an unexpected breaking change), thus VCS allow for inconsistent versions to be committed, and still require work from developers in identifying the kind of changes made [33, 27].

In this work, we embed the versioning in the programming language, so that the developer specifies as code what each delta is, and also how it relates to other versions. This allows for (formal) verification on if and how the different versions interact with each other; it allows for clients to use newly introduced code without changing their existing program; it is well-suited for targeting software for a specific version, producing artifacts containing only the necessary code; for providing a version-aware development environment (drawing inspiration from [23]) in which a developer may edit a snapshot and have the changes automatically committed with the appropriate version tags. We extend previous work [5] to provide a language-based VCS for Python programs, where versions and their relations are specified as code in the program. The features that strictly extend [5] are:

- A mechanism for defining transformations (which we call *lenses*) between method interfaces in different, related, versions. This allows the developer to specify how the evolution of a method interface is to be handled by clients, so that they do not have to manually adapt their code to account for the new definition.
- Support for mutability and side-effects. Featherweight Java (FJ) is a functional language and, as such, does not model side effects. In this work, we instantiate our core calculus in Python, a mainstream language with new challenges in comparison to FJ, particularly concerning mutability. To do so, we ensure that mutability and side-effects are well reflected when transitioning between versions with different state representations.

In this setting, the developer of a versioned program defines how the versions of the program relate to each other, and provides each evolution step as code, to define how clients should evolve between versions. As such, clients can then get new features from other versions without their code breaking, and without any need for manual refactoring: the evolution steps provided by the developer are used to adapt the code to the client version, so that they can use it without breaking.

The diagram in Figure 1 provides the intuition on the parallels between traditional version control systems and our approach. With the developer providing each evolution step as code, we allow clients to migrate automatically, thus removing the need for migration tools (which can also introduce bugs) to help clients do that. The traditional repository operations, such as committing a file, or merging two branches, are well supported in our setting, by defining the appropriate version graph. Finally, we provide a slicing procedure to allow developers to issue a release for a given version, without having to manually perform operations on the repository (e.g. backporting a security fix to another branch). The resulting slice, corresponding to a release for a given version, ensures that the release conforms to the versioning graph, i.e. it does not introduce unintended breaking changes.

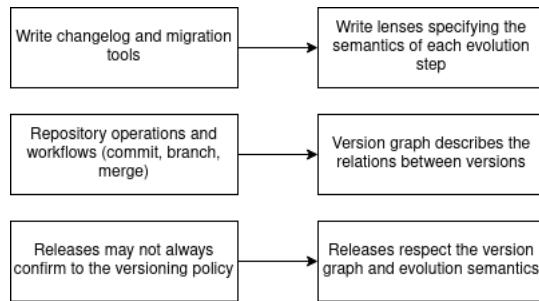

Figure 1 Diagram describing the parallels between version control systems and our approach.

The main contributions of this paper are as follows:

- Extending the work in [5], with method lenses and programs with state and side-effects.
- Instantiating the core calculus in Python to add support for versioned programs.
- Extending a type system for Python to account for versioned programs.
- Introducing a slicing compiler that can generate a projection of a versioned Python program for a single target version.

We expect this approach to provide static guarantees of safe code reuse from previous snapshots, as well as ensuring forward and backward compatibility between related versions through type-safe state transformation functions.

The remainder of this document is structured as follows: section 2 provides a running example to illustrate the ideas in this work; section 3 describes in detail our technical approach; section 4 evaluates the approach using public Python packages and provides the empirical results; section 5 discusses the related work in this space; section 6 discusses the limitations of this work and how we plan to address them; section 7 summarises our results.

2 Example

In Figure 2, we present examples of two Python programs: a versioned library program (Figure 2a) and a client program that uses a specific version of that library (Figure 2b). The versioned program (Figure 2a) contains a version graph describing how the different versions relate to each other (lines 1-3). The class `Name` of this program contains versioned definitions of methods, which are annotated with the version in which they are introduced.

In this example, there are three different versions of the library program, the class `Name`. The program starts with the definition of a version graph for class `Name`. Version `init` is the starting point of the example, and includes the definitions of fields `first` and `last`, and of methods `display` and `set_last`. Note that, in version `bugfix`, the developer introduces a new definition of method `display` (lines 15-17), but otherwise makes no changes. This new definition supersedes the previous one for clients running in the context of version `init`. This is indicated by the `replaces` relationship between versions `bugfix` and `init`.

Finally, in version `full` the developer introduces a new constructor (lines 9-11), where they change the internal state representation of the class (line 11), and a new method, `get_full_name` (lines 21-23). Contrary to version `bugfix`, these new definitions are only meant for clients that are specifically running in the context of version `full`, and does not affect clients in other versions. The code from version `init` is available in the new versions, allowing it to be safely reused.

 **Figure 2** Client and library code.

The version graph (lines 1-3) is a set of version decorators defining a name for a new version and the type of relationship (`upgrades` or `replaces`) they have with other versions. The type of relationship describes how the new version affects the existing version graph, including versions introduced earlier: if the code is to be implicitly available for clients in previous (related) versions, then the type `replaces` is used. This ensures clients running in a previous version will have the new definitions available without having to update their code (e.g. bug or security fixes). Otherwise, if the new version is a backward-incompatible extension of a previous one (c.f. class inheritance), then the type `upgrades` is used. This ensures that definitions introduced in an `upgrade` version are only available for clients running explicitly in that version. These decorators can be provided by the developer (i.e. while developing the program) or, for existing programs, they can be (naively) inferred from the repository (e.g. the version graph for the repository in Figure 3a is depicted in Figure 3b).

The library program also contains several versioned programming elements, such as constructors (lines 5-11) and methods (lines 15-23), which are decorated with the version in which they are introduced.

The client program (Figure 2b) uses version `full` of the library. It uses the `__init__` method (line 3) introduced in version `full`; the `set_last` (line 4) and `display` (line 5) methods introduced in previous versions; and the attribute `fname`, which is the only field of class `Name` in version `full`.

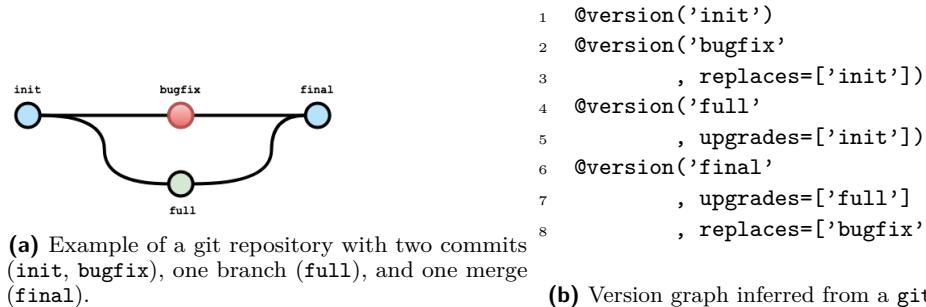

Figure 3 Repository and its corresponding version graph.

To resolve methods for the client at version `full`, we perform a method lookup operation taking the version graph into account: the available definition of method `set_last` is the one introduced in version `init`; the definition of method `display` is the one from version `bugfix`, because it replaces the definition in version `init`. Given that these definitions are available at version `full`, clients should be able to safely use them in that context.

However, since these methods use a different internal representation of class `Name`, we can not use them as-is in version `full`, as that would result in an error since the class fields do not match. We propose that, instead of re-implementing all the methods missing from the new representation (of version `full`), the developer provides a mapping between the fields of versions `init` and `full`. This mapping, which we call a *get lens* (Figure 2c), represents the inner semantics of the evolution step.

A *get lens* is introduced by a method with a decorator of the form `@get(v, v', f)`, that maps how field `f` of version `v'` is derived from the state in version `v`. For instance, the lens from version `full` to version `init` of field `first` (Figure 2c, lines 4-8) defines how the field `first`, in version `init`, is obtained from the state of version `full`. Lenses are the building blocks for developers to express evolution steps in the form of code.

The versioning-aware method lookup policy coupled with lenses allows clients to use code from different versions at runtime in a way that respects the version graph and the evolution semantics specified by the developer.

It is also possible to obtain a static, self-contained, slice of a versioned program for a specific target version. This slice will include all code available throughout the version graph for that target version, using the lookup policy described earlier. Again, since this can include code that uses different internal state representations, the slicing procedure rewrites such expressions using the corresponding lenses so that they are correct in the context of the target version, as hinted at earlier.

For example, at version `init`, the available definition for method `display` is the one introduced in the `bugfix` version. As such, this definition must be included in the slice for version `init` (Listing 1). Since both versions `init` and `bugfix` share the same internal representation of class `Name` (version `bugfix` does not define its own class fields), in the slice for version `init` we do not need to rewrite the method `display`, as it already complies with the state of version `init`.

```

1 class Name:
2     def __init__(self, first: str, last: str):
3         self.first = first
4         self.last = last
5     def display(self):
6         return f'{self.last}, {self.first}'

```

Listing 1 Slice of a versioned Python class for version `init`.

At version `full`, the available definition for methods `display` and `set_last` are introduced in versions `bugfix` and `init`, respectively. These definitions must be included in the slice for version `full` (Listing 2). In this case, since version `full` introduces a new internal representation of class `Name` (by changing the fields from version `init`), then the definitions of methods `display` and `set_last` do not conform to this representation, as they are defined in the context of other versions. As such, we need to rewrite the methods using the corresponding lenses for fields `first` and `last` (Listing 2, lines 12-21), so that they match the context of version `full`.

```

1  class Name:
2      def __init__(self, full: str):
3          self.fname = full
4      def display(self):
5          return f'{self.lens_last()}, {self.lens_first()}'
6      def set_last(self, name: str):
7          __name = name
8          self.fname =
9              self.lens_full(first=self.lens_first(), last=__name)
10     def get_full_name(self):
11         return self.fname
12     def lens_full(self, first, last):
13         return f'{first} {last}'
14     def lens_first(self):
15         if ' ' in self.fname:
16             return self.fname.split(' ')[0]
17         return self.fname
18     def lens_last(self):
19         if ' ' in self.fname:
20             return self.fname.split(' ')[1]
21         return ''
```

Listing 2 Slice of a versioned Python class for version `full`.

Both the library and client programs are valid Python programs¹. The library program can be fed as input to our compiler to extract a projection for a given version. The result of this is a valid Python program without any version annotations. The client program, when fed to an interpreter, is executed following the operational semantics described in this work for multi-version program execution.

3 Design

The ideas presented in this work are mainly language-agnostic, provided the language has support for objects and mutability. To implement these ideas, we instantiate this work in the Python programming language [1]. We chose Python for the following reasons:

- Being a mainstream and widely adopted language facilitates the evaluation of the approach using publicly available repositories of both software libraries and their corresponding clients.

¹ For brevity, the statement to import the decorators, which is necessary for the code to run, is omitted here

- In comparison with other mainstream languages that provide similar features (e.g. Java, C#), Python’s less complex syntax usually results in simpler programs [22]. This, again, facilitates the empirical evaluation of the approach, as the code patterns will be simpler to grok.
- From an implementation point of view, Python’s dynamic nature allows us to quickly prototype a solution that implements the ideas discussed in this work.

Our implementation works with a large subset of the Python language. Particularly, we do not provide semantics for the versioning of: `async/await` statements, `yield` statements, list comprehensions, and modules². The implementation also works under the assumption that the program is typed, either manually or with the help of automated type inference tools [6, 17, 32, 21]. This requirement should not be deemed too restrictive, since the practice of providing type annotations in Python programs is becoming increasingly common [7].

On top of this, we provide a type-checker and a slicing procedure for versioned Python programs. The type-checker is an extension of `Pyanalyze`, a type-checker developed by Quora that also annotates the AST nodes with their corresponding types. We extend `Pyanalyze` with support for versioned lookup of fields and methods, ensuring the correct type are inferred. The type-checker ensures the soundness of the program against its version graph, and provides the following guarantees for well-typed programs:

- A client that follows the versioning policy, defined in the version graph, will never have their code break.
- If a method needs to be rewritten for a different, related, version, it will always succeed and never produce a type error.

The slicing procedure allows for the projection of code to a specific version, inspired by software product lines and other technical approaches, such as programming variability and CI/CD pipelines. This procedure is implemented on top of a rewriting mechanism to allow library developers to release the code targeting a specific version. For well-typed programs, the slicing procedure ensures that:

- All necessary code for the target version, according to the specification in the version graph, is included.
- All the code included from other, related versions, is well-typed in the context of the target versions, by applying state or method transformations when necessary (using lenses).
- Client code that targets the sliced projection will always type-check, even if the resulting slice includes code from other versions.

The remainder of this section is structured as follows:

- Section 3.1 describes how to define versioned elements in a program.
- Sections 3.2 and 3.3 describe the versioned lookup disciplines for fields and methods respectively.
- Section 3.4 describes the use of lenses, particularly how they affect the result of a slice for a version to ensure that it is well-typed in the presence of elements from different, related versions.
- Section 3.5 describes the rewriting procedure, which is crucial to ensure that code from different versions included in a slice is always well-typed.
- Section 3.6 describes the details of the slicing procedure, that allows library developers to produce the code that targets a specific version.

² Although we do not provide versioning semantics for these elements, they can still be used in a versioned program; however, they will not follow the semantics described here.

3.1 Versioned programming elements in Python

To add support for versioning elements in Python programs, we provide the following class and function decorators³. The motivation for using decorators is that they are enough to implement the semantics described here, without requiring changes to the language syntax:

```

1  @version(<version>, <replaces>, <upgrades>)
2  @at(<version>)
3  @get(<from>, <at>, <name>)
4  @run(<version>)

```

 **Listing 3** Decorators for versioned Python programs.

These decorators allow programmers to define new versions of a class (line 1) by providing a name (`<version>`) and the relation to other versions, if any (`<replaces>` and `<upgrades>`); to introduce class methods in a version (line 2); to define class lenses that map how a field or a method (`<name>`), defined in the context of a version (`<at>`), is mapped to the context of another version (`<from>`) (line 3); and to indicate that a function should run in the context of some version (`<version>`) (line 4).

The type-checker ensures the soundness of the decorators presented here. It ensures that all version references are defined; that the version graph is acyclic; that the attribute specified in a lens (`<name>`) exists in the context of its `<at>` version, if it corresponds to a field name, and that it exists on both versions, if it corresponds to a method name; that the return type of a `get` lens matches the type of its corresponding field, or the type of its corresponding method (`<name>`); and that a class method defined at some version (`<version>`) is type-checked against the context of that same version (namely, when resolving field and method types).

The `@run` decorator defines the operational semantics to provide an environment for multi-version program execution. Additionally, we provide static semantics for versioned program slicing, so that developers are able to extract a static projection of code for a specific version. This is based on the concepts of class field and method lookup, version lenses (provided by the developer), and program slicing. We present these concepts in greater detail in the following sections.

3.2 Class field lookup

When type-checking a method of a class defined at some version v , we might encounter field access expressions (e.g. `return self.f`). To check such expressions, we need to know 1) if the field exists in that version of the class and 2) what its type is. Since fields can be defined across multiple versions of the same class, the standard (syntactic) field lookup discipline will not yield the correct field set for a given version.

As such, to be able to type-check a program, we need to define a lookup policy for class fields at a given version ($fields(C, v)$), so that we know which fields are or are not available at that version, and what their types are.

In our setting, a version (v) of a class (C) may either redefine its fields (e.g. by introducing or removing a field) or inherit the fields of related versions. The version(s) in which the fields of v are defined are called the *base versions* of v . Each version in the graph has one or more corresponding base versions for a given class ($bases(C, v)$).

³ For readers unfamiliar with Python, decorators are a method of applying a transformation to a function or a class. Except for the `run` decorator, none changes the decorated function or class (i.e. they act as syntactic hints to infer the version context.)

A field is defined in a version of a class by assigning, in any method at that version, a value to an attribute of the method caller⁴ (this is the first parameter of the method, typically named `self`).

This is expressed in rule (FIELDS-AT) (Figure 4). We start by collecting methods available at version v ($methods(C, v)$) and selecting only those tagged for version v ($at(m) = v$, where at performs a syntactic lookup of the method version decorator). Then, we collect all parameters to this method ($parameters(m)$), and inspect the method's body to check if there is an assignment to an attribute of the first parameter ($A_0.f = e \in body(m)$), which corresponds the class instance, and, if so, we collect its type (T). Finally, we check all previous related versions (W) to ensure that, if f is defined in a previous version, its type is different than the type defined at v ($C \vdash_w f : T' \wedge T \neq T'$). If the type is the same, the field is considered to be inherited, and not explicitly defined at v .

Note that, in this and all subsequent inference rules, we use some helper functions (at , $args$, $parameters$, $upgrades$, $replaces$, and $body$) that perform standard syntactic lookup of nodes in the AST (e.g. $parameters$ returns all parameters for a given method definition).

For instance, in Figure 2a (lines 7 and 8), fields `first` and `last` are introduced in version `init`, in the constructor of that version. Note that the field is only considered to be introduced in this version (as opposed to inherited) if it is not a field, with the same type, of any parent version. We make a small exception (not expressed in rule (FIELDS-AT) for brevity) for the constructor: there, a developer can redefine fields with the same name and type from other related versions⁵.

To lookup the bases of a version v , we start by collecting the fields defined explicitly at that version given the procedure described earlier ($fields_at(C, v)$). If this set is not empty, then the base of version v is simply itself (rule (BASE-SELF)). Otherwise ((rule (BASES))), the bases of v are the union of bases from the versions it upgrades and replaces (W), using the same lookup logic.

Finally, to lookup the (versioned) fields for a class C in version v ($fields(C, v)$), we collect the union of fields in all base versions of v (rules (FIELDS), (FIELDS-SELF)).

Note that, in this setting, these lookup rules are different from those presented in [5]. In particular, in this work, a version of a class can have *multiple* base versions, as opposed to a single one: as such, the lookup logic for fields is also slightly different, since we can lookup fields on multiple base versions.

In the example of Figure 2a, the base version of `bugfix`, in which no fields are explicitly defined, is `init`; the base version of `full` is itself. If we were to add a new version to this program, `final`, that merges versions `full` and `bugfix`

```
@version('final', upgrades=['full', 'bugfix'])
```

then the base versions of `final` would be versions `full` (the base of itself) and `init` (the base of `bugfix`); its fields would be the union of all fields in these versions (`first`, `last`, and `fname`).

The base versions are used in all typing and reduction rules to ensure that the version graph is respected when resolving class fields..

⁴ This follows the approach of most Python type-checkers, such as MyPy.

⁵ This is to account for the *semantic* (as opposed to syntactic) evolution of a field, when its name and type are still preserved.

 \\
 \frac{bases(C, v) = \{ v \}}{fields(C, v) = fields_at(C, v)} \text{ (FIELDS-SELF)}
 \end{array}$$

Figure 4 Inference rules for field and base version lookup.

3.3 Method lookup

Similar to class fields, class methods can be defined across multiple versions of the same class. As such, the standard method lookup discipline will not yield the correct definition of a method for a given version, since there can be multiple definitions with the same name across different versions. Consider the following (abstract) example of a class with three related versions. Version 1 introduces a definition for methods `n` and `m`. The other versions introduce a definition for method `m`:

```

@version('1')
@version('2', upgrades=['1'])
@version('2.1', replaces=['2'])
class C:
    @at('1')
    def n(self): ...
    @at('1')
    def m(self, x): ...
    @at('2')
    def m(self, x): ...
    @at('2.1')
    def m(self, y): ...

```

Listing 4 Evolution of a method between versions.

The intuition here is that clients running at version 1 should use the definition of `m` introduced in that version, since there is no definition of `m` that replaces the one from version 1. Clients at version 2 should use the definition of `m` introduced at version 2.1, since this is declared as a replacement over version 2; and clients at version 2.1 should use the definition of `m` introduced in that version. For method `n`, all versions use the definition from version 1, which is local to version 1 and inherited in version 2 (and, subsequently, in version 2.1).

To comply with the version graph, we must also define a lookup policy for class methods at a given version, as illustrated above. The reader may notice that the definition of `m` introduced in version 2.1 – which should be available to clients in version 2 – has a different interface from the local definition of `m` at version 2 (parameter `x` is renamed to `y`). Intuitively, this means that client code is written for version 2, which may call method `m` using keyword

arguments (i.e. `C().m(x=...)`), which type-checks against the local interface, cannot simply use the new definition, as that would introduce a type error (no parameter named `x`, missing parameter `y`).

As such, the lookup of a method `m` at version `v` must return both the interface (to comply with clients targeting `v`) and its implementation (to comply with new definitions introduced in replacement versions). The lookup discipline for methods works in the following order:

Local definition. Search for a local definition of `m` introduced at version `v`. If any is found, that definition corresponds to the interface and implementation of `m` for version `v`.

Parent definition. If no local definition was found, search all versions that `v` either upgrades or replaces for a definition of `m`. If any is found, that definition corresponds to the interface and implementation of `m` for version `v`. If there are multiple matches, they must be the same definition. Otherwise, a conflict occurs, and the program is not well-typed.

Replacement definition. Finally, search all replacement versions of `v` for an implementation of `m`. If no interface was found yet (either locally or inherited from a parent version), it means `m` was introduced in a replacement version, so that interface is the one available to clients at version `v`. In any case, if there are multiple matches, they must be the same definition. Otherwise, a conflict occurs and the program is not well-typed.

This lookup policy is illustrated in the example above, where, for version 2, the interface of `m` is the one from the local definition at 2, and the implementation is from the definition at version 2.1. Later in this section, we describe how to use one interface with a different implementation. For now, it's important to retain that the lookup of methods must respect the version graph, and take into account how the client code is typed (i.e., against which interface). For method `n`, the interface and implementation at version 2 is the one inherited from version 1.

This lookup policy is used to type-check function calls at a given version; to detect missing lenses between methods of different versions, when the interface differs from the interface of the implementation (e.g. method `m` at version 2 in the previous example); to detect conflicts in the version graph; to select method definitions when providing a slice for a target version; and to find the code to execute at runtime.

3.4 Version lenses

The lookup policy for class methods, described earlier, allows for a version `v` of a class to use methods introduced in another (parent or replacement) version `t`. In such cases, there are two situations where we need to pay special attention:

- The implementation provided by the lookup policy is defined at another version, `t`, which has a different state representation (i.e. different base versions from `v`).
- The interface provided by the lookup policy is different than the interface of the implementation, and the signatures of the interfaces differ (e.g. method `m` in version 2 of the previous example).

In the first case, since the state representation of the class is different, the method body may not comply with the representation of version `v`: this is illustrated in Figure 2a, where method `display`, available for version `full`, complies with the state of another version (`init`). Intuitively, this means that, to use such implementations, we must introduce a mapping between the fields used in the method body and the fields of the target version (in this case, version `full`), otherwise we would introduce type errors.

In the second case, since the interface of the method is different from the interface available for clients at version `v`, we can not simply use the new definition, since client code is typed against a different interface (as such, doing so would introduce a type error). Intuitively, this means that, to use the new implementation, while preserving the type correctness of clients at `v`, we must introduce a mapping between the two interfaces.

These mappings, called *lenses*, for fields and methods, are described in more detail in the remainder of this subsection.

3.4.1 Field lenses

Consider again the example in Figure 2a, where the interface and implementation of method `display` for version `full` is from version `bugfix` (Figure 2a, line 17). In version `full`, class `Name` has no `first` nor `last` field, so this definition of method `display` is not well-typed in version `full`. For a client in version `full` to correctly use this code, we need to rewrite the method body, so that it complies with the desired state.

The type system requires that the developer defines the necessary lenses at version `full` for the fields at version `init` (Figure 2c). Intuitively, these lenses express how each field evolved from the state of version `full`. In this case, the lenses are simple: split the full name on a whitespace, if any, and return the corresponding component (if it exists). Later, when projecting the code for version `full`, the lenses are used to rewrite field expressions in the method body so that they are well-typed in the context of version `full`.

Each field lens is a standard class method, annotated with a `@get` decorator, of the form `@get(<at>, <from>, <name>)` (Listing 3, line 3), with a single argument (the method caller, `self`). In practical terms, the implementation of the lens answers the question: “In the context of version `<at>`, how do I represent the field `<name>` of version `<from>?`”. The type system ensures that the body of a lens is type-checked in the context of its `<at>` version (in this case, version `full`); that `<name>` is a field in version `<at>`; and that the return type of the lens matches the type of field `<name>` in version `<at>` (in this case, `str`).

Field lenses are a suitable mechanism for modelling common software evolution patterns, such as renaming a field, changing its type, or refactoring its representation (as in the example of Figure 2a, where we join both fields in a single one).

Evolution patterns that mostly concern text manipulation (as opposed to program semantics), are typically considered breaking changes (e.g. changing the name of a field in a class). In our setting, these patterns are well supported, as it is always possible for the developer to express such a pattern in the form of a lens. If they do so, then these patterns can be applied successfully without introducing breaking changes.

For instance, a lens to rename a field (`f`, to `t`) from version 1 to 2 is expressed by:

```

1  @get('1', '2', 't')
2  def rename_f_t(self):
3      return self.f
4  @get('2', '1', 'f')
5  def rename_t_f(self):
6      return self.t

```

and allows clients in version 1 to use code from version 2, thus making it a non-breaking change; and for code in version 2 to reuse code from version 1, so that the developer does not need to rewrite methods that use field `f`. In these cases, the lenses can be synthesised with the help of editor tools, instead of manually implemented by developers (c.f. refactoring tools in Bides)⁶.

⁶ This is discussed in greater detail in section 6.

Evolution patterns that concern program semantics, such as changing the type of a field, are not always possible to model with a lens. For instance, in the previous example (Figure 2c), we showed how to model such a pattern (refactoring two fields into one).

However, consider the case where we want to refactor a list (in version 1) into a dictionary (in version 2, that replaces 1). Assuming the semantics of the program dictate that the elements of the list correspond to the values in the dictionary, then we can devise a lens that maps the dictionary to the list (e.g. `return list(self.data.values())`, where `data` is the dictionary), which allows the developer to reuse code from version 1 while working in the context of version 2. But what about the other way around? If we want to map the list to a dictionary, it may not be possible to infer the keys⁷ (for instance, if they are provided by the client when creating the dictionary).

In such cases, the type system detects an error: the `replaces` relationship between the two versions defined in the graph implies that clients in version 1 should be able to use all code from version 2 – but without a lens this is not possible.

In such cases, where the developer can not define a lens for a field (e.g. `data`), then the code does not comply with the version graph, as the lens is missing. Intuitively, this indicates that the developer introduced a breaking change from version 1 to version 2, so clients can not migrate automatically. To fix this, the developer must change the version graph and use the `upgrades` relationship between both versions instead.

This typing discipline reflects the nature of a breaking change when evolving class fields, as it prevents the developer from issuing such a change in a replacement release, which, in the absence of a lens, would make the client code crash. Instead, by using the `upgrades` relationship, the developer instructs clients to adapt manually, by migrating to the new version and then type checking their code in that context, correcting manually for any errors.

3.4.2 Method lenses

Similar to field lenses, method lenses map how (possibly different) interfaces of the same method evolve between different, related versions.

Consider again the example in Listing 4, where method `m` is refactored in version 2.1 by renaming parameter `x` to `y`.

In this case, the `replaces` relationship implies that clients in version 2, whose code is written using the interface from that version (i.e. with parameter `x`), should be able to use the new implementation of `m` automatically, without their code breaking:

```
1  @at('2')
2  def client():
3      return C().m(x=...)
```

Since the client code is written against the interface defined at version 2, to use the new implementation, the type system requires that the developer define a method lens at version 2 for method `m` at version 2.1. This lens expresses how the method evolved from one version to the other, so that clients can safely use this new definition without rewriting their code. Later, when projecting the code for version 2, the lenses are used to rewrite method definitions, so that they conform to the interface of version 2 while using the implementation from version 2.1. The following is an example of a method lens that renames argument `x` to `y`, while otherwise preserving the semantics:

⁷ Whether this is possible or not depends on the program's intended semantics.

```

1  @get('1', '2', 'm')
2  def lens_m(self, f: Callable[[C, P], T], x: P) -> T:
3      return f(y=x)

```

 **Listing 5** Method lens to rename a parameter

A method lens is a standard class method, annotated with a `@get` decorator (Listing 3, line 3). The body of each lens function is type-checked in the context of the `<from>` version. The type system ensures that the method (`<name>`) is available in both versions (`<from>` and `<at>`), and that the return type of the lens function (`T'`) matches the return type of method `<name>` in version `<from>`.

A method lens takes a reference to the instance object (first parameter, `self`); a reference to the method definition in version `<from>` (`f`), whose signature matches the type of method `<name>` in version `<at>` (in the example, the signature of `f` corresponds to the type of `m` at version 2.1); and all positional and keyword arguments that method `<name>` takes in version `<at>` (in this case, `x`). The parameter `f` is to aid the developer statically expressing how the calls map between the two versions.

In the above example, `f` is a reference to the definition of `m` in version 2. As such, the developer can express how a method call from a client in version 1 maps to the corresponding method in version 2, in this case by calling `f` and passing `x` as the value to `y`.

Method lenses are a suitable mechanism for modelling common software evolution patterns, such as adding/removing/reordering parameters, changing the type of parameters, and changing a method's return type.

Evolution patterns that mostly concern text manipulation (as opposed to program semantics), are typically considered breaking changes (e.g. changing the name of a parameter in a method). In our setting these patterns are well supported, as it is always possible for the developer to express such a pattern in form of a lens, as hinted in the previous example. If they do so, then these patterns can be applied successfully without introducing breaking changes for clients.

The same approach can be used for methods that evolve semantically, not just textually. Consider the following example, of a method that returns a boolean, and is refactored to return 0 instead of `True` and 1 instead of `False` (the implementation details are omitted here as they are not relevant):

```

1  @at('2')
2  def m(self) -> bool: ...
3  @at('2.1')
4  def m(self) -> int: ...

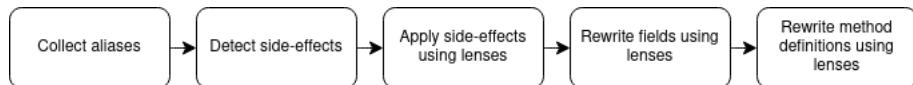

```

Again, the `replaces` relationship between version 2 and 2.1 indicates the developer wants clients in version 2 to use the refactored method introduced in 2.1. As such, the type system requires that they provide a lens expressing how the result of a call to the new implementation, defined in version 2.1, can be mapped to the type of the interface, introduced in version 2. The lens takes as parameter `f` a function that returns an `int`, matching the definition in version 2.1, and returns a value of type `bool`, matching the definition at version 2:

```

1  @get("2", "2.1", "m")
2  def lens_m(self, f: Callable[[C], int]) -> bool:
3      return f() == 0

```

■ **Figure 5** Diagram describing the pipeline of the rewriting procedure.

A client using method `m` in version 2, such as:

```

1 @at('2')
2 def client():
3     return not C().m()
  
```

can use the new code from version 2.1 without refactoring their code, since the mapping from `int` to `bool` (the expected return type for clients in version 2) is provided by the lens.

Similar to field lenses, notice how, when a method evolves semantically, it may not always be possible to devise a lens that models the evolution step, depending on the semantics of the change. Once again, in those cases, to fix the typing error (missing lens), the developer must change the version graph, and define the new version as an upgrade, indicating to client that they must migrate manually and refactor their code to adjust to the new interface.

Method lenses allow clients to use new code without any need for manually refactoring, so developers can express versioning workflows with typical breaking changes, such as changing method signatures, and automatically have clients complying with the versioning policy established in the respective version graph.

3.5 Rewriting procedure

The concept of lenses, described in the previous subsection, allows clients to use code from a version different than the one their code is targeting, even in the presence of different state representations (i.e. class fields) and different method interfaces, respecting the evolution pattern specified by the developer. To do so, we must rewrite the methods that are defined in different versions, so that they conform to the client's version context.

This section describes the procedure to rewrite methods defined at some version `v` so that they match the context of the client version `t`. By doing so, we allow clients to use the new methods without introducing type errors, accounting for side effects and ensuring they are preserved across different version contexts.

The diagram in Figure 5, illustrates the pipeline of the rewriting procedure to rewrite a definition of method `m` from version `v` (where it is defined) to version `t` (which the client is running). Below, we describe each step of this pipeline in detail.

3.5.1 Collecting aliases

In Python, object references are passed by value. When we assign the value of an instance field to a variable, if the variable is mutated, the changes will be reflected back in the instance field. As such, to (statically) detect side-effects on instance fields, we first need to keep track of aliases (to fields) in a given method. Consider the following example of a method `m` at version `v` that appends an element to a list field:

```

1 @at('v')
2 def m(self):
3     x = self.f
4     x.append(1)
  
```

In this example, simple static analysis would not be enough to detect that `self.f` is mutated (since the `append` method is called on a variable, not on a field). So, we need to know that `x` is an alias to a class field (in this case, `f`). To do so, we perform static analysis on assignment statements to collect the aliases of class fields in scope in each method.

From the assignment statement in the above example, we can infer that `x` is an alias to the field `f` of the method caller's class. In some cases, we can also detect if assigning the result of other types of expressions such as a variable, the result of a function call, a list index expression, and so on, also results in a reference to a mutable object field.

We collect all aliases of mutable object fields in a method to use in the next steps, so that we can ensure that the side effects in the code for version `v` are correctly applied when we rewrite it for version `t`.

3.5.2 Detecting side-effects

Now that we have collected all aliases to fields within a method, we can start performing static analysis to detect side-effects. This is crucial to ensure that side-effects on fields of other versions are correctly carried over to the target version, `t`, to which we are rewriting the code. Conversely, detecting cases where no side-effects are produced, avoids having redundant rewrites of such expressions.

The intuition here is the following: we will be using field lenses (in this case, from version `v` to `t`) to rewrite fields (this is detailed further in this section); but, since field lenses are pure functions (i.e. they do not mutate the object calling them), the side effects would be lost if we simply replaced the field by its corresponding lenses – in which case, the side effect would apply to the result of the lens, but not to the current state representation of the class in version `t`.

Consider the following example of method `m` defined at version `v`, where the call to method `pop` will have a side effect on the state of the object (by removing the first element of the list stored in field `f`):

```

1  @at('v')
2  def m(self):
3      x = self.f.pop()
```

We detect side effects to object fields by identifying expressions where the field is passed as a mutable reference to a method⁸ (in this case, method `pop`), so that we can preserve them when rewriting.

To do so, we start by extracting the field to a (new) local variable, rewriting its occurrence in the assignment, and then assigning back to the field the value of the local variable:

```

1  @at('v')
2  def m(self):
3      _x = self.f
4      _x.pop()
5      self.f = _x
```

This logic is expressed in the following rules. In rule (Rw-FIELD-CALL), we rewrite method calls that mutate the calling object. We start by collecting all methods available in the target version `t` ($methods(C, t)$), and selecting those defined at a version other than `t` (i.e.

⁸ It is not always possible to do so by static analysis. For instance, the functions from the Python standard library, such as `pop`, are compiled from C code, which we can not analyse statically. In these cases, we naively assume that function mutates its arguments.

those that need rewriting). Then, for each method, we inspect its body to check if there is a method called on an object ($obj.m'(A) \in body(m)$, where A are the arguments passed in the call). Finally, we check if method m' mutates its caller: this is given by the helper function $mutates(T, m', P_0)$, where T is the object's type and P_0 is the first parameter of method m' (i.e. its caller). If so, we need to rewrite the method call. As shown in the previous example, we start by declaring a new, unused, variable ($x = fresh()$) and assign the object to it ($x = obj$). Then, we call the method on this variable, passing the same arguments rewritten for the context of version t ($x.m'(A')$, where A' is the result of rewriting arguments A). Finally, we assign the value of x back to the object.

In rule (Rw-FIELD-ARGS) (Figure 6), we rewrite method calls that mutate their arguments. Similar to the previous rule, we start by collecting all methods available in the target version t ($methods(C, t)$), and selecting those defined at a version other than t (i.e. those that need rewriting). Then, for each method, we inspect its body to check if there is a method called on an object ($obj.m'(A) \in body(m)$, where A are the arguments passed in the call)⁹. Finally, we select all arguments which are mutated by m' (A'), and we create a fresh variable for each of these arguments (X). To rewrite the call, we start by assigning to each fresh variable the current value of its corresponding argument ($x_i = A'_i$). Then, we call the method, replacing each (mutated) argument with its corresponding variable ($\{A'/x\}$). Finally, we assign to the arguments the value of their corresponding variable (which was mutated in the method call).

$$\begin{array}{c}
 \frac{\begin{array}{c} m \in methods(C, t) \quad v = at(m) \quad v \neq t \\ obj.m'(A) \in body(m) \quad \Gamma \vdash_v obj : T \quad P = parameters(m') \\ mutates(T, m', P_0) \quad A \underset{v \rightsquigarrow t}{\sim} A' \quad x = fresh() \end{array}}{obj.m'(A) \underset{v \rightsquigarrow t}{\sim} x = obj; x.m'(A'); obj = x} \text{ (Rw-FIELD-CALL)} \\[10pt]
 \frac{\begin{array}{c} m \in methods(C, t) \quad v = at(m) \quad v \neq t \quad obj.m'(A) \in body(m) \\ \Gamma \vdash_v obj : T \quad A' = \{ a \in A \mid mutates(T, m', a) \} \\ X = \{ fresh() \mid a' \in A' \} \end{array}}{obj.m'(\bar{a}) \underset{v \rightsquigarrow t}{\sim} \bar{x}_i = \bar{A}'_i; obj.m'(\{A'/x\}); A'_i = x_i} \text{ (Rw-FIELD-ARGS)}
 \end{array}$$

■ **Figure 6** Rules to rewrite fields.

Notice how the code is still typed for the context of version v . This procedure is used whenever object fields (or aliases) are passed as mutable arguments to functions, as described earlier, and also across all language statements, such as loops, return, try-raise, and so on. For example, consider the following example, where an object field is mutated as a condition of an if statement:

```

1  @at('v')
2  def m(self):
3      if self.f.pop():
4          return True

```

To rewrite this statement, we create two new references: one for the object's fields ($_x$, as described earlier); and another for the condition value of the if statement ($_y$). Finally, to

⁹ Note that this rule also applies for functions (e.g. `sort`, which sorts a list in place) and not just methods. For brevity, that case is elided here, although it follows the same logic.

apply the side effects of the method call (`pop`), we assign the value of this reference back to the object's field, before executing the if statement. This ensures the semantics of the (original) code in version `v` are preserved:

```

1  @at('v')
2  def m(self):
3      _x = self.f
4      _y = _x.pop()
5      self.f = _x
6      if _y:
7          return True

```

By the end of this step we should have all side effects to fields expressed as simple assignments of the form `self.f = _v`, where `_v` is the variable holding the value after side-effects are applied.

3.5.3 Rewriting assignments to fields

Following up on the previous step, we now have all side effects expressed as assignments to fields. To rewrite the assignments to the target version `t`, we use the corresponding lenses.

The intuition here is the following: when the developer defines a lens (from `v` to `t`) for a field (`f`), the lens expresses how to compute the value of the field given the state of the object at version `t`. As such, any fields of `v` that appear in the lens will be affected by an assignment to field `f` in the context of version `v`.

Consider the example of method `set_last` (Figure 2a), that assigns a value to field `last`. Since this method is available at version `full`, we must have a way to express how a change to field `last`, in version `init`, affects the state of this version. This is called a *put* lens.

By analysing the lenses from version `init` to version `full` we see that field `last` appears in the lens for field `fname`:

```

1  @get('init', 'full', 'fname')
2  def lens_full(self):
3      return f'{self.first} {self.last}'

```

In practice, this indicates that the value of the field `fname`, in version `full`, is affected by the value of field `last`, in version `init`: if we run the code for this lens, replacing `self.last` with the value that we are assigning to the field, we obtain the matching side effect in field `fname` that results from the assignment. As such, the developer need not provide a definition for a *put* lens, as we can synthesise one from its corresponding *get* lens.

To do so, we add a parameter for each field referenced in the *get* lens, and replace the field reference in the lens body with the (matching) function parameter. The synthesised *put* lens for field `fname` at version `full` is:

```

1  @put('init', 'full', 'fname')
2  def lens_full(self, first, last):
3      return f'{first} {last}'

```

To rewrite an assignment for field `f`, we start by synthesising all necessary *put* lenses. These are synthesised from the corresponding *get* lenses defined at version `v`, for any field (`f'`) from version `t`, that make a reference to field `f` in their body (rule (SYNTH-PUT-LENSSES)). This ensures that a change to field `f`, in version `v`, has its side effects applied to fields `f'` of version `t`.

In the previous example there was only one lens in version `init` using field `last`, so that is the one that is synthesised; in cases where there is more than one, we synthesised all necessary put lenses and unfold the original assignment into multiple assignments, each using a *put* lens for the affected fields. For instance, in Figure 2c, in the lenses from version `full` to version `init`, field `fname` appears in two lenses. This means that both lenses would be needed to correctly apply side effects to field `fname` when rewriting such an assignment to version `init` (which would reflect on fields `first` and `last`, using the same logic).

Now that we have the necessary *put* lenses synthesised, we can use them to rewrite the assignment. For example, to rewrite method `set_last` for version `full`, we can use the synthesised *put* lens (`lens_full`) to apply the side effects resulting from the assignment. To do so, we pass the assigned value (`name`) as the argument to the corresponding field (`last`). To all other unaffected field parameters (i.e. `first`), we pass their current value (in the context of the version where the method is defined, i.e. `self.f` for field `f`).

Finally, to ensure that this code is well-typed in the context of version `t`, we replace all field references (in this case, `self.first`) using the corresponding *get* lens (Figure 2c, line 2), as described in the next subsection. This is expressed in rule (Rw-ASSIGNMENT), where we start by detecting assignments to fields in the method's body ($obj.f = e$), then we rewrite the right-hand side to match the context of version t (e), and finally collect all *put* lenses that affect field f (P). To rewrite the assignment, for each field of t affected by the assignment (F''_i), we assign the result of its corresponding *put* lens (P_i), passing the rewritten value for all unaffected fields ($F_i = F'_i$), and the rewritten assigned value for the assigned field ($f = e'$). The translation of the assignment for version `t` is then:

```
1 def set_last(self, name):
2     self.fname = self.lens_full(first=self.lens_first(), last=name)
```

$$\frac{m \in methods(C, t) \quad v = at(m) \quad obj.f = e \in body(m) \quad \Gamma \vdash_v obj : T \quad e \underset{v}{\rightsquigarrow}_t e' \quad F = \{ f_i \mid f_i \in fields(C, v) \wedge f_i \neq f \} \quad F' = \{ f_i \underset{v}{\rightsquigarrow}_t f'_i \mid f_i \in F \} \quad F'', P = \{ f', put_lenses(T, v, t, f) \mid f' \in fields(C, t) \}}{obj.f = e \underset{v}{\rightsquigarrow}_t obj.F''_i = obj.P_i(F_i = F'_i, f = e')} \text{ (Rw-ASSIGNMENT)}$$

3.5.4 Rewriting field references

As described earlier (section 2), if the method at version `v` contains expressions of references to class fields (e.g. `obj.f`), we need to rewrite these expressions, using the corresponding *get* lens, so they comply with the state of version `t`.

In this step, we do not account for field references to which the previous cases apply as those are already compliant with the target version (i.e. assignments, aliases, and function call arguments).

For example, in Figure 2a, the implementation of method `display` for version `full` is defined in the context of another version, `bugfix`. This definition makes references to fields (`first` and `last`) that are not defined in the context of version `full`. As such, we need to rewrite these references so that they comply with the state of version `full`.

To do so, we replace field occurrences with a call to their corresponding *get* lens provided by the developer (Figure 2c, lines 1-10). This ensures that the code is well-typed in the context of the target version `full`, and that it respects the evolution semantics described by the developer in the implementation of the lenses (rule (Rw-FIELD)):

$$\begin{array}{l}
 1 \quad \text{def display(self):} \\
 2 \quad \quad \text{return f'`\{self.lens_last()\}, {self.lens_first()}`'} \\
 \\
 m \in \text{methods}(C, t) \quad v = \text{at}(m) \quad \text{obj}.f \in \text{body}(m) \\
 \Gamma \vdash_v \text{obj} : T \quad f \in \text{fields}(T, v) \quad l = \text{lens}(T, t, v, f) \\
 \hline
 \text{obj}.f \underset{v \rightsquigarrow_t}{\sim} \text{obj}.l() \quad (\text{Rw-FIELD})
 \end{array}$$

3.5.5 Rewriting method definitions

As described earlier, method lenses allow clients to use new method interfaces and implementations without any need for manually refactoring, allowing developers to express versioning workflows with typical breaking changes and making them non-breaking. This mechanism applies to cases where the method signature or semantics have changed between versions.

Consider again the example in Listing 4 with two implementations of the same method, `m`, where a parameter is renamed from `x` to `y`, a typical breaking change. The semantics of this change is expressed in the lens provided by the developer for this method (Listing 5). With this lens, we can allow the clients of version 2 to use the definition of `m` introduced in version 2.1 without refactoring their code.

To do so, we use the method lens to rewrite the implementation of method `m` when extracting a slice for version 2. The intuition here is that we want to preserve the interface of version 2, since that is what the client code is written against, while using the implementation of version 2.1, which the developer introduced as a replacement for the old definition.

To rewrite the definition using the method lens, we start by adding the new definition of method `m` (from version 2.1) to the program and renaming it, so that we don't introduce a conflict (line 2). Then, we rewrite the body of this method, according to the rewriting procedure described in this subsection, so that it complies with the state of 2. Then, we rewrite the lens function, by removing the parameter `f` (line 4) and replacing it in the body with a reference to the (renamed) method from version 2.1 (line 5). Finally, we rewrite the body of method `m` in version 2 to make a call to the method lens (line 7).

```

1  class C:
2      def __v2_1_m(self, y: int) -> int: ...
3      def lens_m(self, x: int) -> int:
4          return self.__v2_1_m(y=x)
5      def m(self, x: int):
6          return lens_m(x=x)

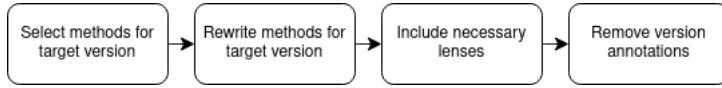

```

The rewriting of method definitions across different versions ensures that clients can write their code against the old interface while taking advantage of the new implementation. This concludes the presentation of the rewriting procedure, which we will use to produce a slice of the program that targets a specific version, as described in the following subsection.

3.6 Program slicing

We propose a slicing procedure, built on top of the rewriting procedure described earlier, applying static program transformations, to extract code for a specific target version from a versioned program. The result should include all code available in that version according to the versioning policy provided by the version graph.

The intuition for the slicing procedure is to be able to project code for a specific release, similar to techniques used in software product lines or variability programming settings.

■ **Figure 7** Diagram describing the pipeline of the slicing procedure.

At its core, the slicing procedure relies on the rewriting procedure to ensure that any code that is reused from other versions is safe to use in the context of the target version t , respecting the evolution semantics specified by the developer in the lenses.

Now that we have defined our rewriting procedure, we can use it to produce a slice for a target version t . In Figure 7, we present a diagram with the pipeline of the slicing procedure. Below, we describe each step of this pipeline in detail:

Select methods. We start by selecting the method definitions (their interface and corresponding implementation, as defined by the lookup policy described earlier) of C that are available at version t , according to the versioning policy of the version graph and the lookup functions described in subsection 3.3. This is expressed in rule (SL-METHODS).

$$\frac{M = \text{methods}(C, t)}{M \subset \text{methods}(\text{slice}(C, t))} \quad (\text{SL-METHODS})$$

Rewrite methods. Given the methods selected in the previous step, we rewrite those that either 1) have an implementation defined at a (base) version other than t or 2) the developer has provided a lens for (i.e. the methods whose semantics have changed). We rewrite these methods using the procedure described earlier so that they match the context of the target version t .

Select lenses. Since the rewriting procedure may need lenses to rewrite expressions for the context of t , we will need to include those (and only those) in the final result. We collect all necessary *get* and *put* lenses (rules (SL-GET-LENSES) and (SL-PUT-LENSES)) that are required for the rewriting procedure, rewrite them to match the context of version t , and include them in the resulting slice for this version. Rule (SL-GET-LENSES) expresses the logic for including *get* lenses: we check each method (m) of the target version (t) that is defined in a different version (v) and, if its body contains a field access expression on an object ($obj.f$) of type T , and a lens is defined between versions v and t of class T for field f ($\text{lens}(T, t, v, f)$), we include it in the final slice of T . Rule (SL-PUT-LENSES) expresses the logic for including *put* lenses: we check each method (m) of the target version (t) that is defined in a different version (v) and, if its body contains a field assignment expression on an object ($obj.f = e$) of type T we iterate over all (*get*) lenses for fields of version t in class T (L), and finally we include the ones where field f is used (L_f).

$$\frac{m \in \text{methods}(C, t) \quad v = \text{at}(m) \quad v \neq t \quad obj.f \in \text{body}(m) \quad \Gamma \vdash_v obj : T \quad l = \text{lens}(T, t, v, f) \quad C' = \text{slice}(T, t)}{l \in \text{methods}(C')} \quad (\text{SL-GET-LENSES})$$

$$\frac{m \in \text{methods}(C, t) \quad v = \text{at}(m) \quad v \neq t \quad obj.f = e \in \text{body}(m) \quad \Gamma \vdash_v obj : T \quad L = \{ \text{lens}(T, v, t, f') \mid f' \in \text{fields}(T, t) \} \quad L_f = \{ l \mid l \in L \wedge \text{self}.f \in l \} \quad C' = \text{slice}(T, t)}{L_f \subset \text{methods}(T')} \quad (\text{SL-PUT-LENSES})$$

$$\frac{l = \text{lens}(C, v, t, f) \quad F = \{ f \mid s \in \text{body}(l) \wedge s = \text{self}.f \} \quad l' = l \{ \text{args} = F \}}{\text{put_lens}(C, v, t, f) = l'} \quad (\text{SYNTH-PUT-LENSES})$$

Remove version annotations. Finally, to produce the slice for version t , we remove any version annotations that may exist, so that the end result is a standard Python program that can be fed to the interpreter to be executed.

In Listing 2, we present the slice of the program in Figure 2a for version `full`. The resulting slice includes the fields and methods of version `full` as defined by the lookup policies described earlier, and any lenses that are necessary to rewrite statements from other versions (e.g. lines 5 and 9).

4 Evaluation

In this section, we empirically evaluate the applicability of our approach by answering the following research questions:

- RQ1.** Can library developers mitigate the occurrence of breaking changes in common evolution patterns?
- RQ2.** Can clients update a library dependency without having to manually refactor their code to account for breaking changes?

4.1 Evaluation design

To setup the evaluation, we started by gathering a set of publicly available Python software libraries with at least two major version releases, v and t . We opted for popular packages, since, given their widespread adoption, these are likely to affect a higher number of clients. We also took care to select packages with different kinds of changes such as renaming methods, fields, or changing method signatures, to better illustrate the applicability of our approach.

For each library, L , we start by defining the version graph. Since we are trying to turn major versions into minor (i.e. so that clients can upgrade transparently without breaking), we define the later version as a replacement of the previous (major) version:

```
1 @version('v')
2 @version('t', replaces=['v'])
```

Then, we select the commit tagged for versions v and t and add the respective version annotations (`at('v')`, `at('t')`) to the methods in each commit. Now that we have the version graph defined and all elements annotated with their corresponding versions, we run the type-checker to detect any missing lenses. We implement the missing lenses, if possible, according to the description stated in the migration guide for L , which corresponds to the semantics the developers intend for each change.

At this stage, we should have a program that type-checks against its version graph (again, if the lenses are possible to implement). Finally, we extract a slice of library L for version v . Now, we can evaluate the applicability of our approach in two ways:

Using client code. In some cases, we were able to use a client program (C) to check if the slice of L for version v conforms to the migration semantics the library developer defined. To do so, we select the commit of C that targets version v of L and type-check this against the slice of L for version v . If the program type-checks, the approach is validated.

Guided by examples in migration guide. As the reader may have understood by now, this evaluation requires a bit of manual labour to setup. This is expected, since the ideas described in this work are more suitable to be applied throughout the development cycle, instead of applied to existing codebases. As a result, it was not feasible to validate some libraries against existing client code. In those cases, we simply used the examples stated in the migration guide (or modelled them ourselves if there are none), and validated the approach in the same way described in the previous point.

4.2 Evaluation results

We conducted our experiments using the libraries listed in Table 1, using client code where possible. The table shows the selected library, the start and target versions we chose, the client used to validate the approach (if any), the number of breaking changes¹⁰, and how many we were able to successfully model.

■ **Table 1** Libraries and clients selected for the experimental evaluation.

Library	Start version	Target version	Client	Changes	Successful
tensorflow	1	2	gpt-2	19	14
emoji	1.7	2	ntfy	1	1
metaapi-python-sdk	22	23	—	2	2
netbox	3.5	3.6	—	5	4
twillio-python	7	8	—	17	14

The following is a summary of the results we obtained for each library:

tensorflow. Out of 19 breaking changes that affected the `gpt-2` package, forcing its developers to migrate manually to support version 2.0 of `tensorflow`, we were able to model 14 successfully. The changes we were unable to model relate to the refactors of `tensforflow` between the two versions, that essentially force the developer to re-structure (and not just rewrite) their code – and our approach does not provide any mechanism for specifying such changes (i.e. clients must always migrate manually). The most relevant example in this case study is the removal of the `tf.multinomial` method. The migration guide points client developers to use another method instead, `tf.random.categorical`. This change can be modelled in our approach by providing a method lens for the `tf.multinomial` method from version 1 to version 2, and implement the lens to use the `tf.random.categorical` method instead.

emoji. Version 2 of the `emoji` package introduces 2 breaking changes, one of which affects the client package `ntfy`. This change involves removing a boolean parameter, `use_aliases`, which defaults to `False`, from method `emojize`. In version 2, client developers should pass `language='alias'` instead of `use_aliases=True`. Our approach is able to model this successfully, by defining a method lens for `emojize` that passes the appropriate value to `language` depending on the value of `use_aliases`. As such, the client package does not need to manually refactor to use the new version.

metaapi-python-sdk. The 2 breaking changes introduced in version 23 of this package involve the rename of a method (`enableMetastatsHourlyTarification` is renamed to `enableMetaStatsApi`), and the rename of a field (`metastatsHourlyTarificationEnabled` is renamed to `metastatsApiEnabled`). Both are supported in our setting and can be successfully implemented, by using a method and a field lens respectively, to allow clients to migrate without refactor.

netbox. Out of the 5 breaking changes introduced in version 3.6, we were able to model 4. The change we were unable to model concerns a dependency (PostgreSQL) that must be upgraded. Since we do not yet support versioning of modules, this is not possible in our setting. The remainder of the changes involve: renaming a field (`device_role` field on the `Device` class is renamed to `role`); changing the name and type of a field

¹⁰When determining the number of breaking changes, we ignored some which fall outside of the scope of this work, particularly when concerning external dependencies.

(field `choices` from the `CustomField` class is renamed to `choice_set`, and its type is changed from a dictionary to `CustomFieldChoiceSets`); removing fields from a class (fields `napalm_driver` and `napalm_args` are removed from the `Platform` class); and changing the return type of a method (reports and scripts are returned within a `results` list). All of these were successfully modelled in our setting.

twillio-python. Out of the 17 breaking changes introduced in version 8, we were able to model 14. The changes we were unable to model concern the renaming of classes: class `ConversationsGrant` is replaced by `VoiceGrant`; and class `IpMessagingGrant` is replaced by `ChatGrant`). We can not model such cases since our type system restricts method lenses (in this case, the constructor method `__init__`) to return the same type as the original definition¹¹. The remainder of the changes involve renaming methods (12 instances) and changing the signature of a method, by removing a parameter (2 instances). All of these were successfully modelled in our setting.

4.3 Evaluation answers

From the results presented in the previous section, we answer the research questions with:

RQ1. Yes, library developers can mitigate (and in some cases, eliminate) the occurrence of breaking changes using our approach.

RQ2. Yes, in most cases clients can update without refactoring their code manually.

5 Related work

Program slicing. In his seminal paper, Weiser [31] describes program slicing as a method for automatically decomposing a program, starting from a subset of its behaviour, and reducing it to a minimal form which still produces that behaviour. This technique is employed in many software engineering activities such as debugging, testing, maintenance and parallelization.

Komondoor et al. [16] propose using slicing to identify duplication in source code, by using program dependence graphs and program slicing to find clones (instances of duplicated code) that are then displayed to the programmer. In the same thread, Gupta et al. [11] suggest a new approach for locating faulty code, with the use of a delta debugging algorithm to identify a minimal failure-inducing input which is then used to compute a forward dynamic slice that is intersected with the statements in the backward dynamic slice of the erroneous output, to compute a failure-inducing chop.

More recently, Maras et al. [18] have applied program slicing to extract the code implementing a certain behaviour for a client-side web application, based on a web page dependency graph. Maruyama et al. [19] propose a slicing mechanism to extract code changes necessary to construct a particular class member of a Java program, based on the history of past code changes which are represented by edit operations recorded on source code of a program, helping programmers avoid replaying edit operations that are non-essential to the construction of class members they are analysing.

To the best of our knowledge, ours is the first attempt to use slicing techniques to handle program variability and versioning.

Update programming. Erwig and Ren [9], Apel and Hutchins [3] introduce an extension to Haskell that supports update programming, where a program is an abstract data type whose building blocks are language terms. They provide a mechanism to script changes in

¹¹This is detailed later on, in section 6.

programs, creating new terms and changing existing ones. Hazelnut [24] is a core calculus that builds on typed “holes” and a gradual type theory that features a type system for expressions with holes and a language of edit actions ensuring that every edit state has static meaning. Both these approaches allows for progressive program construction, as well as giving semantic meaning to incomplete code. We maintain the history of programming versions, well-formed by construction, instead of defining semantics for partial programs [25]. Such history is a guide to the program slicing procedure in VFJ, unlike others where an edit calculus is needed to understand changes ([19]).

Delta-oriented programming. Schaefer et al. [28] introduce DOP, a programming language for designing software product lines based on the concept of program deltas. The implementation of software product lines is divided into a core module, comprising a complete valid product, and a set of delta modules, changes to be applied to the core module to target other products/variations. The language further ensures that all product variations are well typed.

Multiversion systems analysis. The analysis of multiversion systems is usually a project management activity that tries to detect change patterns in the code, and assessing risks of interference between development threads that may result in the introduction of vulnerabilities [14], code repetition [15] and maintenance hurdles [4, 13, 8, 30], and the other difficulties in the management of multiple versions [10, 34, 12, 29]. Our approach acts preventively by detecting illegal evolution steps in the development history and also complements update and delta oriented programming approaches [2, 9, 28] by recording a modification history and allowing (legal) branching in the code base.

6 Limitations and future work

Support for versioned modules. Currently, we do not support versioning of modules. In doing so, we would be able to 1) declared versioned elements at the module level (e.g. functions, constants, variables) and 2) defined versioned imports of packages (i.e. at some version v , we want to import version t of package p). The main challenge is devising a syntax for declaring a module-level version graph (since we use decorators, which are only valid for classes and functions), and devising a syntax for versioned imports.

Structural typing for lenses. Currently, the type system requires that method lenses return the same type (or a subtype) of the original method definition. This forbids us from, for example, defining a lens to rename a class C to D (which would be reflected on the lens of `__init__` method of C , by returning an object of type D). Since our type checker uses nominal sub-typing, this is not possible (since D is not syntactically declared as a subtype of C). As such, we intend to define a structural sub-typing discipline for method lenses.

Inlining for lenses. The rewriting procedure for methods and fields replaces their occurrences with calls to the corresponding lenses. However, from the experiments we conducted, it’s clear that these are, more frequently than not, single line expressions (e.g. when renaming a method argument, or renaming a field). To declutter and optimize the resulting slice, we intend to implement an `@inline` decorator for lenses whose body is a single return statement, to indicate that the lens can be inlined instead of rewriting to a function call.

Version-aware development environment. From a user experience perspective, we believe this approach is not yet suitable for adoption. As such, we intend on implementing tools for a version-aware development environment that would automate most of the common refactoring practices (e.g. moving a method, renaming a field). We are working on an extension for VS-Code to do so, and also plan on extending `rope`, a refactoring library for Python, to account for refactoring of versioned programs. Ideally, the developer would

apply the refactor from the extension in the IDE, and the versioned program would be changed accordingly to include the proposed refactor (for instance, renaming a method would introduce a new definition and its corresponding lens).

7 Conclusions

We build on prior work that presents a language-based approach for a version control system incorporating semantic knowledge of the evolution steps in the code and allowing code sharing and reuse across versions of a software product. We extend it with support for method transformations, and for state and side-effects in an imperative setting.

We instantiate this approach in a large subset of the Python programming language, and demonstrate its applicability by evaluating it against different versions of popular Python packages. We show that this approach is suitable for capturing common software evolution steps, rich versioning workflows, and streamlining the delivery of a snapshot for a given version. We provide a type system to detect conflicts and unintended breaking changes, that operates on a semantic level on top of the entire version graph and its classes, and a slicing compiler to extract the Python code targeting a single version.

Abstract

Call graphs play a crucial role in analyzing the structure and behavior of programs. For JavaScript and other dynamically typed programming languages, static call graph analysis relies on approximating the possible flow of functions and objects, and producing usable call graphs for large, real-world programs remains challenging.

In this paper, we propose a simple but effective technique that addresses performance issues encountered in call graph generation. We observe via a dynamic analysis that typical JavaScript program code exhibits small levels of indirection of object pointers and higher-order functions. We demonstrate that a widely used analysis algorithm, wave propagation, closely follows the levels of indirections, so that call edges discovered early are more likely to be true positives. By bounding the number of indirections covered by this analysis, in many cases it can find most true-positive call edges in less time. We also show that indirection-bounded analysis can similarly be incorporated into the field-based call graph analysis algorithm ACG.

We have experimentally evaluated the modified wave propagation algorithm on 25 large Node.js-based JavaScript programs. Indirection-bounded analysis on average yields close to a 2X speed-up with only 5% reduction in recall and almost identical precision relative to the baseline analysis, using dynamically generated call graphs for the recall and precision measurements. To demonstrate the robustness of the approach, we also evaluated the modified ACG algorithm on 10 web-based and 4 mobile-based medium sized benchmarks, with similar results.

1 Introduction

The construction of accurate call graphs is crucial for various static analysis tasks. Call graphs provide a comprehensive representation of the calling relationships between functions, enabling analysis techniques such as vulnerability and bug detection, program comprehension, and refactorings [7, 20, 18, 3, 29]. Static call graph analyzers aim to over-approximate, meaning that they may include false positives, i.e., unexecutable call edges. Analysis time

10:2 Indirection-Bounded Call Graph Analysis

tends to correlate with the number of call edges produced, so improving precision can also improve analysis time. Although soundness is desirable, all existing practical whole-program analyses by design sacrifice some amount of soundness to achieve useful precision and scalability [15]. This perhaps makes them unsuitable for code optimization purposes, but other use cases can tolerate false negatives (e.g., many bug finding and vulnerability detection tools aim to expose issues but not to prove their absence). Nevertheless, achieving high accuracy and low analysis time for large, real-world programs is challenging due to the inherent complexity of call graph generation. Analysis time is often prohibitively large, so it is important to explore new approaches that can substantially reduce analysis time even if the price is slightly more false negatives.

As JavaScript has both objects and functions as first-class values, and it has no static type system, constructing call graphs for JavaScript programs generally requires reasoning about the possible flow of objects and functions through the program being analyzed. Functions frequently appear both as arguments and return values of other functions and as values of object fields. State-of-the-art call graph analyzers for JavaScript are based on subset-based flow-insensitive analysis techniques [2]. Objects are typically modeled using allocation-site abstraction [20, 6], or more coarsely using field-based analysis [7, 8]. Functions are tracked using variations of control-flow analysis [17]. In general, the analyses can be expressed using conditional subset constraint systems, which are solved using cubic-time algorithms [21, 25].

Such algorithms build a call graph for a given program iteratively until a fixpoint is reached. Iteration is necessary because of indirections that may occur. For example, if a higher-order function f contains a call $g(\dots)$ to a function that is provided via a parameter g of f , then the call edges for that call site cannot be resolved until the analysis has inferred the calls to f . Similarly, the possible values at an object field read operation $x.a$ generally cannot be obtained until the analysis has inferred which objects x may reference. Different analysis algorithms solve the analysis constraints in different orders, but there is one algorithm, the wave propagation algorithm by Pereira and Berlin [21], that directly follows the levels of indirections, as we explain in detail in Section 4. That algorithm was designed for points-to analysis but is also well suited for call graph analysis.

Interestingly, in real-world code, we observe that function values typically do not flow through many levels of indirection, which means that call graph analysis only needs few iterations to infer most of the possible call edges. In Section 2 we show that creating call graphs for higher-order functions (if not involving objects) requires only as many iterations as the maximum order of the functions, and a similar property holds when objects are involved. Therefore, when wave propagation-style analysis has reached a certain number of iterations, all call edges that are discovered after that point must be false positives that arise only due to analysis imprecision (assuming an idealized sound analysis). Thus, simply by terminating the wave propagation algorithm after a fixed number of iterations, we can reduce analysis time while only missing the relatively few call edges that involve high levels of indirection. This also works when objects are involved; however, due to the asymmetric nature of field read and field write operations (see Section 2) it is beneficial to leave analysis constraints for field read operations and method calls unbounded. This is the first work to utilize observations about low levels of indirection in data flows to achieve a more scalable static analysis.

Another program analysis technique that has proven effective for JavaScript programs is the approximate call graphs (ACG) algorithm of Feldthaus et al. [7]. This algorithm applies field-based analysis, meaning that objects are modeled more abstractly, which generally leads to faster but also less accurate analysis compared to techniques that use allocation-site abstraction of objects. We demonstrate that the ACG algorithm can also easily be adapted to indirection-bounded analysis.

The proposed approach is inspired by the recent work of Mathiasen and Pavlogiannis [16] on the complexity of Andersen’s pointer analysis. One of their key results is that a version of pointer analysis where the number of store operations (corresponding to field write operations in our setting) in witnesses of points-to relations is bounded can be solved in sub-cubic time. They conjecture that the level of indirection of store operations is typically small in practice, but they have left the practical realizations and an experimental evaluation for future work, which we explore here in the context of call graph analysis for JavaScript.

Compared to ad hoc approaches to reduce analysis time, for example, stopping analysis after a time-out, the proposed indirection-bounded approach gives more predictable and interpretable outcomes because of the connection to the program semantics. That is, the results of indirection bounding under a particular bound are deterministic, and one can give a precise semantic characterization of the types of data flows that will be missed due to the bound. Also, instead of tuning time-outs for individual programs, indirection-bound analysis gives good results with a fixed bound applied uniformly for all programs.

In summary, the contributions of this paper are:

- We propose the use of *indirection-bounded* analysis (Section 4) for achieving faster call graph analysis while with little sacrifice in recall, which can be a useful compromise when analyzing large, real-world programs.
- We demonstrate via a dynamic analysis (Section 3) that typical JavaScript programs tend to exhibit small levels of indirections of object pointers and higher-order functions, thereby semantically justifying the use of indirection-bounded analysis.
- By incorporating indirection-bounded analysis into an existing state-of-the-art call graph analyzer for JavaScript that uses the wave propagation algorithm, we present experimental results (Section 5) on 25 large open source programs, showing that the approach on average (geometric mean) results in a 2X speed-up of the analysis with only 5% reduction in recall (and nearly identical precision) relative to the baseline analysis when using dynamically generated call graphs for measuring recall and precision. For many use cases, this can be a valuable trade-off between analysis time and recall. Applying the technique on 10 web-based and 4 mobile-based medium-sized benchmarks using the modified ACG algorithm similarly resulted in an approximately 2X speed-up in analysis time, with only a 1% reduction in recall (again with nearly identical precision).

2 Motivating Examples

In a call graph, call sites and functions are represented as nodes, and a directed edge from node a to node b indicates that call site a may invoke function b at runtime. Sometimes, individual call sites are abstracted by their enclosing function, so that the call edges are from functions to functions.

The accuracy of a call graph construction technique can be measured by its precision and recall relative to the (noncomputable) semantically correct call graph for a given program, or using a call graph produced via one or more dynamic executions of the program as an approximation. (A sound analysis will have perfect recall, but as noted in Section 1, practical analyses are not fully sound.) Different use cases have motivated different metrics in the literature [5]. With the *call site targets* metric [7], precision for a specific call site is computed as the percentage of true (i.e., semantically possible) call targets among those predicted by the static analysis, and recall is the percentage of predicted targets among the true targets. The precision and recall for an entire program are then computed as the averages over all call sites that are semantically reachable. A variant is the *call edge sets* metric [30], which computes precision and recall by comparing the sets of call edges produced by the static

analysis and the dynamic analysis. The *reachable functions* metric [26] and the *reachable edges* metric [10] instead compare the sets of functions or call edges, respectively, that are reachable from the program entry points (e.g., application modules).

Figures 1 and 2 contain five small example JavaScript programs that illustrate the indirections that can arise when computing call graphs. The red edges show the call edges, pointing from call sites to functions. In Figure 1a, function `f5` is a higher-order function, which is called at line 14 with `f4` as argument. The function `f4` is itself a higher-order function that is then called at line 12 with `f3` as argument, etc., until finally line 3 calls `f1`. In other words, `f5` is a 5'th-order function, `f4` is a 4'th-order function, etc. This means that the call edge from the call site marked `#1a` must be discovered before the call edge for `#2a`, etc., until after a total of 5 indirections have been resolved, the call edge for `#5a` can be found. Figure 1b shows a similar example of a 5'th-order function where also 5 levels of indirections arise, but this time due to return values rather than arguments. As we explain in Section 4, analysis algorithms like wave propagation [21], ACG [7], or 0-CFA [24] can compute the call graphs for these programs in 5 iterations. 5'th-order functions are not common in real-world code, which we can exploit to terminate analysis early and save time without risking too many missed call edges (i.e., false negatives).

A similar situation arises when objects and field access operations are involved. In Figure 2a, lines 25–28 set up a simple object structure. The variables `f1`–`f5` all refer to the same function in this case, but via different levels of indirections. Specifically, discovering the call edge for `f5` at call site #5c requires 5 levels of indirection because of the chain of field reads at line 33. Such long chains of field reads operations (sometimes split into smaller parts with variables holding intermediate results) are not uncommon in real-world code, which is why we give special treatment to these operations in the following sections.

On the other hand, it is perhaps less obvious how field write operations can lead to high levels of indirections. Figure 2b shows an example where call site #5d has 5 levels of indirection. That call site cannot be resolved until the analysis has discovered that `x0.f4` is an alias of `x0`. This in turn requires discovering that the field write on the previous line updates `x0.f4`, since `x0` and `x3` are aliases, and so on through each of the aliasing relations established by the preceding lines.¹

Finally, Figure 2c shows an example with chains of method calls, combining objects and functions. Since each method call consists of a pair of a field read and a function call, this example involves a total of 10 levels of indirection to resolve call site #5e. As with chains of field reads, this pattern is also common in real code (e.g., with fluent interfaces [9]), which suggests that method calls should be treated in the same way as field reads in indirection-bounded analysis.

3 Dynamic Indirection Bound Estimation

To confirm the intuitions from Section 2 regarding the depth of indirections encountered in real code, we designed a dynamic analysis to estimate the *minimum indirection bound* required for a static analysis to discover each function call observed during execution. With this dynamic analysis, we can observe the true bound under which function values flow to their invocations in an execution, independent of any static analysis limitation or approximation. If these minimum indirection bounds are observed to typically be low, that provides good evidence that using low indirection bounds in a static analysis will preserve most analysis recall. Here we present the design of the dynamic analysis and give results from a study across a large set of benchmarks.

3.1 Language

The first column of Table 1 defines the types of canonical statements in a core language. (The constraint rules in the second column will be explained in Section 4.1.) The statement types are standard for a flow- and context-insensitive Andersen-style points-to analysis [2] for a JavaScript-like language. A program is a set of functions, each of which contains statements of the types shown in the table (more complex assignments and expressions can be normalized to these forms via temporary variables). We elide details of standard language constructs like conditionals, loops, etc., as they are not relevant given our focus on flow-insensitive static analysis. We assume for simplicity that local variable names are unique across functions.

The values in the language are either object values, written `{}` (like a JavaScript object literal) or (first-class) function values, written `p => ...` (using JavaScript arrow syntax). Without loss of generality we assume every function has one parameter and returns some

¹ One might expect that nested object initialization would yield a high level of indirections via field writes, e.g.: `x = { f: ... }; y = {};` `z = {};` `y.b = x;` `z.a = y;` `z.a.b.f();` But, this code has only *one* level of indirection due to field writes, as objects are copied to the base variables for all field writes without indirection. The indirection level due to field reads is 3, due to the call.

Table 1 Statement types for our analysis and the corresponding static analysis constraint rules (discussed in Section 4).

Statement Type	Constraint Rule
$x = \{ \}_i$	$\{o_i\} \subseteq pt(x)$
$x = p \Rightarrow_i \{ \dots \}$	$\{f_i\} \subseteq pt(x)$
$x = y$	$pt(y) \subseteq pt(x)$
$x = y.f$	$\frac{o_i \in pt(y)}{pt(o_i.f) \subseteq pt(x)}$
$x.f = y$	$\frac{o_i \in pt(x)}{pt(y) \subseteq pt(o_i.f)}$
$x = y(z)$	$\frac{f_i \in pt(y) \quad pt(z) \subseteq pt(p_i) \quad pt(ret_i) \subseteq pt(x)}{pt(z) \subseteq pt(p_i) \quad pt(ret_i) \subseteq pt(x)}$
$\text{return}_i x$	$pt(x) \subseteq pt(ret_i)$

value. The first two statement types respectively allocate a new object or new function value and assign it to a variable; each such statement has a unique label i . An $x = y$ statement copies between variables. For object fields, $x = y.f$ loads field f and $x.f = y$ stores to field f . We assume a JavaScript-like semantics where writing to a non-existent object field f creates f on the object (obviating the need for field declarations). Finally, we have $x = y(z)$ statements for calling functions, and $\text{return } x$ statements for returning values. The label i on each return statement identifies the containing function.

3.2 Dynamic Analysis

Here we present our dynamic analysis to estimate minimum indirection bounds. The analysis does not provide an exact value for these bounds; it may under-estimate due to lack of input coverage or unhandled language features, and it may over-estimate due to an imperfect simulation of the static analysis. Still, we have found its results to be accurate in practice (via manual inspection) and useful for understanding indirection levels in real programs.

Algorithm 1 gives pseudocode for our dynamic analysis. We assume the analysis is implemented via an interface similar to that provided by frameworks like Jalangi [23], where a callback provided by the analysis is invoked before and possibly after the execution of each program statement. In Algorithm 1, the callback is the `HANDLESTMT` procedure. For all statement types, we assume `HANDLESTMT` is invoked before the statement s executes, except for calls $x = y(z)$, where we require the callback both before and after (to respectively handle parameter passing and returns).

The dynamic analysis relies on a function α that given an expression e , first evaluates e to a value v and then returns the allocation site for v (i.e., the label of the statement that allocated v). The dynamic analysis tracks bounds for allocation sites instead of individual dynamic values to match the finite abstraction of values typically used by static call graph builders. For readability, in the remainder of this section we refer to values and their allocation sites interchangeably.

Algorithm 1 Dynamic bounds estimation.

```

1: SELECTIVE: boolean
2:  $V$ : map from variable and value to indirection level bound
3:  $F$ : map from object field and value to indirection level bound
4: procedure HANDLESTMT( $s$ )
5:   match  $s$ 
6:     case  $x = \{ \}_i$  or  $x = p \Rightarrow_i \{ \dots \}$ :
7:        $V[x, i] \leftarrow 0$ 
8:     case  $x = y$ :
9:        $v \leftarrow \alpha(y)$ 
10:       $V[x, v] \leftarrow \min(V[x, v], V[y, v])$ 
11:    case  $\text{return}_i x$ :
12:       $v \leftarrow \alpha(x)$ 
13:       $V[\text{ret}_i, v] \leftarrow \min(V[\text{ret}_i, v], V[x, v])$ 
14:    case before  $x = y(z)$ :
15:       $f_i \leftarrow \alpha(y), v \leftarrow \alpha(z)$ 
16:       $t \leftarrow \max(V[y, f_i] + 1, V[z, v])$ 
17:       $V[p_i, v] \leftarrow \min(V[p_i, v], t)$ 
18:    case after  $x = y(z)$ :
19:       $f_i \leftarrow \alpha(y), v \leftarrow \alpha(\text{ret}_i)$ 
20:       $t \leftarrow \max(V[y, f_i] + 1, V[\text{ret}_i, v])$ 
21:       $V[x, v] \leftarrow \min(V[x, v], t)$ 
22:    case  $x = y.f$ :
23:       $b \leftarrow \alpha(y), v \leftarrow \alpha(y.f)$ 
24:      if SELECTIVE then
25:         $t \leftarrow \max(V[y, b], F[b.f, v])$ 
26:      else
27:         $t \leftarrow \max(V[y, b] + 1, F[b.f, v])$ 
28:       $V[x, v] \leftarrow \min(V[x, v], t)$ 
29:    case  $x.f = y$ :
30:       $b \leftarrow \alpha(x), v \leftarrow \alpha(y)$ 
31:       $t \leftarrow \max(V[x, b] + 1, V[y, v])$ 
32:       $F[b.f, v] \leftarrow \min(F[b.f, v], t)$ 
33:  end match
34: end procedure

```

Algorithm 1 computes two maps, V and F . The V map records for each variable x and value v the minimum observed indirection bound under which v flowed to x in the execution. Retaining only the minimum bound for each variable x and value v makes sense for our use case, as a sound static analysis models all possible data flows, and hence would discover the flow of v to x under that minimum bound. F is similar but is keyed on object fields $b.f$, where b is a value and f is a field name. After the analysis completes, the minimum observed indirection bound for discovering that call $x = y(z)$ invokes function f is simply $V[y, f]$.

We now describe the handling of each type of statement in turn. For a creation of an object or function at allocation site i (line 6), $V[x, i]$ is set to 0, as the flow does not involve any indirections. For an assignment $x = y$ (line 8), where v is the value of y , $V[x, v]$ is set to be the minimum of its current value and $V[y, v]$ (since we aim to find minimum observed indirection bounds). Return statements (line 11) are handled just like assignments, updating the bound for the synthetic ret_i variable for the enclosing function.

10:8 Indirection-Bounded Call Graph Analysis

The next case (line 14), handling parameter passing, is the first involving an indirection, here via a call. Here, f_i is the function value being invoked, and v is the value of the parameter. Recall from the discussion of Figure 1a in Section 2 that to discover data flow into a formal parameter from a call site, the analysis must first discover the data flow of the invoked function to the call; the parameter flow occurs at an increased indirection level. Hence, to discover the parameter data flow from this call, the indirection bound must be at least $V[y, f_i] + 1$. Note that finding the flow also requires discovering that v flows to actual parameter z , so the true bound for this flow is the maximum of these two flows (line 16). Finally, line 17 updates the bound for formal parameter p_i to be the minimum observed thus far. Handling of the return value after a call completes (line 18) is analogous to handling of parameters.

Handling of field reads (line 22) and field writes (line 29) is also similar to that for parameter passing. Here, as discussed in Section 2, the increase in indirection level occurs because the static analysis must first observe the data flow of the relevant object into the base variable of the dereference. For both reads and writes, the base object is named b in the pseudocode, and we add 1 to the bound for the flow of b to the statement in each case (line 27 for reads, line 31 for writes). Recall from Figures 2a and 2b that writing code with a high indirection level for field reads is more natural than doing the same for field writes. Accordingly, the pseudocode has a flag `SELECTIVE` to control whether reads should be treated as bounded when computing estimates. If `SELECTIVE` is true, reads are not treated as bounded, and 1 is *not* added to the bound for the flow of b to the base variable y (see line 25). In our implementation, `SELECTIVE` also controls bounding of method calls; this is not shown in Algorithm 1 since our core language (Table 1) contains only function calls (with no receiver argument), not method calls.

Algorithm 1 may over-estimate the bounds required of a static analysis since it does not propagate information from later assignments to previous calls. Consider this JavaScript example:

```
1 x = function f1() { ... };
2 y = /* some flow with minimum bound 2 yielding f1 */
3 z = y;
4 z();
5 y = x;
```

After Algorithm 1 completes, $V[z, f_1]$ will be 2, since f_1 was initially copied to y via a flow of bound 2 (line 2) and then copied to z . However, due to line 5, there exists a flow of f_1 to y with bound 0. The algorithm updates $V[y, f_1]$ accordingly, but does not propagate this update to $V[z, f_1]$. This issue could be addressed by tracing the execution operations and computing a fixed point over that trace; we used the single-pass approach as we did not observe this over-estimation to occur in practice.

3.3 Study Results

Here we present results of applying our dynamic analysis to a suite of Node.js benchmarks to measure minimum indirection bounds in practice.

Implementation. We implemented the analysis atop the NodeProf framework for Node.js dynamic analysis [28]. For scalability, we separated the analysis into a trace generation phase that runs during program execution, followed by a post-processing phase to compute the bounds. For trace generation, NodeProf does not invoke a single callback for assignments, but instead invokes separate callbacks for reads and writes of both variables and object fields. To adapt Algorithm 1 to this structure, we maintain an additional map S from each value

Table 2 Number of call edges with each minimum bound across all benchmarks, for configurations with SELECTIVE enabled and disabled, respectively.

Configuration	0	1	2	3	4	5	6	7	8	9	10-19	20+
SELECTIVE enabled	40,087	16,560	5,958	2,207	356	29	16	-	-	-	-	-
SELECTIVE disabled	37,589	10,064	5,825	3,610	2,214	1,705	992	442	644	676	1,311	141

v to the bound t for v corresponding to the location (variable or field) from which it was most recently read. Then, t is used when updating the bound at the next variable or field write. So, for a statement $x = y$, the analysis first sees a read of v from y , and it sets $S[v]$ to $V[y, v]$. Then, when handling the subsequent write of v to x , it uses $S[v]$ instead of $V[y, v]$ for the bound update (line 10 in Algorithm 1).

Benchmarks and methodology. We created a suite of 74 Node.js benchmarks for our study, as no standard benchmark suite was available. These were randomly selected among the top 1,000 highest ranked JavaScript projects on GitHub which both had unit tests available and that worked correctly with our dynamic analysis infrastructure and implementation. We exercised each benchmark by running its unit test suite. In total, these runs executed calls at 60,601 distinct call sites.

Results. Table 2 gives the results from our study. We present results for two configurations. The first is our preferred configuration, with SELECTIVE enabled, so reads and method calls are treated as unbounded. The second row gives results when all indirections are bounded. Each column shows how many dynamic call graph edges (from call site to callee function) could be discovered within that bound. The numbers are aggregated across all the benchmarks, for a total of 65,213 call edges (greater than the number of distinct call sites, since some sites invoke different functions on different execution paths).

The results show that in both configurations, most call graph edges can be found within a small bound; more than 57% of edges are discoverable within a bound of 0, i.e., the function data flow involves no indirections. Note, however, that with SELECTIVE enabled, significantly more edges are discoverable within bound 1 (6,496 more than with SELECTIVE disabled), and the long tail of call edges with minimum bound 7 or higher is eliminated. In fact, with SELECTIVE disabled, we discovered calls with a bound as high as 75. This result confirms the intuition from Section 2 that long chains of field reads and method calls can occur regularly in real-world programs, justifying special handling.

Overall, the data from our study provide promising evidence that an indirection-bounded static analysis could discover most true call graph edges within a small bound. For the SELECTIVE configuration, roughly 96% (62,605 / 65,213) of calls are reached within bound 2. These insights guided our static analysis design, described in Section 4.

Examples. For the configuration with SELECTIVE enabled, below is an example of a call that involves 4 levels of indirections, from the `express-react-views` benchmark (heavily simplified for readability). Calls that require even higher indirection bounds are rare, as depicted in Table 2, and are challenging to extract due to their complexity.

10:10 Indirection-Bounded Call Graph Analysis

```

1 // in async.js library
2 function series(tasks) {
3     /*0*/_parallel(eachOfSeries, tasks);
4 }
5 function _parallel(eachfn, tasks) {
6     /*1*/eachfn(tasks, function cb1(task) {
7         /*3*/task(function cb2() {});
8     });
9 }
10 function eachOfSeries(tasks, task_cb) {
11     for (var task of tasks) { /*2*/task_cb(task); }
12 }
13 // in client code
14 /*0*/series([function f(next) { /*4*/next(); }]);

```

The `async.js` library provides a function `series` for running all task callbacks in a provided array. Internally, this functionality is implemented using layers of higher-order functions, leading to the high bound. The calls above are commented `/*0*/` through `/*4*/` to show their bounds. The layered implementation inside `async.js` does enable code reuse within the library, but it leads to convoluted and hard-to-understand control flow, as shown above. As the data in Table 2 show, calls like these requiring bound 4 or greater are quite rare across our benchmarks (only 0.6% of call edges).

In contrast, with `SELECTIVE` disabled, natural code patterns can lead to high bounds, as discussed in Section 2. For example, consider the following code from the `express` benchmark:

```

1 block.paragraph = edit(block._paragraph)
2     .replace('hr', block.hr) /*2*/
3     .replace('heading', '{0,3}#{1,6}+') /*4*/
4     .replace('lheading', '') /*6*/
5     .replace('blockquote', '{0,3}>') /*8*/
6     .replace('fences', '{0,3}({:{3,}|~{3,}})[^\n]*\n') /*10*/
7     .replace('list', '{0,3}({:[*+-]|1[.])}') /*12*/
8     .replace('html', '</?({:tag}({:+|\n|?})|<({:script|pre|style!--})') /*14*/
9     .replace('tag', block._tag) /*16*/
10    .getRegex(); /*18*/

```

This code uses a fluent interface [9]: the `edit` and `replace` methods both return `this`, allowing for chaining of method calls. Each step in the chain involves a field read (to access the method) followed by a call, thereby adding 2 to the minimum bound for this configuration. So, the final call to `getRegex` has 18 levels of indirection. We studied calls with higher bounds and found that they involved a complex mix of field reads and method calls, often spread across multiple functions and files.

4 Indirection-Bounded Call Graph Construction

In this section, we present static call graph construction algorithms that allow for indirection bounding. We first describe a constraint-based formulation of the wave propagation algorithm [21] (Section 4.1), and then present a simplified version for solving the constraints (Section 4.2). In Section 4.3 we extend the algorithm with indirection bounding. Finally, in Section 4.4 we show how further simplifications yield a bounded version of the ACG algorithm of Feldthaus et al. [7]. The static analyses presented in this section work independently of the dynamic analysis presented in Section 3. The purpose of the dynamic analysis was to provide evidence and insights that support the static analysis design by showing how indirection works in different scenarios. This semantic justification helps validate the conclusions drawn from static analysis and ensures the bounding approach is reliable.

4.1 Analysis Formulation

The second column of Table 1 gives constraint rules for computing an Andersen-style points-to analysis for our statement types. The rules are standard; see [25] for a more detailed description. The constraints define what values (objects or functions) must be present in the points-to set of each variable and object field. Given a solution to the constraints, a call graph can be extracted by adding an edge from each call site $x = y(z)$ (or from the function containing the call site) to each function $f_i \in pt(y)$.

Concrete values are abstracted using allocation sites; we write o_i or f_i for an object or function, respectively, allocated at site i . As in the dynamic analysis formulation (Section 3.2), we assume a formal parameter variable p_i and a return variable ret_i for each function f_i . The constraints for field read, field write, and call statements are *conditional* constraints [1] – they each impose new subset constraints based on the contents of another points-to set. For example, the constraint for $x = y(z)$ checks if f_i is present in $pt(y)$, which indicates that $y(z)$ may invoke f_i . In this case, new subset constraints are imposed to capture the data flow from actual parameter z to formal p_i and from the returned value ret_i to x . These conditional constraints correspond directly to the notion of indirections discussed in Sections 2 and 3. Our approach implements indirection bounds by bounding the handling of these conditional constraints, leveraging the structure of the wave propagation algorithm, to be described next.

4.2 Simplified Wave Propagation

Algorithm 2 presents pseudocode for a simplified version of the wave propagation algorithm [21], the basis of our bounding technique. The pseudocode eschews many optimizations critical to the efficiency of the full wave propagation algorithm, including worklists, cycle elimination, and topological sorting. We simplify the pseudocode to clearly expose the two alternating phases of the algorithm, *propagation* and *edge addition*, the aspect of the algorithm most critical to bounding.

Algorithm 2 computes the points-to relation pt using a flow graph G . Each node in G represents a variable or an object field, and each edge $n \rightarrow n'$ in G represents a subset constraint $pt(n) \subseteq pt(n')$ from Table 1. The main entry point is the ANALYZE procedure at line 4.

The algorithm begins with the INIT procedure (line 12), which initializes pt and G based on the simple (non-conditional) constraints for value creation, variable copy, and return statements in Table 1. Then, at lines 6–11, the algorithm alternates between calls to PROPAGATE and ADDEGES until pt and G reach a fixed point. PROPAGATE (line 22) uses a fixed-point loop to ensure that for each edge $n \rightarrow n'$ currently in G , $pt(n) \subseteq pt(n')$. Then, ADDEGES (line 29) processes each field read, field write, and call statement and updates G with new edges based on the current value of pt and the corresponding conditional constraints in Table 1. The clean separation between propagation and edge addition is a key characteristic of wave propagation; it leverages this structure to efficiently eliminate cycles in the constraint graph and compute a topological ordering to minimize propagation work [21].

4.3 Adding Bounds

Given the structure of the wave propagation algorithm, adding bounding of all indirections is straightforward. Algorithm 2 already separates its handling of conditional constraints, which correspond to indirections, into the ADDEGES procedure. So, bounding indirections simply requires limiting the number of times that ADDEGES runs to be less than the bound. We have found that in real implementations that use the wave propagation structure, adding bounding is similarly straightforward.

10:12 Indirection-Bounded Call Graph Analysis

 **Algorithm 2** Simplified wave propagation algorithm.

```

1:  $P$ : program to analyze
2:  $pt$ : points-to relation, initially empty
3:  $G$ : flow graph, initially empty
4: procedure ANALYZE()
5:   INIT()
6:   repeat
7:      $pt' \leftarrow pt$ ,  $G' \leftarrow G$ 
8:     PROPAGATE()
9:     ADDEDGES()
10:    until  $pt' = pt \wedge G' = G$ 
11: end procedure
12: procedure INIT()
13:   for each  $x = \{ \}^i \in P$  do
14:      $pt(x) \leftarrow pt(x) \cup \{ o_i \}$ 
15:   for each  $x = p \Rightarrow_i \{ \dots \} \in P$  do
16:      $pt(x) \leftarrow pt(x) \cup \{ f_i \}$ 
17:   for each  $x = y \in P$  do
18:      $G \leftarrow G \cup \{ y \rightarrow x \}$ 
19:   for each  $\text{return}_i x \in P$  do
20:      $G \leftarrow G \cup \{ x \rightarrow \text{return}_i \}$ 
21: end procedure
22: procedure PROPAGATE()
23:   repeat
24:      $pt' \leftarrow pt$ 
25:     for each edge  $n \rightarrow n'$  in  $G$  do
26:        $pt(n') \leftarrow pt(n') \cup pt(n)$ 
27:     until  $pt' = pt$ 
28: end procedure
29: procedure ADDEDGES()
30:   for each  $x = y.f \in P$ ,  $o_i \in pt(y)$  do
31:      $G \leftarrow G \cup \{ o_i.f \rightarrow x \}$ 
32:   for each  $x.f = y \in P$ ,  $o_i \in pt(x)$  do
33:      $G \leftarrow G \cup \{ y \rightarrow o_i.f \}$ 
34:   for each  $x = y(z) \in P$ ,  $f_i \in pt(y)$  do
35:      $G \leftarrow G \cup \{ z \rightarrow p_i, \text{return}_i \rightarrow x \}$ 
36: end procedure

```

Recall that Section 3.3 showed that field reads often require higher bounds than other indirections, matching the intuition of Section 2. Algorithm 3 is a variant that only bounds indirections via field writes and calls, while leaving handling of field reads unbounded; the changes compared to Algorithm 2 are emphasized with blue (lines 4, 7 and 12). Variables *bound* and *i* are introduced, and only the ADDEDGES procedure of Algorithm 2 is modified. The modified code first adds edges to G based on field reads without checking the bound (lines 5–6). Then, field write and call statements are processed, but only if the field read processing added no new edges to G (the $G' = G$ check on line 7). If handling of reads adds new edges to G , then ADDEDGES returns without incrementing *i*, and another phase of propagation is run (see line 8). Hence, the algorithm only handles stores and calls and increments *i* (lines 8–12) once propagation and edge addition from field reads have iterated to a fixed point.

Algorithm 3 Algorithm 2 modified to bound indirections except for field reads.

```

1: bound: bound on indirections
2: i: current iteration, initially 0
3: procedure ADDEDGES()
4:    $G' \leftarrow G$ 
5:   for each  $x = y.f \in P, o_i \in pt(y)$  do
6:      $G \leftarrow G \cup \{o_i.f \rightarrow x\}$ 
7:   if  $G' = G \wedge i < bound$  then
8:     for each  $x.f = y \in P, o_i \in pt(x)$  do
9:        $G \leftarrow G \cup \{y \rightarrow o_i.f\}$ 
10:    for each  $x = y(z) \in P, f_i \in pt(y)$  do
11:       $G \leftarrow G \cup \{z \rightarrow p_i, ret_i \rightarrow x\}$ 
12:     $i \leftarrow i + 1$ 
13: end procedure

```

The $G' = G$ check on line 7 is crucial for getting the full benefit of unbounded field reads. Consider the following example:

```

1 var y = {...};
2 var x = y.a.b.c;
3 x.m = p => {...};
4 x.m(...);

```

We have three nested field reads at line 2 and one field write on the resulting object at line 3. With unbounded field reads, one would expect the call at line 4 could be discovered with an indirection bound of 1. But, without checking for $G' = G$ at line 7, the counter *i* for writes and calls would still be incremented while handling the reads, exhausting the bound before the relevant data flow from reads was discovered. Algorithm 3 discovers the call with *bound* = 1, as desired. In our implementation, constraints from JavaScript method calls (see Figure 2c in Section 2) are also handled in an unbounded manner, similar to handling of field reads in Algorithm 3.

4.4 Bounded ACG

The ACG algorithm of Feldthaus et al. [7] is a well-known technique for building JavaScript call graphs. ACG uses a field-based modeling of field accesses, unlike the field-sensitive formulation of Table 1. In ACG, reads and writes of object fields are modeled as assignments to and from global variables, and hence they do not introduce indirections for the analysis. Algorithmically, both the original ACG analysis and an indirection-bounded variant can be phrased as a simplified version of wave propagation. Pseudocode for indirection-bounded ACG is given in Algorithm 4; code related to bounding is again shown in blue (lines 12 and 15). The ANALYZE and PROPAGATE procedures (elided) are identical to those in Algorithm 2. Field reads and writes are now handled similarly to assignments in INIT (line 6). ADDEDGES is modified to remove all handling of field accesses. The only remaining indirections to handle in ADDEDGES are calls, as in 0-CFA [24]. Bounding is also simplified compared to Algorithm 3, as field reads do not require any special treatment.

5 Evaluation

We have implemented the techniques of Section 4 in two different analysis frameworks. The first, JELLY [19, 12], implements a field-sensitive call graph analysis using an algorithm like wave propagation [21], and is targeted at Node.js programs. The second, WALA [8], has

 **Algorithm 4** Bounded ACG algorithm [7], as a modified version of Algorithm 2.

```

1: bound: bound on indirections
2: i: current iteration, initially 0
3: procedure INIT()
4:   for each x = p =>i {...} ∈ P do
5:     pt(x) ← pt(x) ∪ {fi}
6:   for each x = y, x = z.y, or z.x = y ∈ P do
7:     G ← G ∪ {y → x}
8:   for each returni x ∈ P do
9:     G ← G ∪ {x → reti}
10: end procedure
11: procedure ADDEGES()
12:   if i < bound then
13:     for each x = y(z) ∈ P, fi ∈ pt(y) do
14:       G ← G ∪ {z → pi, reti → x}
15:     i ← i + 1
16: end procedure

```

an implementation of the ACG algorithm and is targeted at browser-based applications. We modified these implementations to optionally use bounding as described in Sections 4.3 and 4.4.

With these implementations, we performed an experimental evaluation to assess the effectiveness of indirection-bounded call graph construction. We designed our evaluation to answer the following main research questions:

1. How are *analysis running time*, *recall* and *precision* impacted by different values of the indirection bound?
2. How does bounding of field reads and method calls (disabling the SELECTIVE flag of Section 3.2) impact the overall effectiveness of the analysis?

5.1 Benchmarks

For Node.js benchmarks, we further filtered the benchmarks used in the dynamic study (Section 3.3) based on the following three criteria. Initially, we required the dynamic call graph to contain at least 50 call edges to provide a sufficient basis for comparing the precision and recall of the static call graph. Then, we required JELLY could compute a static call graph with a recall of at least 20% as compared to the dynamic call graph; this eliminated some benchmarks where JELLY analyzed only a small portion of the code (typically due to unsupported test frameworks). This criterion also eliminated cases where JELLY ran out of memory. Second, we required that JELLY took at least 15 seconds to analyze the benchmark; for benchmarks that can be analyzed quickly, there is no need for bounding.

This filtering led to a set of 25 benchmarks, whose details are given in Table 3. The benchmarks are large, with thousands of functions and ranging up to more than 9.8MB of code. For each benchmark, the table gives the numbers of packages, modules and functions, the code size, and the analysis time, precision, and recall for JELLY when run without bounding.

For assessing WALA, we constructed a suite of 14 web and mobile benchmarks, shown in Table 4. We included the 10 programs from the TodoMVC suite that were used by Chakraborty et al. in their study [4], and we re-used their test harness to exercise the programs. We also included four sample React Native applications, encompassing the starter

app, a to-do app, a chat app, and a bidding app, all gathered from GitHub. We chose apps we could run successfully in a simulator and that worked with our analysis infrastructure, and we manually developed a test harness for each to exercise the code. For these apps, we constructed call graphs for the final shipping version of the code, which is bundled as a single file; hence, package and module counts are omitted in the table. The mobile benchmarks are much larger and more complex than the web benchmarks, explaining the higher analysis times and lower recall for those programs. While some of the smaller benchmarks in this suite can be analyzed very quickly, we retained them in the suite due to the challenge of manually exercising dynamic behaviors in web and mobile apps.

5.2 Experimental Configuration

In our experiments we measure precision and recall using the call site targets metric described in Section 2, i.e., by comparing sets of possible call targets at call sites. We found that this metric most robustly captured the data flows discovered by the static analysis. We also experimented with the reachable functions and reachable edges metrics (see Section 2). These metrics showed similar trends as for the call site targets metric, but are also more fragile since discovery of one additional call graph edge sometimes dramatically impacts overall reachability, making the results harder to interpret.

Table 4 Web and Mobile benchmarks used for experiments with WALA.

Benchmark	#Pkgs	#Mods	#Funs	Code Size (kB)	Analysis Time (secs)	Precision (%)	Recall (%)
Vanillajs	2	8	131	30	0.32	90.13	98.64

We ran the JELLY experiments on a machine with an 8-core Intel Core i7-11700 processor and 32GB of RAM, running Ubuntu 20.04.6 LTS. For the WALA experiments we used a Google Cloud virtual machine with a 4-core Intel Broadwell Xeon CPU and 64GB RAM running Ubuntu 20.04.6 LTS.

5.3 Results

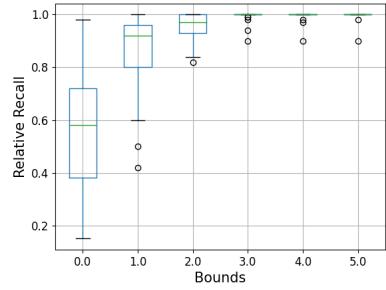

Figure 3 presents our main results for the JELLY experiments. For these experiments, field read and method call indirections were unbounded, the preferred configuration as discussed in Sections 2 and 3.3. The box plots give analysis time and recall relative to the unbounded JELLY analysis. The ideal for a bounded analysis would be to have recall as close to 1.0 as possible, so no recall is lost compared to unbounded, with analysis time as close to 0.0 as possible, maximizing performance. The analysis time data points sometimes extend above 1.0 primarily due to noise in the running time measurements. Additionally, the number of cycle elimination runs in wave propagation [21] can be affected by the use of different types of bounds in the analyzer. This variance can slightly increase or decrease overall analysis running time, depending on the number of cycles in the constraint graph.

Studying Figures 3a and 3b, indirection bound 2 gives the best balance of analysis time improvement and recall. The average analysis time speed-up is roughly 2X (ranging from 0.9X–23.9X), while the average relative recall is 95% (82%–100%) of the unbounded analysis. The high relative recall matches the results of our dynamic study (Section 3.3), where we observed that 96% of dynamic calls were discoverable within a bound of 2. At bound 1, recall loss is significant at 17%, whereas bound 3 shows a minimal recall loss of only 1%, although the analysis time increases significantly. At bound 2, the recall loss is moderate at 5%, offering a balance between recall and analysis time.

Figure 4 gives results for our WALA experiments. Here, we see that bound 1 yields a good overall trade-off, with a roughly 2X average speed-up (1.1X–21.4X) with an average relative recall of 99% (91%–100%). Bound 2 yields 99.99% relative recall on average with a smaller average speedup of 1.6X. We believe the higher recall numbers at lower bounds compared to JELLY are due to the fact that the ACG algorithm has fewer types of indirections

to bound (see Section 4.4), and hence more data flow is discovered within a lower bound. For the web benchmarks, the largest observed performance improvements were for the largest benchmarks (e.g., for React we saw a 21X improvement). It would be useful future work to evaluate bounding on a suite of larger web and mobile benchmarks, but exercising such benchmarks to get good coverage of dynamic behaviors can be challenging (due to many user interactions, server-side state, etc.).

Finally, Figure 5 gives data for our second research question, showing results for JELLY with all indirections bounded, including field reads and method calls. Here, the bound with the closest analysis time / recall trade-off to our main configuration is bound 5, with a relative recall distribution fairly similar to bound 2 in Figure 3b. However, at this bound we see some higher outliers in analysis time, ranging up to 89% of the unbounded analysis time. Further, as shown in Section 3.3, with this configuration there is a long tail of calls that require a much higher bound to discover; in Figure 5b, even at bound 5, there is one benchmark with relative recall below 80% and five below 90%. Given these considerations, and the naturalness of code patterns with high numbers of field read and method call indirections (Sections 2 and 3.3), we believe analysis with selective bounding is the better choice for more robust results.

Without indirection bounding, there were 31 benchmarks that could not be analyzed because they caused the analyzer to run out of memory. With indirection bounding, 7 of those benchmarks can be successfully analyzed without running into memory issues.

5.4 Threats to Validity

A threat to the external validity of our evaluation is our choice of benchmarks. For Node.js we chose a large set of realistic benchmarks in a principled manner (see also Section 3.3). For web and mobile we have smaller sets of benchmarks, due to challenges in exercising such benchmarks to collect dynamic data. It is possible that on other types of benchmarks, bounding will be less effective. Our results may also be internally invalid due to bugs in our implementation. We have a variety of regression tests to check correctness of our results and we have done extensive manual inspection of complex examples, reducing this threat. Finally, our choice of call site targets as the precision/recall metric is another threat to external validity. We chose this metric since it best measures the overall effectiveness of the static analysis in capturing function data flows. But, there could be scenarios where a client relies on certain critical edges being present in the static call graph, and those particular edges require a bound greater than 2 to discover. In such cases, a higher indirection bound (or other heuristics) would be required to produce a useful static call graph, leading to higher analysis time.

6 Related Work

The most closely related work is the recent study by Mathiasen and Pavlogiannis [16] on the complexity of different variants of Andersen’s classic pointer analysis. Most importantly, they presented an algorithm for solving Andersen-style pointer analysis instances with bounded numbers of store operations in witnesses of points-to relations, and proved that the algorithm runs in almost quadratic time. In comparison, the indirection-bounded analysis that is based on wave propagation or ACG remains cubic time for a fixed bound. As mentioned in Section 1, Mathiasen and Pavlogiannis conjecture that the level of indirection is typically small but without giving empirical evidence and without experimentally evaluating the effects on analysis time, precision and recall. Furthermore, their work focuses on a C-like language with field-insensitive analysis and without involving higher-order functions, whereas we consider field-sensitive hybrid call graph and pointer analysis for JavaScript. It remains an open problem whether their complexity results can be adapted to field-sensitive analysis. The algorithm and theoretical complexity results by Mathiasen and Pavlogiannis are based on Dyck reachability and matrix multiplications, whereas we base our approach on the wave propagation algorithm that is known to work well in practice. For example, wave propagation is used in the SVF analysis tool for LLVM [27] and also constitutes the core of the PUS constraint solver [14].

Mathiasen and Pavlogiannis [16] additionally showed that their bounded analysis technique is perfectly parallelizable, in contrast to ordinary Andersen pointer analysis. It will be interesting in future work to investigate whether that theoretical property can be exploited in practice to parallelize indirection-bounded call graph analysis.

Horwitz [11] studied a similar notion of levels of pointer indirection, but for reasoning about the analysis precision loss that may occur when normalizing pointer operations, which is not immediately related to bounded analysis techniques.

Uttre and Palsberg [31] introduced a mechanism for analyzing library code only partially to speed up whole-program static analysis of application code. Their technique retains precision but, like indirection-bounded analysis, may lose some recall. We believe such approaches could be combined with indirection-bounded analysis to speed up analysis even further.

Uttre et al. [30] (and follow-up work [13]) propose the notion of a call-graph pruner, which aims to improve analysis precision by eliminating call edges that are likely to be false positives. Like indirection-bounded analysis, that technique may negatively affect recall but in practice often achieves a good balance between precision and recall. The technique works as a post-processing phase and as such does not improve analysis time, and it relies on a learning algorithm that does not provide semantics-based, predictable outcomes.

Bounds have often been used in configuring the abstraction used by a static analysis, e.g., k -limiting for context sensitivity or access path length [25]. Indirection bounding is fundamentally different, in that it heuristically terminates the core fixpoint computation of the analysis before a fixed point is reached. Hence, unlike the aforementioned types of k -limiting, indirection bounding impacts analysis soundness, trading off a small amount of recall for improved scalability.

As pointed out in Section 1 it is well known that practically all whole-program static analyzers have imperfect recall [15], but the analysis results are still useful for many use cases. Reif et al. [22] and Sui et al. [26] investigated this phenomenon empirically for state-of-the-art analyzers for Java, and Antal et al. [3] have made a similar study for JavaScript call graph analysis tools. The more recent work by Chakraborty et al. [4] introduced a method for quantifying the root causes of missing edges in call graphs produced by a field-based static analysis for JavaScript [7]. The dynamic analysis used by Chakraborty et al. inspired the technique presented in Section 3.

7 Conclusion

Indirection-bounded analysis is a simple but effective approach for speeding up call graph analysis while missing relatively few call edges. The approach complements the theoretical results of Mathiasen and Pavlogiannis by providing a practical algorithm and empirical evidence, and it generalizes their bounded mechanism to a language with higher-order functions and to field-sensitive analysis. The results of the dynamic analysis presented in Section 3 indicate that real-world JavaScript code tends to have low levels of indirection of function calls and field writes, which gives a semantic justification of the approach. We have demonstrated that indirection-bounded analysis is straightforward to incorporate into Pereira and Berlin’s wave propagation algorithm and also into the field-based ACG algorithm by Feldthaus et al., and that it can be advantageous to choose a fixed bound independent of the individual programs being analyzed.

For future work, it may be interesting to explore the potential of indirection-bounded analysis for other programming languages, and to investigate whether the parallelizability results of Mathiasen and Pavlogiannis also hold in presence of higher-order functions and field-sensitive analysis.

Data Availability. The supplementary material at <https://zenodo.org/doi/10.5281/zenodo.12720724> contains the benchmarks used in the experimental evaluation and instructions for using indirection-bounded analysis with the open source analysis tools JELLY and WALA.

Abstract

Noninterference guarantees that an attacker cannot infer secrets by interacting with a program. Information flow control (IFC) type systems assert noninterference by tracking the level of information learned (pc) and disallowing communication to entities of lesser or unrelated level than the pc . Control flow constructs such as loops are at odds with this pattern because they necessitate downgrading the pc upon recursion to be practical. In a concurrent setting, however, downgrading is not generally safe. This paper utilizes *session types* to track the flow of information and contributes an IFC type system for message-passing concurrent processes that allows downgrading the pc upon recursion. To make downgrading safe, the paper introduces *regarding policies*. Regarding policies are expressed in terms of integrity labels, which are also key to safe composition of entities with different regarding policies. The paper develops the type system and proves *progress-sensitive noninterference* for well-typed processes, ruling out timing attacks that exploit the relative order of messages. The type system has been implemented in a type checker, which supports security-polymorphic processes.

1 Introduction

With the emergence of new applications, such as Internet of Things and cloud computing, today's software landscape has become increasingly *concurrent*. A dominant computation model adopted by such applications is *message passing*, where several concurrently running processes connected by channels exchange messages. A further common aspect is the need for security, ensuring that confidential information is not leaked to a (malevolent) observer.

Information flow control (IFC) type systems [36, 39, 42] rule out information leakage by type checking. These systems statically track the level of information learned by an entity and disallow propagation to parties of lesser or unrelated levels, given a security lattice. The ultimate property to be asserted by an IFC type system is noninterference, a program equivalence statement up to the confidentiality level of an observer. The gold standard is *progress-sensitive noninterference* (PSNI) [24], which treats divergence as an

11.2 Regrading Policies for Flexible IFC in Session-Typed Concurrency

observable outcome. PSNI thus only equates a divergent program with another diverging one, whereas *progress-insensitive noninterference* (PINI) regards divergence to be equal to any outcome. Especially in a concurrent setting, PSNI is a sine qua non because the *termination channel* [36] can be scaled to many parallel computations, each leaking “just” one bit [4, 40].

Guaranteeing PSNI, or even PINI for that matter, can become both a blessing and a curse in a concurrent setting. To ensure such a strong property, IFC type systems have to be very restrictive. The troublemakers, in particular, are control flow constructs, such as loops and if statements. Whereas IFC type systems for sequential languages allow the `pc` label¹ to be lowered to its previous level for the continuation of a control flow construct, even if the construct itself runs at high, this treatment is no longer safe in a concurrent setting [39]. To uphold noninterference, IFC type systems for concurrent languages typically forbid high-security loop guards and may even put restrictions on if statements, depending on thread scheduling and attacker model [35, 37, 39].

The use of linearity provides some relief [7, 20, 46–48], allowing high-security loop guards. Linearity also facilitates race freedom, key to guaranteeing observational determinism and, thus, the absence of certain timing attacks [7, 20, 48]. A family of concurrent languages that employ linearity are *session types* [9, 26, 27, 30, 43]. Session types are used for message-passing concurrency, typically in the context of process calculi, where concurrently running processes communicate along channels. A distinguishing characteristic of session types is their ability to assert *protocol adherence*. A session-typed channel prescribes not only the types of values that can be transported over the channel but also their relative sequencing.

In this paper, we develop a flow-sensitive IFC session type system that not only supports recursive processes with arbitrary recursion guards, including high-security ones, but also identifies synchronization patterns that make it safe for the process body to downgrade to the initial `pc` level upon recursion. We refer to this adjustment of confidentiality level as *regrading*. To enforce the safety of regrading, we complement confidentiality with *integrity* [8]. Integrity allows prescribing a process a *regrading policy*, ensuring that any confidential information learned during the high-security parts of the loop cannot be rolled forward to the next iteration. Processes are *polymorphic* in the confidentiality and integrity labels, ensuring maximal flexibility of the IFC type system.

We contribute a type checker for our IFC type system, yielding the language **SINTEGRITY**. The type checker supports security-polymorphic processes using local *security theories*. Well-typed processes in **SINTEGRITY** enjoy PSNI. To prove this result, we develop a *logical relation* for integrity, showing that well-typed processes are self-related (fundamental theorem, Thm. 1). We then prove that the logical relation is closed under parallel composition and that related processes are bisimilar (adequacy theorem, Thm. 3).

Regrading is related to robust declassification [6, 15, 33, 44, 45, 49], as both allow downgrading the `pc` using integrity. In contrast to declassification, which deliberately releases information and thus intentionally weakens noninterference, regrading preserves noninterference. The distinction also manifests in how integrity is used. Whereas integrity is used in robust declassification to convey how trustworthy the information is on which a regrading decision is based, integrity in our work is used to impose extra synchronization policies on regrading processes to prevent leakage by downgrading the `pc` upon recursion. As such, regrading constitutes a more permissive IFC mechanism.

¹ The `pc` (program counter) label approximates the level of confidential information learned up to the current execution point.

Contributions

- The notion of a regrading policy to downgrade a process' confidentiality, retaining PSNI.
- The language **SINTEGRITY**, a flow-sensitive IFC session type system for asynchronous message-passing with confidentiality and integrity to support regrading policies.
- A logical relation for integrity to prove that **SINTEGRITY** processes satisfy PSNI.
- A type checker for **SINTEGRITY**, available as an artifact.

The complete formalization with proofs is available as a technical report (TR) [21].

2 Motivating example and background

This section provides an introduction to session-typed programming and IFC control based on a running example. Our language **SINTEGRITY** is an *intuitionistic linear session type* language [9, 41]; thus, our presentation is specific to that family of session types.

We use a simple bank survey as an example. The survey is carried out by an analyzer at a bank to decide whether to buy or sell a share of stock. The analyzer's decision depends on the opinion of two groups of participants, queried by two surveyors, and a strategy provided by a tactician. For simplicity, we assume that each group of participants only consists of one participant, and the surveyors simply pass the opinion of their participant to the analyzer.

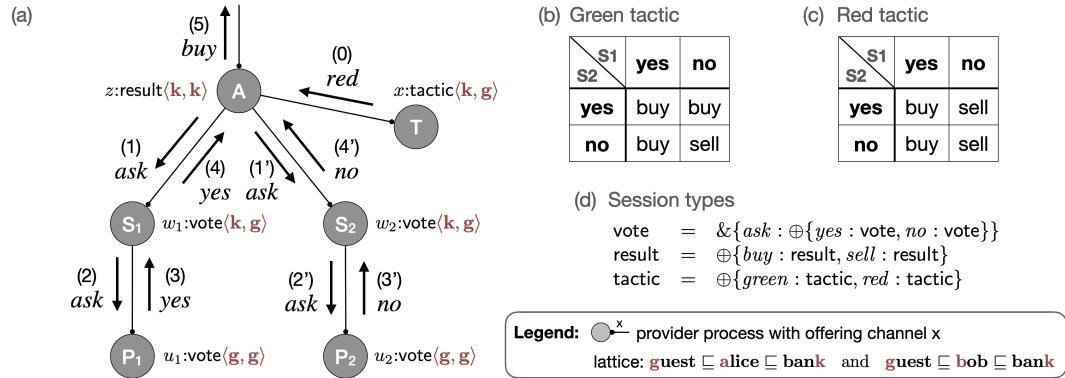

Figure 1 Bank survey: (a) process configuration, (b)/(c) red/green tactic, (d) session types.

A runtime configuration of processes for this example is shown in Fig. 1(a): the analyzer process A, the tactician process T, the surveyor processes S₁ and S₂, along with their participant processes P₁ and P₂, resp. The processes are connected by the channels u₁, u₂, w₁, w₂, x, and z. The figure shows the communications between the analyzer, surveyors, and participants along these channels, with arrows indicating the message being exchanged. The analyzer sends the message *ask* to surveyor S₁ to request a poll (1). Surveyor S₁ then sends the message *ask* to participant P₁ to get their opinion about buying a share (2). Once the surveyor receives P₁'s vote (i.e., either *yes* or *no*) (3), it relays the vote back to the analyzer (4). The analogous communication pattern is repeated between the analyzer and surveyor S₂ and participant P₂ (1'-4'). The final decision whether to *buy* or *sell* (5) of the analyzer is based on the tactic provided by the tactician. For simplicity, we assume that the tactician chooses either a *green* or *red* tactic (0). In the green tactic, the analyzer decides to buy the share if at least one of the surveyors votes yes. In the red tactic, the analyzer buys the stock if the first surveyor votes to buy, regardless of the opinion of the second one (see Fig. 1(b-c)).

Table 1 SINTEGRITY constructs. Upper half: types and terms (before and after exchange), operational meaning, and polarity. Lower half: spawn and forward terms and operational meaning.

Session type (b/a)	Process term (b/a)	Description
$x : \oplus \{\ell : A_\ell\}_{\ell \in L}$	$x : A_k \quad x.k; P$	P provider sends label k along x , continues with P
	$\text{case } x(\ell \Rightarrow Q_\ell)_{\ell \in L}$	Q_k client receives label k along x , continues with Q_k
$x : \& \{\ell : A_\ell\}_{\ell \in L}$	$x : A_k \quad \text{case } x(\ell \Rightarrow P_\ell)_{\ell \in L} \quad P_k$	provider receives label k along x , continues with P_k
	$x.k; Q$	client sends label k along x , continues with Q
$x : A \otimes B$	$x : B \quad \text{send } y x; P$	P provider sends channel $y : A$ along x , continues with P
	$z \leftarrow \text{recv } x; Q_z$	Q_y client receives channel $y : A$ along x , continues with Q_y
$x : A \multimap B$	$x : B \quad z \leftarrow \text{recv } x; P_z$	P_y provider receives channel $y : A$ along x , continues with P_y
	$\text{send } y x; Q$	Q client sends channel $y : A$ along x , continues with Q
$x : 1$	$- \quad \text{close } x$	- provider sends “close” along x and terminates
	$\text{wait } x; Q$	Q client receives “close” along x , continues with Q
$x : Y$	$x : A \quad -$	- recursive type definition $Y = A$ (Y occurs in A)
Judgmental rules		
$(x^{(c,e)} \leftarrow X[\gamma] \leftarrow \Delta) @ \langle c_0, e_0 \rangle; Q_x$		spawn X along $x^{(c,e)}$ with arguments Δ , substitution γ , and running security $\langle c_0, e_0 \rangle$, then continue with Q_x
$x \leftarrow y$		forward $x : A$ to $y : A$

The protocols for these communications can be specified by the session types shown in Fig. 1(d), using the connectives of Table 1. The connectives are drawn from intuitionistic linear logic and obey the following grammar:

$A, B ::= \oplus \{\ell : A_\ell\}_{\ell \in L} \mid \& \{\ell : A_\ell\}_{\ell \in L} \mid A \otimes B \mid A \multimap B \mid 1 \mid Y$,
where L ranges over finite sets of labels denoted by ℓ and k , amounting to primitive values in our system. Type variable Y is a fixed point whose definition $Y = A$ is given in a global signature Σ . The latter is used to define general recursive types. Recursive types must be *contractive* [23], demanding a message exchange before recurring, and *equi-recursive* [19], avoiding explicit (un)fold messages and relating types up to their unfolding. All three types *vote*, *result*, and *tactic* are recursive.

Table 1 provides an overview of SINTEGRITY types and terms. A crucial characteristic of session-typed processes is that a process *changes* its type along with the messages it exchanges. A process’ type therefore always reflects the current protocol state. Table 1 lists state transitions caused by a message exchange in columns 1 and 2 with corresponding process terms in columns 3 and 4. Column 5 describes the computational behavior of a type.

Linearity ensures that every channel connects exactly two processes, thus imposing a *tree* structure on a configuration of processes, as witnessed by Fig. 1(a). We adopt a form of session types corresponding with intuitionistic linear logic, which moreover introduces a distinction between the two processes connected by a channel, identifying one as the *parent* and the other as the *child*, turning the configuration into a *rooted tree*. The parent and child processes have mutually dual perspectives on the protocol of their connecting channel: The child has the perspective of the *provider* and the parent that of a *client*. Column 5 of Table 1 describes the perspective of the client and provider for each type. We assign a polarity to each session type which determines whether the type has a sending semantics or a receiving semantics. For positive types, the provider sends, and the client receives; for negative types, the provider receives, and the client sends. The types with positive polarity are $\oplus \{\ell : A_\ell\}_{\ell \in L}$, $A \otimes B$, and 1 , and the types with negative polarity are $\& \{\ell : A_\ell\}_{\ell \in L}$ and $A \multimap B$.

Figure 2 Secure process implementations of analyzer and surveyor (see Fig. 1), accepted by SINTEGRITY but rejected by existing IFC session type systems

Each process in a configuration is uniquely identified by the channel that connects it to its parent, which we also refer to as its *offering* (or *providing*) channel. We consider the session type of a process to be the protocol of its offering channel. For example, the participant process P_1 in Fig. 1 has type *vote*, which is also the type of the process' offering channel u_1 that connects P_1 to its client S_1 . We say that the client S_1 *uses* the channel u_1 .

The connectives \otimes and \multimap , not used in the example, allow sending channels along channels. Such higher-order channels change the connectivity structure of a configuration: from the perspective of the provider, \otimes turns a child into a sibling and \multimap a sibling into a child. The former is achieved by sending a subtree to the parent and the latter by receiving a subtree from the parent. § 5.4 showcases an example that uses higher-order channels.

It is now time to explore how to implement the processes of our bank survey example. Fig. 2 gives the process definitions of the analyzer and surveyor. A process definition consists of the process signature (first two lines) and body (after =). The first line indicates the typing of channel variables used by the process (left of \vdash) and the type of the providing channel variable (right of \vdash). The former are going to be child nodes of the process. The second line binds the channel variables. In **SINTEGRITY**, \leftarrow generally denotes variable bindings. The channels and the process definitions are annotated with confidentiality and integrity levels (e.g., `<bank, guest>` and `@(guest, guest)`). We will later describe the meaning of these annotations; the reader can safely ignore them for now.

The analyzer first waits to receive a tactic from the tactician along channel x . In either branch (i.e., *green* or *red*), the analyzer proceeds by requesting a vote from surveyors S_1 and S_2 , after which it communicates its decision along its offering channel z before recurring. We remark that the notation $z \leftarrow A \leftarrow w_1, w_2, x$ used for a tail call does not precisely match up with Table 1 because we are deferring a discussion of security annotations and substitutions for security-polymorphic processes to § 5.1. Moreover, a tail call is syntactic sugar for a spawn combined with a forward; i.e., $z \leftarrow A \leftarrow w_1, w_2, x$ desugars to $z' \leftarrow A \leftarrow w_1, w_2, x; z \leftarrow z'$.

We implement a surveyor by two processes S and S' to take advantage of **SINTEGRITY**'s support for regrading, as we will detail in § 3.1. The surveyor starts out as process S and calls process S' right after having received the request from its parent, the analyzer.

Suppose that the tactic is a secret that a participant shall not deduce. The implementations in Fig. 2 respect this security condition: the analyzer interacts with the participants via the surveyors the same regardless of the tactic it received. Existing IFC session type systems [7, 20], however, reject these implementations, because they view the analyzer as

tainted as soon as it learns the secret tactic, and disallow further communication with the participants via the surveyor. This paper relaxes this restriction – while preserving PSNI – and allows the tainted surveyor to interact with the participants while putting safeguards in place (synchronization patterns, § 3.2–§ 3.3 and § 5.2) that prevent the surveyor from leaking the tactic.

3 Key ideas

This section develops the main ideas underlying our flexible IFC session type system; the type system and dynamics is given in § 5. The latter is asynchronous, i.e., non-blocking sends and blocking receives (see § 4.2 and § 5.3). An asynchronous semantics allows for a more permissive noninterference statement since message receipt is not observable.

It may be helpful to foreshadow our attacker model (detailed in § 6.1). We assume that an attacker knows the implementation of all processes and can observe messages sent over channels with lower or equal confidentiality level than the attacker. The attacker cannot measure time but can observe the relative order in which messages are sent along different observable channels. As we aim for PSNI, we need to ensure that an attacker is unable to deduce any information from non-reactiveness either.

3.1 Regrading confidentiality

It is now time to consider the red annotations $\langle c, e \rangle$ on channels and the green annotations $@\langle c_0, e_0 \rangle$ on process terms in Fig. 2, where c, d, c_0 , and e_0 range over levels in the security lattice $\text{guest} \sqsubseteq \text{alice} \sqsubseteq \text{bank}$ and $\text{guest} \sqsubseteq \text{bob} \sqsubseteq \text{bank}$. We focus on the first components c and c_0 for now, which denote confidentiality labels. They are adopted from existing IFC session type systems [7, 20], which are based solely on confidentiality.

The first component c of the pair $\langle c, e \rangle$ indicates the *maximal confidentiality* of a process, i.e., the maximal level of secret information the process may ever obtain. As to be expected, the analyzer (A), the tactician (T), and both surveyors (S_1 and S_2) have maximal confidentiality bank , as they are affiliated with the bank and have the clearance of knowing the secret tactic. The processes associated with the participants have the lowest maximal confidentiality guest , as they must not gain any information about the bank’s secrets.

The first component c_0 of the pair $@\langle c_0, e_0 \rangle$ denotes a process’ *running confidentiality*. It denotes the highest level of secret information a process has obtained so far and thus is analogous to the pc label in imperative languages, making the type system flow-sensitive. The running confidentiality is capped by the maximal confidentiality, i.e., $c_0 \sqsubseteq c$. When defining a process, a programmer must indicate the process’ maximal confidentiality as well as the *initial* running confidentiality at which the process starts out when spawned.

An IFC type system increases the running confidentiality accordingly, whenever information of higher confidentiality is received, and disallow sends from senders with a higher or incomparable running confidentiality than the recipient. For example, the analyzer starts with the running confidentiality guest . When it receives the secret from the tactician, its running confidentiality increases to bank . After the receive, the analyzer can still send the message ask to a surveyor as the maximal confidentiality of the surveyor is bank . However, as soon as the surveyor receives this message from the analyzer, its running confidentiality increases to bank , which prevents it from sending messages to participants, whose maximal confidentiality is guest , because $\text{bank} \not\sqsubseteq \text{guest}$.

To address this limitation of existing IFC session type systems, we develop *regrading policies*. A regrading policy is polymorphic in a level f of the security lattice and certifies that, when regrading the running confidentiality to f , any secrets of confidentiality $d_s \not\sqsubseteq f$ learned so far will not affect future communications of confidentiality at most f after regrading.

To convey the regrading policy that a process must obey, we introduce *integrity annotations*, amounting to the second components in the pairs $@\langle c_0, e_0 \rangle$ and $\langle c, e \rangle$. We refer to e_0 as the *running integrity* of the process and to e as the *minimal integrity* of the process. The running integrity specifies what level a process is allowed to regrade to and is capped by the minimal integrity, i.e., $e_0 \sqsubseteq e$. For example, the surveyor process S runs at $@\langle bank, guest \rangle$ after having received the request from the analyzer, where the running integrity $guest$ licenses it to drop its running confidentiality as low as $guest$ upon tail-calling, but forces it to obey that policy too. The minimal integrity e of a process is naturally capped by its maximal confidentiality c , i.e., $e \sqsubseteq c$, because a process cannot learn (and thus drop) more secrets than it is licensed to. As a result, a process with maximal confidentiality and minimal integrity $\langle c, c \rangle$ effectively amounts to a non-regrading process.

We draw both integrity and confidentiality levels from the same security lattice, but interpret integrity levels *dually*, as usual: the lower a level in the lattice, the higher its integrity². For regrading this means that the lower the level a process regrades to, the stricter the process' policy becomes. The **SINTEGRITY** type system thus increases the running integrity of a process upon receiving from a process with a higher minimal integrity and disallows sends from a process of a higher or incomparable running integrity than the minimal integrity of the recipient (see § 5).

The process definitions in Fig. 2 only use concrete levels from the security lattice for confidentiality and integrity annotations. To increase code reusability, **SINTEGRITY** supports *security-polymorphic* process definitions. Such definitions range over security variables for confidentiality and integrity levels and may state constraints on these variables. The constraints must be satisfied upon spawning, which is checked by the **SINTEGRITY** type checker using a security theory. § 5 expands on security-polymorphic process definitions.

3.2 The need for regrading policies

While a regrading policy licenses regrading, it also imposes restrictions on a process' communication patterns to guarantee noninterference. To distill these restrictions, we next explore insecure implementations of the analyzer-surveyor example from § 2 that do not satisfy PSNI.

3.2.1 Hasty analyzer – optimization may introduce a timing attack

In the red tactic, the decision of the analyzer does not depend on the result provided by the second surveyor. Hence, one may be tempted to optimize the analyzer implementation by refraining from asking the opinion of the second surveyor in the branch corresponding to the red tactic (see A_H in Fig. 3). As appealing as this optimization seems, it leads to a leak. An attacker of confidentiality level $guest$ can simultaneously observe the sequence of messages transmitted along channels u_1 and u_2 of confidentiality $guest$, which connect the participants to the surveyors, and thus, can deduce which secret tactic was chosen: in case of the green tactic, the sequence of messages along u_1 and u_2 has the recurrence $u_1.ask; u_1.(yes/no); u_2.ask; u_2.(yes/no)$,

² We adopt the following convention to avoid any confusion: we use “running integrity”, “minimal integrity”, and “integrity level” for elements in the security lattice, and otherwise just “integrity”. Thus, when the integrity level in the lattice increases, the integrity decreases.

```

 $w_1:\text{vote}(\text{bank}, \text{guest}), w_2:\text{vote}(\text{bank}, \text{guest}), x:\text{tactic}(\text{bank}, \text{guest}) \vdash A_H :: z:\text{result}(\text{bank}, \text{bank})$ 
 $z \leftarrow A_H \leftarrow w_1, w_2, x =$ 
 $\text{case } x \text{ (green} \Rightarrow w_1.\text{ask}; \text{case } w_1 \text{ (yes} \Rightarrow w_2.\text{ask}; \text{case } w_2 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_H \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{buy}; (z \leftarrow A_H \leftarrow w_1, w_2, x))$ 
 $| \text{no} \Rightarrow w_2.\text{ask}; \text{case } w_2 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_H \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{sell}; (z \leftarrow A_H \leftarrow w_1, w_2, x))$ 
 $| \text{red} \Rightarrow w_1.\text{ask}; \text{case } w_1 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_H \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{sell}; (z \leftarrow A_H \leftarrow w_1, w_2, x))) @\langle \text{guest}, \text{guest} \rangle$ 

 $w_1:\text{vote}(\text{bank}, \text{guest}), w_2:\text{vote}(\text{bank}, \text{guest}), x:\text{tactic}(\text{bank}, \text{guest}) \vdash A_R :: z:\text{result}(\text{bank}, \text{bank})$ 
 $z \leftarrow A_R \leftarrow w_1, w_2, x =$ 
 $\text{case } x \text{ (green} \Rightarrow w_1.\text{ask}; \text{case } w_1 \text{ (yes} \Rightarrow w_2.\text{ask}; \text{case } w_2 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_R \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{buy}; (z \leftarrow A_R \leftarrow w_1, w_2, x))$ 
 $| \text{no} \Rightarrow w_2.\text{ask}; \text{case } w_2 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_R \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{sell}; (z \leftarrow A_R \leftarrow w_1, w_2, x))$ 
 $| \text{red} \Rightarrow w_1.\text{ask}; w_2.\text{ask}; \text{case } w_1 \text{ (yes} \Rightarrow \text{case } w_2 \text{ (yes} \Rightarrow z.\text{buy}; (z \leftarrow A_R \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{buy}; (z \leftarrow A_R \leftarrow w_1, w_2, x))$ 
 $| \text{no} \Rightarrow \text{case } w_2 \text{ (yes} \Rightarrow z.\text{sell}; (z \leftarrow A_R \leftarrow w_1, w_2, x)$ 
 $| \text{no} \Rightarrow z.\text{sell}; (z \leftarrow A_R \leftarrow w_1, w_2, x)))$ 
 $@\langle \text{guest}, \text{guest} \rangle$ 

```

 **Figure 3** Insecure hasty analyzer A_H and reckless analyzer A_R , rejected by SINTEGRITY.

whereas it has the recurrence $u_1.\text{ask}; u_1.(yes/no)$ for the red tactic. Observing, for example, the sequence $u_1.\text{ask}; u_1.(yes/no); u_2.\text{ask}; u_2.(yes/no); u_1.\text{ask}; u_1.(yes/no)$, the attacker can deduce that the first tactic used was green and the second one was red. These leaks constitute *timing attacks* because the attacker cannot deduce the secret by only looking at a single channel, but needs to observe the relative timing of messages passed along two or more channels.

3.2.2 Reckless analyzer – be careful with synchronization

The previous example shows that a send along a channel, present in one branch, but omitted from another, may lead to a leak. One may naively suspect that these leaks only involve sends. The analyzer version A_R in Fig. 3 showcases the opposite: mismatched receives are at least as dangerous as mismatched sends. In the original implementation (Fig. 2), the analyzer synchronizes the communications of surveyors and participants across branches, ensuring, in particular, that the second participant always casts their vote after the first. The reckless analyzer A_R breaks this synchronization in the red branch by swapping the order of $\text{case } w_1$ and $w_2.\text{ask}$. This minimal change allows the two surveyors to run concurrently when the tactic is red and produce the sequence of messages $u_2.\text{ask}; u_2.(yes/no); u_1.\text{ask}; u_1.(yes/no)$ along channels u_1 and u_2 , a sequence that is impossible to produce in the green tactic (recall that receives are blocking, but sends are not). Both A_H and A_R leak the secret with a timing attack, i.e., the simultaneous observation of the relative order of sends along several channels.

There is a subtle connection between timing attacks and leaks due to the non-reactivity of a process. For instance, let us assume that the second participant loops internally and never casts its vote. The attacker can then deduce the secret tactic in the hasty implementation of the analyzer by only observing the communications of the first participant along u_1 : the sequence $u_1.\text{ask}; u_1.(yes/no); u_1.\text{ask}; u_1.(yes/no)$ indicates that the prior tactic was red. A similar scenario holds for the reckless analyzer when the first participant is non-reactive.

3.3 Regrading policies in a nutshell

Our model allows the running confidentiality of a process to be dropped as low as its running integrity. Performing such a venturous act, needs a corresponding safety net in place: a regrading policy that is polymorphic in the running integrity to preserve noninterference. The examples in § 3.2 suggest that a regrading policy must enforce the following properties:

1. The continuation of a process after regrading must not depend on any secret higher than or incomparable to its running integrity. That is, when branching on a secret \mathbf{d}_s , the same process must be spawned for the recursive call in every branch, if that process regrades to a level \mathbf{e}_0 such that $\mathbf{d}_s \not\leq \mathbf{e}_0$.
2. Whether a process reaches its regrading point or not must not depend on any secret higher than or incomparable to its running integrity.

The latter property is violated in both analyzer implementations of Fig. 3, amounting to a leak. In the hasty implementation A_H , the second surveyor only gets to the regrading point if the secret tactic is green. In the reckless implementation A_R , if the secret tactic is green, the second surveyor gets to the regrading point only if the first participant casts their vote, whereas if the secret is red, there is no such chaining.

The above properties capture semantically what conditions secure processes that employ regrading must meet to observe PSNI. In § 5.2 we develop static checks that, when satisfied by a process, ensure that the process also meets these semantic conditions. We refer to those checks as *synchronization pattern* checks, and they are enforced by the **SINTEGRITY** type checker. The pattern checks are of the form $\Psi \models P \sim_{(d,f)} Q$ and synchronize P and Q in terms of their communication actions: if P outputs along channel x , so must Q , and if P inputs along channel x , so must Q , and vice versa. The pattern checks are invoked pairwise for every two branches, P_i and P_j , in a **case** statement, requiring that $\Psi \models P_i \sim_{(d,f)} P_j$. The check is conditioned on the running confidentiality d and running integrity f at the branching point.

An important feature of our regrading policies is that they are *compositional*. We take advantage of the fact that intuitionism imposes a rooted tree structure on process configurations and require that a configuration aligns with the security lattice: for every child process and parent process with maximal confidentiality and minimal integrity $\langle \mathbf{c}, \mathbf{e} \rangle$ and $\langle \mathbf{c}', \mathbf{e}' \rangle$, resp., it must hold that $\langle \mathbf{c}, \mathbf{e} \rangle \sqsubseteq \langle \mathbf{c}', \mathbf{e}' \rangle$, ensuring that a child process can learn at most as much as its parent and has at least an as stringent regrading policy as its parent. We design our type system to preserve this property as an invariant.

4 Blueprint for Formal Development

Before delving into the formal development, we review the statics and dynamics of a vanilla intuitionistic session type system and give a roadmap for the upcoming technical sections. We use the intuitionistic session type system introduced by Toninho et al. [9, 41] as our vanilla intuitionistic session type system. **SINTEGRITY** enhances such a vanilla session type system with confidentiality and integrity annotations to establish PSNI. **SINTEGRITY** adopts the former from existing intuitionistic IFC session type systems [7, 20]. The integrity annotations as well as the synchronization patterns are contributions unique to **SINTEGRITY**. The addition requires us to define the relationships between all these levels, expressed as invariants, and the development of synchronization patterns. Similar to the system in [7] our language supports general recursion and allows processes to be polymorphic in confidentiality levels. **SINTEGRITY** extends label polymorphism to also accommodate integrity levels.

4.1 Vanilla intuitionistic session types – statics

Process terms and session types are built by the grammar in § 2 and Table 1. The process typing judgment is of the form $\Delta \vdash_{\Sigma} P :: x:A$, to be read as: “*Process P provides a session of type A along channel x, given the typing of sessions offered along channels in Δ*. Δ is a linear typing context consisting of the channels connecting P to its children, and x connects P to its parent. The global signature Σ includes recursive type definitions and process definitions.

4.1.1 Process term typing

Fig. 4 lists the process term typing rules. The parts in red are specific to SINTEGRITY and can be ignored for now; we discuss them in § 5. As is usual in intuitionistic linear session type languages, the rules are given in a sequent calculus. When read from bottom to top, the rules closely follow the behavior described in Table 1: right rules describe a type from the point of view of a provider, and left rules from the point of view of a client. For example, rule \oplus_{R_1} describes the behavior of the process that provides a channel with the protocol $\oplus\{\ell:A_\ell\}_{\ell \in L}$: it chooses a label $k \in L$ and sends it to the client along channel x , and then continues by checking process P providing A_k in the premise. Note that the typing rules \oplus_{R_1} and \oplus_{R_2} are identical, ignoring the security annotations. Rule FWD ensures that the type of the two channels involved in forwarding is the same. Rule SPAWN spawns a new child process X along the fresh channel x ; it first checks that X is defined in the signature (first premise) and thus is well-typed and then continues with type-checking the continuation Q (last premise).

4.1.2 Signature checking

To support general recursive types, we employ a global signature Σ comprised of all process definitions. Each process definition is typed individually, assuming that the other processes in the signature are well-typed. The signature also comprises recursive type definitions. When typing a process with a recursive protocol, the signature is consulted to unfold the definition.

For example, the signature for the bank survey example in § 2 consists of the definitions for processes A , S , and S' as shown in Fig. 1 and the definition of recursive types as shown in Fig. 1(d). In our formal development, we use a more concise syntax for process definitions than what is shown in Fig. 1. In particular, we write them in the form of $\Delta \vdash X = P::(z:A)$. For instance, the concise version of the process definition for process S in Fig. 1, ignoring its security annotations, is $u:\text{vote} \vdash S = \text{case } w \ (\text{ask} \Rightarrow (w \leftarrow S' \leftarrow u)) :: w:\text{vote}$.

Type checking starts with typing the signature by the rules listed in Fig. 5; again, ignore the parts in red for now, as they will be discussed later in § 5. The rules are in a sequent calculus and should be read from bottom to top. Rule Σ_3 ensures that each process definition in the signature is well-typed. It invokes the process term typing judgment for a process definition relative to the entire global signature Σ (fifth premise) and continues with checking the rest of the signature (sixth premise). Rule Σ_2 ensures that all recursive types in the signature are well-formed via its first premise, the judgment $\Vdash_\Sigma A \text{ wfmd}$. This judgment denotes a well-formed session type definition, which, if recursive, must be *equi-recursive* [19] and *contractive*. Equi-recursiveness ensures that types are related up to their unfolding without requiring explicit (un)fold messages (see rules TVAR_R and TVAR_L). Contractiveness demands an exchange before recurring.

4.2 Vanilla intuitionistic session types – dynamics

At runtime, process definitions result in a configuration of processes structured as a forest of rooted trees. The nodes in the forest represent runtime processes and messages, denoted as $\text{proc}(y_\alpha; P)$ and $\text{msg}(M)$, resp. We use metavariables \mathcal{C} and \mathcal{D} to refer to a configuration and formally define it as a set of runtime processes and messages (the nodes in the tree). The connection between the nodes will be inferred through configuration typing. In $\text{proc}(y_\alpha, P)$, the metavariable y_α represents the process’ offering channel, and P represents the process’ source code (where free variables have been substituted by channels). Runtime messages $\text{msg}(M)$ are a special form of processes created to model asynchronous communication: we

implement asynchronous sends by spawning off the message $\mathbf{msg}(M)$ that carries the sent message M . A sent message M can be of the form $x.k$, $\mathbf{send} y x$, or $\mathbf{close} x$, corresponding to label output, channel output, and a termination message, resp.

Runtime channels y_α are annotated with a generation subscript α , which distinguishes them from channel variables y used in the statics. Using generation subscripts, we can ensure that both the sender and receiver agree on a new name for the continuation channel without explicitly passing the name in a message. We will see an example of using generation subscripts in the next paragraph.

4.2.1 Asynchronous dynamics

We chose an asynchronous semantics for SINTEGRITY because it weakens the attacker model, allowing a more permissive IFC enforcement, and is also a sensible model for practical purposes. The dynamics is given in Fig. 8 in terms of multiset rewriting rules [14] (again, for now the parts in red can be ignored). Multiset rewriting rules express the dynamics as state transitions between configurations and are *local* in that they only mention the parts of a configuration they rewrite.

For example, in case of $\otimes_{\mathbf{snd}}$, the provider $\mathbf{proc}(y_\alpha, \mathbf{send} x_\beta y_\alpha; P)$ spawns off the message process $\mathbf{msg}(\mathbf{send} x_\beta y_\alpha)$, indicating that the channel x_β is sent over channel y_α . Since sends are non-blocking, the provider steps to its continuation $\mathbf{proc}(y_{\alpha+1}, ([y_{\alpha+1}/y_\alpha]P))$, allocating a new generation $\alpha+1$ of the carrier channel y_α . In $\otimes_{\mathbf{recv}}$, upon receipt of the message, the receiving client process $\mathbf{proc}(y_\alpha, w \leftarrow \mathbf{recv} y_\alpha; P)$ will increment the generation of the carrier channel in its continuation. The scenario is similar for $\oplus_{\mathbf{snd}}$ and $\oplus_{\mathbf{recv}}$, but the sent message is a label in this case, and similar for $\neg o_{\mathbf{snd}}$, $\neg o_{\mathbf{recv}}$ and $\&_{\mathbf{snd}}$, $\&_{\mathbf{recv}}$, except that in these cases the sender is the client and the receiver the provider. In the rules for the termination protocol, i.e., $1_{\mathbf{snd}}$ and $1_{\mathbf{recv}}$, there is no continuation channel. Rule SPAWN creates a process offering along a fresh runtime channel x_0 by looking up the definition of the spawnee in the signature.

The dynamics for the forwarding process $\mathbf{proc}(y_\alpha, y_\alpha \leftarrow x_\beta)$ is often described as fusing the two channels, y_α and x_β . We, however, represent forward as syntactic sugar by including forwarder processes defined by structural induction on the type of the channels involved in the forward, amounting to an identity expansion. The reader may see the TR for the details.

4.2.2 Configuration typing

The configuration typing judgment is of the form $\Delta \Vdash_{\Sigma} \mathcal{C} :: \Delta'$ indicating that the configuration \mathcal{C} provides sessions along the channels in Δ' , using sessions provided along channels in Δ . Δ and Δ' are both linear contexts, consisting of actual runtime channels of the form $y_\alpha:B$. We often use the term *open configurations* to emphasize that our configurations may have external free channels in both Δ and Δ' to communicate with the environment. This is in contrast to restricting Δ to be an empty context, which means the configuration only has external free channels to communicate with a client.

Fig. 7 shows the typing rules, enforcing that the configuration is structured as a forest and the source code of each node is well-typed. For brevity, Fig. 7 omits a channel's generation as well as Σ , which is fixed. The **emp** rule types an empty forest. The **comp** rule types each tree in the forest. The **proc** rule and the **msg** rule check the well-typedness of the root node of a tree when it is a process or message, resp., using the last premises. Well-typedness of the remaining forest is checked by the eighth and fourth premise of the latter two rules, resp. The last premise of the **msg** rule calls message typing rules, which we provide in TR-Sect. 3.3.

The typing rules ensure progress and preservation, i.e., the dynamics can always step an open configuration $\Delta \Vdash \mathcal{C} :: \Delta'$ to $\Delta \Vdash \mathcal{C}' :: \Delta'$.

4.3 Roadmap for SINTEGRITY

To develop the ideas discussed in § 3 and establish PSNI, we supplement the vanilla type system with a security layer. Here, we provide a roadmap to the key parts of our development.

4.3.1 Regrading policy type system

The first step in our formal development is to enrich the process term typing judgment with security levels as $\Psi; \Delta \vdash_{\Sigma} P @ \langle c_0, e_0 \rangle :: x:A \langle c, e \rangle$. Here, Ψ denotes a security theory which includes the security lattice and polymorphic confidentiality and integrity variables. The pair $\langle c_0, e_0 \rangle$ denotes the running confidentiality and integrity of the process, aka its taint level. The pair $\langle c, e \rangle$ denotes the max confidentiality and min integrity of the process. Similarly, each channel in Δ is annotated with a pair of confidentiality and integrity levels denoting its provider's max confidentiality and min integrity.

Similarly, we use security labels to annotate configurations and configuration typing judgments. In particular, runtime processes in configuration \mathcal{C} now have the form $\text{proc}(y_{\alpha} \langle c, e \rangle, P @ \langle c', e' \rangle)$, where $\langle c, e \rangle$ is the pair of max confidentiality and min integrity of the process, and $\langle c', e' \rangle$ is the pair of its running confidentiality and integrity.

The typing rules include security constraints highlighted in red – the ones we have been ignoring in § 4.1. The purpose of these security annotations is to (i) ensure that the taint levels are propagated correctly, (ii) prevent a tainted process from sending information to a process with a lower max confidentiality/higher min integrity, (iii) ensure that a process regrades its running confidentiality only as low as its running integrity, and (iv) verify that the process indeed adheres to the policy enforced by its running integrity. The first three conditions are enforced by imposing the security constraints on the process term typing rules in Fig. 4. The last check is enforced by the synchronization pattern checks in Fig. 6.

4.3.2 PSNI via a logical relation

Our ultimate goal is to prove that well-typed SINTEGRITY processes enjoy PSNI. We prove PSNI as an equivalence up to an attacker's confidentiality level ξ using a logical relation, which then delivers a process bisimulation.

To define PSNI for an open configuration in the shape of a tree $\Psi_0; \Delta \Vdash \mathcal{D} :: u_{\alpha}:T \langle c, e \rangle$, given a global security lattice Ψ_0 fixed for an application, we consider the external free channels $y_{\beta}:B \langle c', e' \rangle \in \Delta, u_{\alpha}:T \langle c, e \rangle$ with max confidentiality $c' \sqsubseteq \xi$. We call the set of these channels that connect a configuration to its environment and that are observable to an attacker, the *confidentiality interface*.

Such an open configuration satisfies noninterference if, when composed with different high-confidentiality processes, behaves the same along the confidentiality interface. We prove that all well-typed open configurations enjoy PSNI by designing a logical relation and showing that (i) all well-typed configurations are self-related (fundamental theorem, Thm. 1) and (ii) any two related configurations are bisimilar (adequacy theorem, Thm. 3).

To prove these results, our logical relation needs to consider some free channels in $\Delta, u_{\alpha}:T \langle c, e \rangle$ that are not directly observable in terms of their confidentiality but can have an observable effect due to their integrity. We thus define a superset of the confidentiality interface that additionally contains channels $y_{\beta}:B \langle c', e' \rangle \in \Delta, u_{\alpha}:T \langle c, e \rangle$ with min integrity $e' \sqsubseteq \xi$. We call this interface the *integrity interface*.

5 Regrading policy type system

This section formalizes SINTEGRITY’s type system with synchronization patterns and asynchronous dynamics. SINTEGRITY supports security-polymorphic process definitions, an example of which is discussed in §5.4.

5.1 Process term typing

Let us recall the process term typing judgment from §4.3:

$$\Psi; \Delta \vdash_{\Sigma} P @ \langle c_0, e_0 \rangle :: x : A \langle c, e \rangle.$$

We read it as: “*Process P, with maximal confidentiality and minimal integrity $\langle c, e \rangle$ and running confidentiality and integrity $\langle c_0, e_0 \rangle$, provides a session of type A along channel x, given the typing of sessions offered along channels in Δ and given a security theory Ψ .*” Δ is a linear typing context with the grammar $\Delta ::= \cdot \mid x : A \langle c, e \rangle, \Delta$. A security theory Ψ is used for type checking security-polymorphic process definitions. It consists of the global security lattice Ψ_0 which is fixed for an application, security variables ψ , and constraints on the variables (see §5.4 and Sect. 2 in the TR).

We impose the following properties on the typing judgment, as discussed in detail in §3. These properties are maintained by typing as invariants. When reading them, note that “high integrity” and “low confidentiality” both mean a “lower level” in the security lattice.

- (a) $\forall y : B \langle d, f \rangle \in \Delta. \Psi \Vdash d \sqsubseteq c, \Psi \Vdash f \sqsubseteq e$: ensuring that a child process can learn at most as much as its parent and has at least an as stringent regrading policy as its parent.
- (b) $\Psi \Vdash c_0 \sqsubseteq c$ and $\Psi \Vdash e_0 \sqsubseteq e$: ensuring that a process knows at most as much as it is licensed to and adheres to at least an as stringent regrading policy as it promises.
- (c) $\Psi \Vdash e_0 \sqsubseteq c_0$ and $\Psi \Vdash e \sqsubseteq c$: ensuring that a process cannot drop more secrets than it knows and is licensed to learn, resp.

Moreover, the typing rules for input and output have to conform to the following schema to make sure that the running confidentiality and running integrity correctly reflect the taint level and that a tainted process does not leak information via a send:

- (1) **after** receiving a message, the running confidentiality and running integrity of the receiving process must be increased to **at least** the maximal confidentiality and minimal integrity of the sending process, and
- (2) **Before** sending a message, the running confidentiality and running integrity of the sending process must be **at most** the maximal confidentiality and minimal integrity of the receiving process.

Conforming to this schema leads to the premises of the form $\Psi \Vdash \langle d_1, f_1 \rangle = \langle c, e \rangle \sqcup \langle d_0, f_0 \rangle$ and $\Psi \Vdash \langle d_0, f_0 \rangle \sqsubseteq \langle c, e \rangle$ to meet condition (1) and (2), resp., above. The judgments are defined formally in Sect. 2 in the TR.

It is time to consider the red security annotations of the typing rules in Fig. 4. We explain how the rules satisfy conditions (1) and (2) above:

- \oplus : There are two versions of the right rule for \oplus . Both versions establish condition (2) on sends without extra premises by the invariant (b). The difference between the two versions lies in whether $\Psi \Vdash c = e$ is derivable or not derivable ($\Psi \nVdash c = e$). If $\Psi \Vdash c = e$ is derivable, then rule \oplus_{R_1} applies; if it is not, rule \oplus_{R_2} applies. In the former case, the client of x , on the receiving side, adjusts its running integrity to at least $e=c$ upon receiving the sent message, and thus, it cannot regrade to a lower (or unrelated) level than c . In the latter case, the min integrity e of the process is strictly lower than its max confidentiality c . This means that the client of x might, in fact, continue to have

Figure 5 Signature checking rules of SINTEGRITY.

The first premise of rule $\oplus L$ updates the running integrity and confidentiality based on x 's security levels to enforce condition (1) for receives. Moreover, as explained in § 3.3, the third premise invokes the pattern check pairwise for every two branches conditioned on the running confidentiality d_1 and running integrity f_1 after the receive. We detail the synchronization pattern check rules later in § 5.2.

- $\&$: The left and right rules for $\&$ are dual to \oplus , except that the sends in $\&_{L_1}$ and $\&_{L_2}$ have to be guarded by their second and third premises, resp., to ensure condition (2) on sends. In $\&_R$, the updated running confidentiality and running integrity is equal to the max confidentiality and max integrity by invariant (b).
- $\otimes, \multimap, 1$: The rules for the rest of the connectives use the same set of premises to ensure conditions (1) and (2). Rules \otimes_R and \multimap_L , moreover, ensure that a channel can be sent over another channel only if they have the same security levels.
- FWD: The forward rule requires that the security levels of the involved channels match.
- SPAWN: The rule relies on an order-preserving substitution $\Psi \Vdash \gamma : \Psi'$, guaranteeing that the security terms provided by the spawner comply with the order expected among those terms by the spawnee. The substitution maps the security terms in the context in the signature to the one provided by the spawner, i.e., $\hat{\gamma}(\Delta'_1) = \Delta_1$. The rule also establishes invariants (a)-(c) for the newly spawned process via the premise $\Psi \Vdash \langle \hat{\gamma}(\psi), \hat{\gamma}(\omega) \rangle \sqsubseteq \langle d, f \rangle$. The running confidentiality and the running integrity of the spawned process will result from applying the substitution to the corresponding levels in the signature, i.e., $\hat{\gamma}(\psi_0)$ and $\hat{\gamma}(\omega_0)$, resp. The premises $\Psi \Vdash f_0 \sqsubseteq \hat{\gamma}(\psi_0)$ and $\Psi \Vdash f_0 \sqsubseteq \hat{\gamma}(\omega_0)$ allow the newly spawned process to start its running confidentiality and integrity at least at the spawner's running integrity f_0 . This facilitates regrading to f_0 in case of a tail call. Note that $\Psi \Vdash f_0 \sqsubseteq \hat{\gamma}(\omega_0)$ prevents the spawnee from employing more pattern checks than the spawner because the spawnee would otherwise be affected by the spawners negligence.

Signature checking. The syntax of process definitions in the signature is also enhanced with the security levels and is of the form $\Psi; \Delta \vdash X = P @ \langle \psi_0, \omega_0 \rangle :: (z:A \langle \psi, \omega \rangle)$. Fig. 5 lists the signature checking rules. Signature checking happens relative to a globally fixed security lattice Ψ_0 of concrete security levels. Rule Σ_3 initiates type-checking of a process definition via its fifth premise and enforces invariants (a)-(c) on the process via the first four premises.

 \end{array}$$

Figure 6 Synchronization pattern checking rules of SINTEGRITY.

5.2 Synchronization patterns

To check synchronization patterns, we use the judgment $\Psi \models P \sim_{\langle d,f \rangle} Q$, defined inductively in Fig. 6. The judgment states that process terms P and Q are *synchronized* in terms of their communication pattern, meaning that if P outputs along channel x , so must Q , and that if P inputs along channel x , so must Q , and vice versa. The check is *conditioned* on the running confidentiality d and running integrity f of the recipient after branching, and is pairwise called for all branches of a **case** statement. Let us assume that right after branching, the known secret of a process (its running confidentiality) is of level d . The goal of the synchronization pattern checks is to rule out any leakage of this secret of level d via regrading. Such leakage is only possible if the process (or any process that receives this secret from it) regrades to a lower or unrelated level than the secret d . However, if $d \sqsubseteq f$, we know that this can never happen. Therefore, if $\Psi \Vdash d \sqsubseteq f$, the judgment $\Psi \models P \sim_{\langle d,f \rangle} Q$ trivially holds. This case is handled by Rule UNSYNC₃ and is a base case of the inductive definition.

The interesting case is when $\Psi \not\models d \sqsubseteq f$, meaning that the process can potentially regrade to a lower (or unrelated) level than d . In this case, the rules have to ensure that the secret d does not affect the ability of the process itself or the processes communicating with it to reach a regrading point. Furthermore, the secret d cannot affect the continuation of the process after regrading. In this case, the rules consider whether the next action in P and Q is a receive, send (except close), spawn, close, or forward:

- The receives are checked to be synchronized in P and Q by the rules RCVLAB and RCVCHAN. The pattern check is invoked inductively on the continuation, with updated running integrity ($f \sqcup e$) to take into account the receive. The confidentiality of the learned secret d , however, remains constant under inductive invocations as it has to continue preventing the leak of the original secret. The receives have to be synchronized as long as $\Psi \not\models d \sqsubseteq f$ holds, since different receives in P and Q might result in one branch reaching the regrading point and the other one not (related to non-reactiveness).
- Different sends in two branches of a process does not impact whether or not the process itself reaches a regrading point (sends are non-blocking). But, it may impact whether or not the other process, on the receiving side, reaches the regrading point based on the secret. If the carrier channel's min integrity e is high enough, the receiving process cannot regrade to a level lower (or unrelated) than d , and we do not need to synchronize the sends. The sends must only be synchronized if the carrier channel's min integrity e is not greater than or equal to the level d of the secret ($d \not\sqsubseteq e$). Rules UNSYNC₁ and UNSYNC₂ correspond to the former case where $d \sqsubseteq e$; for brevity, in these rules, we use process terms with any output prefix defined as $\uparrow_{x^{(c,e)}} .P \triangleq x^{(c,e)}.k; P \mid \text{send } y x^{(c,e)}; P$. And rules SNDLAB and SNDCHAN correspond to the latter where $d \not\sqsubseteq e$. In either case, the pattern check is invoked inductively on the continuation, with unchanged running integrity.
- Similar to the reasoning in the case of sends, if the running integrity of the spawned process and the min integrity of all its channels are high enough, there is no need to synchronize the spawns (UNSYNC-SPAWN rules). Otherwise, the two branches must spawn the same processes with the same arguments (SYNC-SPAWN).
- Rules CLOSE and FWD are the other base cases of the inductive definition. They insist that the two branches P and Q can synchronize their termination behavior.

5.3 Configuration typing and asynchronous dynamics

The configuration typing judgment is of the form $\Psi_0; \Delta \Vdash \mathcal{C} :: \Delta'$, where Ψ_0 is the security lattice and \mathcal{C} is a set of runtime processes $\text{proc}(y_\alpha(c, e), P @ (c', e'))$ and messages $\text{msg}(M)$. Fig. 7 shows the configuration typing. The security premises in the **proc** and **msg** rules enforce the invariants (a)-(c) on the process term judgment before invoking process typing.

The dynamic rules in Fig. 8 take care of updating the running confidentiality and integrity of each process after a receive. For brevity, we write $\langle p \rangle$ to refer to a pair of confidentiality and integrity labels $\langle c, e \rangle$. Rule SPAWN relies on the substitution mapping γ given by the programmer and its lifting $\hat{\gamma}$ to the process term level. It looks up the definition of process X in the signature and instantiates the security variables occurring in the process body using γ . The condition $\hat{\gamma}(\Psi') = \Psi_0$ ensures that all security variables are instantiated with a concrete security level. For brevity, we omit a channel generations as well as Σ , which is fixed.

5.4 Banking example

The following example implements a bank that authorizes transactions made by its customers and sends a copy to their bank accounts. In line with our security lattice, we assume that the bank has two customers, Alice and Bob. To authenticate themselves, a customer sends their

Figure 8 Asynchronous dynamics of SINTEGRITY.

token to the bank. The bank then verifies the token and, if the verification is successful, sends the message *succ* to the customer, otherwise the message *fail*. Moreover, if the verification is successful, the bank creates a transaction statement and sends it to another process that represents the account of the customer in the bank. Once done, the bank continues to serve the next customer by making a recursive call. We assume that the bank alternates between its two customers, Alice and Bob, by making a mutually recursive call from `BankA`, which serves Alice, to `BankB`, which serves Bob, and vice versa. At each recursive call, a bank process regrades its running confidentiality to interact with the next customer. The example showcases a characteristic feature of our type system: it accepts an implementation for a bank that interactively communicates with Alice and Bob without jeopardizing noninterference.

The following session types dictate the above protocol:

$$\begin{array}{ll} \text{customer} = \oplus\{\text{tok}_{black} : \&\{\text{succ} : \text{customer}, \text{fail} : \text{customer}\}, \\ \quad \text{tok}_{white} : \&\{\text{succ} : \text{customer}, \text{fail} : \text{customer}\}\} & \text{account} = \text{transfer} \multimap \text{account} \\ & \text{transfer} = \oplus\{\text{transaction} : 1\} \end{array}$$

Fig. 9 shows the process implementations Bank_A , Bank_B , Customer_A , and Statement_A . The latter two are the implementation of Alice's customer and statement process, resp. The implementation of Customer_A is as expected. Statement_A signals a single transfer by sending the label transaction and terminates. The implementation of corresponding processes for Bob,

■ **Figure 9** Security-polymorphic process definitions.

i.e., Customer_B , and Statement_B , would be similar. The example is typed using the security theory Ψ , consisting of the concrete security lattice Ψ_0 , the security variables ψ and ψ' , and the set of constraints $\{\text{guest} \sqsubseteq \psi \sqsubseteq \text{bank}, \text{guest} \sqsubseteq \psi' \sqsubseteq \text{bank}\}$. (See TR for the formal definition of a security theory.) To execute this program using the dynamics in Fig. 8, we provide the order-preserving substitution $\Psi_0 \Vdash \gamma' :: \Psi$, defined as $\gamma' := \{\psi \mapsto \text{alice}, \psi' \mapsto \text{bob}\}$.

Let us examine the pattern checks $\sim_{\langle \psi, \text{guest} \rangle}$ invoked by $\text{case } y_1(\dots)$ in Bank_A , relating the branches corresponding to black and white tokens. The sends along y_1 match in both branches, as demanded by SNDLAB (since $\Psi \not\Vdash \psi \sqsubseteq \text{guest}$), even though the sent labels are not the same. The unsynchronized spawn and send along w_1 is verified by UNSYNC-SPAWN₁ and UNSYNC₁, resp., since $\Psi \Vdash \psi \sqsubseteq \psi$. The matching tail calls are verified with SYNC-SPAWN.

6 Progress-sensitive noninterference

This section presents our main result, PSNI, which we prove using a logical relation.

6.1 Attacker model

The attacker model assumes a configuration \mathcal{D} with prior annotation of its free channels with security levels, the attacker's confidentiality level ξ , and a nondeterministic scheduler. The attacker knows the source code of \mathcal{D} , can only observe the messages sent along the free channels of \mathcal{D} with confidentiality level $c \sqsubseteq \xi$, and cannot measure the passing of time.

6.2 Noninterference via an integrity logical relation

Noninterference amounts to a process equivalence up to the confidentiality level ξ of an observer. In a message-passing system, it boils down to an equivalence of a configuration with interacting processes. This section focuses on noninterference for tree-shaped configurations. The definition can be extended to forests by enforcing pairwise relation between their trees.

An open configuration $\Psi_0; \Delta \Vdash \mathcal{D} :: x_\alpha:A(c, e)$ has the free channels Δ and x_α to communicate with its external environment; it sends outgoing messages to and receives incoming messages from the environment along these free channels. Two observationally equivalent

Figure 11 Value interpretation of logical relation for left communications.

configurations may only differ in outgoing messages of confidentiality level $c_o \not\sqsupseteq \xi$, assuming that the incoming messages of confidentiality level $c_i \sqsubseteq \xi$ are the same. We introduce a *logical relation* that captures this idea and accounts for integrity and regrading policies.

The logical relation relates two open configurations \mathcal{D}_1 and \mathcal{D}_2 – the two runs of the program under consideration – and asserts that \mathcal{D}_1 and \mathcal{D}_2 send related messages to the environment, if they receive related messages from the environment. The term interpretation of the logical relation, defined in Fig. 10, allows the first configuration \mathcal{D}_1 to step internally until the configuration is ready to send or receive a message across at least one external channel. Then, it requires the second configuration \mathcal{D}_2 to step internally so that the resulting configurations are in the value interpretation of the logical relation, defined in Fig. 11 and Fig. 12. We call the external channels, e.g., $\Delta \Vdash K$ in Fig. 10, the interface of \mathcal{D}_1 and \mathcal{D}_2 . The metavariable K stands for either $x_\alpha:A \langle c, e \rangle$ or simply $_ : 1 \langle \top, \top \rangle$ which refers to an arbitrary unobservable channel.

The idea is to build an interface consisting of those external channels of the configurations that may impact the attacker’s observations. As such, not only do we need to include the observable channels, i.e., with confidentiality level $c \sqsubseteq \xi$, in the interface, but also those with higher integrity than the observer, i.e., with integrity level $e \sqsubseteq \xi$. After all, if a channel’s integrity is high enough (and thus its level is low), the messages along it may affect an observable outcome via synchronization patterns. We call such an interface *integrity interface* since low-confidentiality channels are all high-integrity by typing.

Figure 13 Logical equivalence.

To build an *integrity interface* for \mathcal{D}_1 and \mathcal{D}_2 , we close off their external low-integrity ($e \not\sqsubseteq \xi$) channels on the left by composing the channels with any well-typed provider and on the right with any well-typed client. We may use different low-integrity clients and providers to compose with each program run. These clients/providers can send different and unsynchronized messages along their high-confidentiality and low-integrity connections to \mathcal{D}_1 and \mathcal{D}_2 . The term interpretation is designed to ensure that well-typed configurations do not leak these different messages to the attacker. Fig. 13 defines an equivalence relation between two configurations based on this idea: it composes them with low-integrity providers/clients and calls the term interpretation symmetrically on the compositions. In the definition, we use the projection function to build the integrity interface, e.g., $\Delta \Downarrow^{\text{ig}} \xi$ projects out the channels $y_{\beta}:A\langle c, e \rangle \in \Delta$ with $\xi \not\sqsubseteq e$. The predicate $\mathcal{D}_1 \in \text{Tree}_{\Psi_0}(\Delta \Vdash K)$ indicates that the configuration \mathcal{D}_1 is well-typed. In the term and value interpretations, we generalize this predicate to the binary case, $(\mathcal{D}_1; \mathcal{D}_2) \in \text{Tree}_{\Psi_0}(\Delta \Vdash K)$ indicating that both \mathcal{D}_1 and \mathcal{D}_2 are of the same type.

The term interpretation allows stepping configuration $\mathcal{D}_1 \mapsto^{*\Upsilon_1:\Theta_1} \mathcal{D}'_1$ by iterated application of the rewriting rules defined in Fig. 8. The star expresses that zero to multiple internal steps can be taken. The superscripts $\Upsilon_1; \Theta_1$ denote two sets of channels occurring in the

interface $\Delta \Vdash K$. The set Θ_1 collects the *incoming* channels, i.e., channels that a process in \mathcal{D}_1 is ready to receive from, and the set Υ_1 collects the *outgoing* channels, i.e., channels with a message in \mathcal{D}_1 ready to be sent. Assuming that \mathcal{D}_1 steps to \mathcal{D}'_1 , generating the outgoing channels Υ_1 , \mathcal{D}_2 must be stepped $\mathcal{D}_2 \xrightarrow{*_{\Upsilon_2}} \mathcal{D}'_2$ to produce at least the same set of outgoing channels, i.e., the set Υ_2 such that $\Upsilon_1 \subseteq \Upsilon_2$. The term interpretation then calls the value interpretation on the resulting configurations $\mathcal{D}'_1, \mathcal{D}'_2$ for every channel that has a message ready for transmission in \mathcal{D}'_1 , and thus \mathcal{D}'_2 , and for every channel that has a process waiting for a message in \mathcal{D}'_1 . Insisting on Υ_2 being a superset of Υ_1 ensures progress-sensitive noninterference without timing attacks: if a configuration produces observable messages along a set of channels, the other configuration has to be able to produce the equivalent set of messages with zero or some internal steps. The term interpretation uses focus channels as a subscript to the value interpretation to support simultaneous communications – when there are multiple messages ready to be sent or received along channels in the interface. The subscript $\cdot; y_\alpha$ indicates that $y_\alpha \in \Upsilon_1$ and $y_\alpha; \cdot$ that $y_\alpha \in \Theta_1$.

The value interpretation accounts for every message sent from or received by \mathcal{D}_1 and \mathcal{D}_2 , amounting to two cases per connective: one for a message exchanged along a channel in K and one for a message exchanged along a channel in Δ . We refer to the former as communications to the *right* (Fig. 12) and the latter as communications to the *left* (Fig. 11). The value interpretation generally establishes the following pattern: it asserts relatedness of outgoing messages, but assumes relatedness of incoming messages. For example, $\&$ on the left (l_3 in Fig. 11) *asserts* the sending of related messages and pushes the messages into the environment, yielding $\mathcal{D}'_1, \mathcal{D}'_2$. Now, $\mathcal{D}'_1, \mathcal{D}'_2$, can each step internally, e.g., to consume the incoming messages, requiring them to be in the term interpretation. On the other hand, $\&$ on the right (r_3 in Fig. 12) *assumes* receipt of related messages and pushes the messages into the configurations \mathcal{D}_1 and \mathcal{D}_2 . *Relatedness* for messages is determined by how they can impact the attacker’s observations. If their carrier channel is observable to the attacker, i.e., has confidentiality level $c \sqsubseteq \xi$, then related messages must have the same labels. But if the channel only affects the attacker’s observations via synchronization patterns, related messages may have different labels. The clause $c \sqsubseteq \xi \rightarrow k_1 = k_2$ in the value interpretation conveys this, enforcing equality of the communicated labels only if the channel is observable.

Relatedness for higher-order types (\otimes and \multimap) is a bit more subtle. In particular, it requires future observations along the exchanged channels to be related. For example, l_5 in Fig. 11 for \multimap -left asserts existence of a message $\mathbf{msg}(\mathbf{send}x_\beta^{(c,e)} y_\alpha^{(c,e)})$ and of subtrees \mathcal{T}_1 and \mathcal{T}_2 in \mathcal{D}_1 and \mathcal{D}_2 . The clause comprises two invocations of the term relation, $(\mathcal{T}_1; \mathcal{T}_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta' \Vdash x_\beta : A(c, e)]^m$, asserting that future observations to be made along the sent channel x_β are related, and $(\mathcal{D}'_1; \mathcal{D}'_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta'', y_{\alpha+1} : B(c, e) \Vdash K]^m$, asserting that the continuations \mathcal{D}'_1 and \mathcal{D}'_2 are related. Conversely, r_5 in Fig. 12 for \multimap -right assumes receipt of a message $\mathbf{msg}(\mathbf{send}x_\beta^{(c,e)} y_\alpha^{(c,e)})$ and invokes the term relation $(\mathcal{D}_1 \mathbf{msg}(\mathbf{send}x_\beta^{(c,e)} y_\alpha^{(c,e)}); \mathcal{D}_2 \mathbf{msg}(\mathbf{send}x_\beta^{(c,e)} y_\alpha^{(c,e)})) \in \mathcal{E}_{\Psi_0}^\xi [\Delta, x_\beta : A(c, e) \Vdash y_{\alpha+1} : B(c, e)]^m$.

As we support general recursive types, we need an index to stratify our logical relation [3,5]. We tie our index to the number of *observations* that can be made along the interface $\Delta \Vdash K$, as suggested in [7]. We thus bound the value and term interpretation of our logical relation by the number of observations m , for $m \geq 0$, and attach them as superscripts to the relation’s interface $\Delta \Vdash K$. The base case of the term interpretation, i.e., $m = 0$, is a trivial relation.

The fundamental theorem states that any well-typed SINTEGRITY configuration is equivalent to itself up to the level of an arbitrary observer.

► **Theorem 1** (Fundamental theorem). *For all security levels ξ , and a well-typed configuration $\Psi_0; \Delta \Vdash \mathcal{D} :: u_\alpha : T(c, e)$ we have $(\Delta \Vdash \mathcal{D} :: u_\alpha : T(c, e)) \equiv_{\xi^0} (\Delta \Vdash \mathcal{D} :: u_\alpha : T(c, e))$.*

Proof. We present a proof sketch; see the TR for details. By the definition of logical equivalence (Fig. 13), we first need to close off the external low integrity ($e \not\sqsubseteq \xi$) channels in Δ and $u_\alpha:T\langle c, e \rangle$ by composing \mathcal{D} with arbitrary well-typed providers and clients, resp. We use low integrity clients, \mathcal{T}_1 and \mathcal{T}_2 , and low-integrity providers, \mathcal{B}_1 and \mathcal{B}_2 , to compose with each run, resulting in two configurations, $\mathcal{D}_1 = \mathcal{B}_1 \mathcal{D} \mathcal{T}_1$ and $\mathcal{D}_2 = \mathcal{B}_2 \mathcal{D} \mathcal{T}_2$. Configurations \mathcal{D}_1 and \mathcal{D}_2 are both well-typed for the integrity interface: $\Psi_0; \Delta' \Vdash \mathcal{D}_i :: K$ where $\Delta' = \Delta \Downarrow^{\text{ig}} \xi$ and $K = u_\alpha:T\langle c, e \rangle \Downarrow^{\text{ig}} \xi$. By the definition in Fig. 13, it is enough to show that \mathcal{D}_1 and \mathcal{D}_2 are in the term interpretation with the integrity interface, i.e., $\forall m. (\mathcal{D}_1, \mathcal{D}_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta' \Vdash K]^m$ and $\forall m. (\mathcal{D}_2, \mathcal{D}_1) \in \mathcal{E}_{\Psi_0}^\xi [\Delta' \Vdash K]^m$. We prove the former by induction on m ; the proof of the latter is symmetric. Specifically, we prove a more general theorem (Thm. 6.1 in TR) for any \mathcal{D}_1 and \mathcal{D}_2 with the same observable outcome, using the notion of relevant nodes (Def. 4.2 in TR). By the definition of the term interpretation in Fig. 10, the base case ($m = 0$) is straightforward. For the inductive case, following the first row of Fig. 10, we assume arbitrary Υ_1 , Θ_1 , and \mathcal{D}'_1 such that $\mathcal{D}_1 \mapsto^{*\Upsilon_1, \Theta_1} \mathcal{D}'_1$. We apply a lemma (Lem. 4.5 in TR) stating that \mathcal{D}_2 can simulate the internal steps taken by \mathcal{D}_1 , producing at least the same set of outgoing channels Υ_2 , i.e., $\mathcal{D}_2 \mapsto^{*\Upsilon_2} \mathcal{D}'_2$, such that \mathcal{D}'_1 and \mathcal{D}'_2 continue to have the same observable outcomes. Finally, for every channel x_α in Υ_1 and Θ_1 , we case analyze on the type of x_α , showing that \mathcal{D}'_1 and \mathcal{D}'_2 are in the value interpretation, with x_α being the focus channel. To do so, we use the induction hypothesis to establish that after the corresponding communication with the environment, the continuations of \mathcal{D}'_1 and \mathcal{D}'_2 are related by the term interpretation for a smaller index. \blacktriangleleft

6.3 Adequacy

Next, we prove an adequacy theorem showing that two logically equivalent configurations are *bisimilar* up to observations of confidentiality ξ .

For adequacy, we are interested in a *confidentiality interface*, i.e., channels with observable max confidentiality $c \sqsubseteq \xi$; after all, our goal is to prove that the configurations are equivalent up to the confidentiality of an observer. Because the integrity interface of our logical relation is a *superset* of the confidentiality interface, we need to close off those channels in the integrity interface that are of high-confidentiality ($c \not\sqsubseteq \xi$). Note that these high-confidentiality channels are of high-integrity ($e \sqsubseteq \xi$). To close off these channels, we compose the open configurations with high-confidentiality clients and providers, possibly different ones for each program run. These high-integrity clients and providers are connected to the open configurations via high-integrity channels and, as a result, may affect the observable outcome of the two runs via synchronization patterns. We therefore require them to be logically equivalent.

Based on this idea, Fig. 14 defines the *bisimulation up to* confidentiality ξ denoted as \approx_a^ξ , for two well-typed configurations: it first composes the two configurations with high-confidentiality providers (**Hrel-IPProvider**) and clients (**H-CClient**), while insisting that the high-integrity parts of the providers and clients are logically equivalent (using the relations **Hrel-IPProvider** and **Hrel-ICClient**). Then it invokes an asynchronous bisimulation \approx_a on the compositions. The definition uses a projection function $\Downarrow^{\text{cf}} \xi$ to build the confidentiality interface, e.g., $\Delta \Downarrow^{\text{cf}} \xi$ projects out the channels in Δ with confidentiality $c \not\sqsubseteq \xi$.

The *asynchronous bisimulation* \approx_a invoked by the definition in Fig. 14 uses a labeled transition system (LTS) following the standard definition of asynchronous bisimulation [38]. The relation $\mathcal{D}_1 \approx_a \mathcal{D}_2$ states that every internal step or external action of \mathcal{D}_1 can be (weakly) simulated by \mathcal{D}_2 and vice-versa. For example, when \mathcal{D}_1 takes an action by sending output q via an external channel x_α , i.e., $\mathcal{D}_1 \xrightarrow{x_\alpha q} \mathcal{D}'_1$, the bisimulation ensures that for some \mathcal{D}'_2 , we have $\mathcal{D}_2 \xrightarrow{x_\alpha q} \mathcal{D}'_2$ and $\mathcal{D}'_1 \approx_a \mathcal{D}'_2$. Here, $\xrightarrow{x_\alpha q}$ stands for taking zero or more internal steps before outputting q along x_α . The full definition of bisimulation is in the TR.

$$\begin{aligned}

Figure 14 Asynchronous bisimulation up to observations of confidentiality ξ .

Now we are ready to present our adequacy theorem stating that, given an observer level ξ , logically equivalent configurations are bisimilar up to observations of confidentiality ξ . The proof of the theorem relies on a compositionality lemma, which ensures a harmony between asserts and assumes in the value-interpretation of the logical relation.

Lemma 2 (Compositionality). $\forall m. (\mathcal{D}_1; \mathcal{D}_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta, u_\alpha^{(c,e)} : T \Vdash K]^m$ and $\forall m. (\mathcal{T}_1; \mathcal{T}_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta' \Vdash u_\alpha^{(c,e)} : T]^m$ if and only if $\forall k. (\mathcal{T}_1 \mathcal{D}_1; \mathcal{T}_2 \mathcal{D}_2) \in \mathcal{E}_{\Psi_0}^\xi [\Delta', \Delta \Vdash K]^k$.

Theorem 3 (Adequacy). If $(\Delta_1 \Vdash \mathcal{D}_1 :: x_\alpha:A_1\langle c_1, e_1 \rangle) \equiv_{\xi}^{\Psi_0} (\Delta_2 \Vdash \mathcal{D}_2 :: y_\beta:A_2\langle c_2, e_2 \rangle)$ then $(\Delta_1 \Vdash \mathcal{D}_1 :: x_\alpha:A_1\langle c_1, e_1 \rangle) \approx_a^\xi (\Delta_2 \Vdash \mathcal{D}_2 :: y_\beta:A_2\langle c_2, e_2 \rangle)$.

Proof. Recall from Fig. 14 that \approx_a^ξ composes \mathcal{D}_1 and \mathcal{D}_2 with arbitrary high-confidentiality ($c \not\sqsubseteq \xi$) clients and providers, building a confidentiality interface $[\Delta^c \Vdash K^c]$. Let us call the high-confidentiality providers \mathcal{B}_1 and \mathcal{B}_2 and the high-confidentiality clients \mathcal{T}_1 and \mathcal{T}_2 . We can partition the providers into high-integrity and low-integrity parts to get $\mathcal{B}_1 = \mathcal{B}_1^{HI} \mathcal{B}_1^{LI}$ (similarly for the clients $\mathcal{T}_1 = \mathcal{T}_1^{HI} \mathcal{T}_1^{LI}$), where superscripts HI and LI correspond to high-integrity and low-integrtiy parts, resp. Our goal is to prove $\mathcal{B}_1^{HI} \mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{HI} \mathcal{T}_1^{LI} \approx_a \mathcal{B}_2^{HI} \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{HI} \mathcal{T}_2^{LI}$.

Step 1. The first step is to show that the two compositions are related by the term interpretation as well, i.e., $\forall m. (\mathcal{B}_1^{HI} \mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{HI} \mathcal{T}_1^{LI}; \mathcal{B}_2^{HI} \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{HI} \mathcal{T}_2^{LI}) \in \mathcal{E}[\Delta^c \Vdash K^c]$. To do so, we can use the definition from Fig. 13 for $\equiv_{\xi}^{\Psi_0}$ to compose \mathcal{D}_1 and \mathcal{D}_2 with given low integrity clients and providers $\mathcal{T}_1^{LI}, \mathcal{T}_2^{LI}, \mathcal{B}_1^{LI}$, and \mathcal{B}_2^{LI} to build the integrity interface $[\Delta^i \Vdash K^i]$ and get $\forall m. (\mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{LI}; \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{LI}) \in \mathcal{E}[\Delta^i \Vdash K^i]$. However, this is not enough to achieve our goal as the relation pertains to the integrity interface, and thus, the composition only includes the low integrity providers/clients. To build the confidentiality interface and include the high integrity parts, we use the fact that the high integrity providers \mathcal{B}_1^{HI} and \mathcal{B}_2^{HI} (and clients \mathcal{T}_1^{HI} and \mathcal{T}_2^{HI}) are themselves logically equivalent. We use our compositionality lemma (Lem. 2) to compose the high-integrity channels in the integrity interface with these providers/clients and show that the composition results in two logically equivalent configurations, i.e., $\forall m. (\mathcal{B}_1^{HI} \mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{HI} \mathcal{T}_1^{LI}; \mathcal{B}_2^{HI} \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{HI} \mathcal{T}_2^{LI}) \in \mathcal{E}[\Delta^c \Vdash K^c]$.

Step 2. We complete the proof by connecting our logically related configurations to an observational equivalence relation for session types [7], which is proved sound and complete for asynchronous bisimulation. We first show that our integrity term interpretation implies the observational equivalence relation in [7] when we consider a confidentiality interface, and then use their soundness result to show that the integrity term interpretation $\forall m. (\mathcal{B}_1^{HI} \mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{HI} \mathcal{T}_1^{LI}; \mathcal{B}_2^{HI} \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{HI} \mathcal{T}_2^{LI}) \in \mathcal{E}[\Delta^c \Vdash K^c]$ implies bisimilarity $\mathcal{B}_1^{HI} \mathcal{B}_1^{LI} \mathcal{D}_1 \mathcal{T}_1^{HI} \mathcal{T}_1^{LI} \approx_a \mathcal{B}_2^{HI} \mathcal{B}_2^{LI} \mathcal{D}_2 \mathcal{T}_2^{HI} \mathcal{T}_2^{LI}$.

Next, we briefly explain how our integrity logical relation coincides with the observational equivalence relation (for well-typed configurations) in [7] when considering a confidentiality interface. The observational equivalence in [7] is defined via a logical relation similar to the one developed in this paper, but only considering the confidentiality interface. Let us call the term and value interpretations of our logical relation \mathcal{E}^i and \mathcal{V}^i (defined in Figs. 10–12) and the ones defined in [7] \mathcal{E}^c and \mathcal{V}^c , resp. The relation \mathcal{E}^i is invoked for the integrity interface $[\Delta^i \Vdash K^i]$ in Fig. 13, and similarly \mathcal{E}^c is invoked for the confidentiality interface $[\Delta^c \Vdash K^c]$, where, by definition, Δ^c is a subset of (or equal to) Δ^i and K^c is a subset of (or equal to) K^i . As the integrity logical relation may contain non-observable channels ($c \not\subseteq \xi$), it only insists that the same labels are sent when communication is along observable channels. Concretely, \mathcal{V}^i in lines (l_2) , (l_3) , (r_2) , and (r_3) only insists that the labels k_1 and k_2 sent/received along a channel are the same if $c \sqsubseteq \xi$. However, \mathcal{V}^c always enforces sending the same labels, since a priori the condition $c \sqsubseteq \xi$ holds for all the channels in its interface. In all other regards, \mathcal{E}^i and \mathcal{V}^i have the same definition as \mathcal{E}^c and \mathcal{V}^c . As a result, it is straightforward to observe that given an interface $\Delta^c \Vdash K^c$ with only observable channels (channels with $c \sqsubseteq \xi$), we have $\forall m. (\mathcal{D}_1; \mathcal{D}_2) \in \mathcal{E}^i[\Delta^c \Vdash K^c]^m$ iff $\forall m. (\mathcal{D}_1; \mathcal{D}_2) \in \mathcal{E}^c[\Delta^c \Vdash K^c]^m$. ◀

7 Related work

IFC type systems using linearity. Conceptually most closely related to our work is the work by Zdancewic and Myers on *ordered linear continuations* [46, 47]. The authors consider continuation-passing style (CPS) security-typed languages to verify noninterference not only for source-level programs but also compiled code. The authors observe that the possibility to lower the `pc` label upon exiting control flow constructs, present in imperative source-level languages, is no longer available in a CPS language. To rectify the loss of flexibility they introduce ordered linear continuations. Similar to our pattern checks, ordered linear continuations allow downgrading of the `pc` label after branching on `high`, because linearity enforces the continuations to be used in every branch, in the order prescribed. In contrast to our work, the authors only consider a sequential language and only prove PINI. Our work moreover establishes the connection to integrity, facilitating regrading policies that are polymorphic in the security lattice for ultimate flexibility.

In another line of work Zdancewic and Myers again employ linearity for increased flexibility and a stronger noninterference statement [48]. The authors consider a concurrent language with a store and first-class channels. Their main focus is observational determinism, ensuring immunity to internal timing attacks and attacks that exploit information about thread scheduling. To this end the authors introduce linear channels and a race freedom analysis. Given that **SINTEGRITY** enjoys confluence, like other linear session type languages, it rules out timing attacks that exploit the relative order of messages, which seems to be a stronger property than immunity to internal timing attacks considered by the authors. Moreover, we establish PSNI for **SINTEGRITY**, whereas the authors only prove PINI.

IFC session type systems. In terms of underlying language, the work most closely related to ours is the one by Derakhshan et al. [7, 20]. The authors develop an IFC type system for the same family of linear session types but only consider confidentiality. Their system annotates the process term judgments with running and max confidentiality. Their typing rules only ensure that the running confidentiality (aka taint level) is updated correctly after each receive and that a tainted process does not leak information via send. In particular, the rules do not allow decreasing the taint level at any point. As a result the authors’ type system suffers from the same restrictiveness as other IFC type systems for concurrent languages, requiring each loop iteration to run at the maximal confidentiality reached throughout an arbitrary iteration. For example, the authors’ IFC type system rejects the banking example in § 5.4: as soon as the bank receives a message from one customer, say Alice, it will be tainted and cannot send a message to any other customer, say Bob. In fact, the authors’ IFC type system rejects all well-typed examples presented in this paper even though they enjoy PSNI. We make our IFC type system more flexible by designing synchronization policies to enable regrading of the taint level and using integrity labels to make the policies composable, both of which are novel to our system. Designing these composable policies was an intricate task, particularly due to dealing with both concurrency and general recursion.

Our logical relation for integrity is inspired by Balzer et al.’s [7] logical relation for equivalence. The logical relation for equivalence is defined based on the confidentiality interface. Our logical relation, however, is based on the larger integrity interface to enable the proof of the fundamental theorem. We prove our adequacy theorem by proving compositionality for our logical relation, which then allows us to recast our logical relation in terms of the logical relation for equivalence by the authors, delivering adequacy as a corollary.

IFC type systems for multiparty session types and process calculi. IFC type systems have also been explored for multiparty session types [10–13]. These works explore declassification [10, 12] and flexible runtime monitoring techniques [11, 13]. Our work not only differs in use of session type paradigm (i.e., binary vs. multiparty) but also in use of a logical relation for showing noninterference. Our work is more distantly related with IFC type systems for process calculi [16–18, 25, 25, 28, 29, 31, 34, 48]. These works prevent information leakage by associating a security label with channels/types/actions [29], read/write policies with channels [25, 25], or capabilities with expressions [16]. Honda et al. [29] also use a substructural type system and prove a sound embedding of Dependency Core Calculus (DCC) [2] into their calculus. Our work sets itself apart in its use of session types and meta theoretic developments based on logical relations. Moreover, our IFC type system is more permissive as it allows for regrading of the taint level, while preserving noninterference.

Declassification. Our notion of regrading may seem related to declassification, which has extensively been studied for IFC type systems for functional and imperative languages [1, 6, 15, 22, 32, 33, 44, 45, 49] and allows an entity to downgrade its level of confidentiality. However, our work significantly differs from declassification as it preserves PSNI, whereas declassification systems *deliberately* release information and thus intentionally *weaken* noninterference.

In particular, robust declassification [6, 15, 33, 44, 45, 49] prevents adversaries from exploiting downgrading of confidentiality, by complementing confidentiality with integrity. It uses integrity to ensure that downgrading decisions can be trusted, i.e., cannot be influenced by an attacker. As such, only high-integrity data can influence the taint level to be lowered. This is similar to our system, where the higher the integrity of a process, the lower level it can regrade the taint level. The difference, however, is that we enforce extra synchronization

policies on our high-integrity processes to ensure that they cannot induce information leaks by lowering the taint level. This contrasts with work on robust declassification, which introduces leakage intentionally and thus compromises noninterference.

Mutation-Based Lifted Repair of Software Product Lines

Aleksandar S. Dimovski 

Mother Teresa University, Skopje, North Macedonia

Abstract

This paper presents a novel lifted repair algorithm for program families (Software Product Lines - SPLs) based on code mutations. The inputs of our algorithm are an erroneous SPL and a specification given in the form of assertions. We use variability encoding to transform the given SPL into a single program, called family simulator, which is translated into a set of SMT formulas whose conjunction is satisfiable iff the simulator (i.e., the input SPL) violates an assertion. We use a predefined set of mutations applied to feature and program expressions of the given SPL. The algorithm repeatedly mutates the erroneous family simulator and checks if it becomes (bounded) correct. Since mutating an expression corresponds to mutating a formula in the set of SMT formulas encoding the family simulator, the search for a correct mutant is reduced to searching an unsatisfiable set of SMT formulas. To efficiently explore the huge state space of mutants, we call SAT and SMT solvers in an incremental way. The outputs of our algorithm are all minimal repairs in the form of minimal number of (feature and program) expression replacements such that the repaired SPL is (bounded) correct with respect to a given set of assertions.

We have implemented our algorithm in a prototype tool and evaluated it on a set of `#ifdef`-based C programs (i.e., annotative SPLs). The experimental results show that our approach is able to successfully repair various interesting SPLs.

1 Introduction

A *program family* (Software Product Line - SPL) represents a set of similar programs, known as *variants*, generated from a common code base [2]. SPL engineering has been successfully applied in industry to meet the need for custom-tailored software. For instance, different variants from an SPL can target different platforms or may serve customization requirements for different customers. The variants are specified in terms of *features* selected for that particular variant. The popular `#ifdef` directives from the C preprocessor CPP [43] represent the most common way to implement such (annotative) program families. An `#ifdef` directive specifies under which presence conditions (i.e., feature selections or feature expressions), parts of code should be included or excluded from a variant at compile-time. SPLs are often used in the development of the embedded and safety-critical systems (e.g., mobile devices, cars, medicine, avionics), where their behavioral correctness is of primary interest. In particular, the focus is on applying various verification and analysis techniques from the field of formal methods, which can give stronger guarantees on the correctness of software systems. In the last decade, much effort has been invested in designing specialized so-called *lifted* (family-based) formal verification and analysis algorithms [4, 6, 9, 43, 30, 14, 23, 15, 20, 22, 25, 55], which allow simultaneous verification of all variants of an SPL in a single run by exploiting the commonalities between the variants. They usually return an error trace, which shows

how the given specification is violated. However, the users still need to process the obtained result, in order to isolate the cause of the error to a small part of the code and subsequently to repair the given SPL. Here, we consider the problem of *SPL repair*, which is defined to be a code transformation such that the repaired SPL satisfies a given specification (e.g. assertion). Automatic SPL repair is an important problem since even if an error is identified in the verification phase, the manual error-repair is a nontrivial time-consuming task that requires close knowledge of the SPL. For instance, the error-repair of one variant may cause new errors to appear in other variants due to the feature interaction in the given SPL [3]. Recently, researchers have developed several successful single-program repair tools [28, 37, 40, 42, 45, 46, 48, 50, 51]. However, these tools cannot be directly applied to SPLs as they are only able to handle pre-processed single programs.

In this paper, we lift the mutation-based approach ALLREPAIR [50, 51] for repairing single programs to program families (SPLs). Figure 1 illustrates our lifted repair system. More specifically, we use *variability encoding* [30, 56] to transform program families to single programs, called family simulators, by replacing compile-time variability with run-time variability (non-determinism). The (family) simulator, which contains the computations of all variants of a program family, is then translated into a set of SMT formulas using the CBMC bounded model checker [8]. The conjunction of the obtained SMT formulas is *satisfiable* iff there is an assertion violation in the given simulator iff there is an assertion violation in at least one variant of the original program family. On the other hand, the conjunction of the obtained SMT formulas is *unsatisfiable* iff all assertions are valid in the given simulator iff all assertions are valid in all variants of the original program family. We use a bounded notion of correctness, since we consider only bounded computations in which each loop and recursive call are inlined at most b times. Each statement in the simulator corresponds to a formula in the obtained set of SMT formulas, which can be partitioned into subset S_{hard} encoding parts of the program that cannot be changed and subset $S_{\text{soft}} = S_{\text{soft}}^{\text{F}} \cup S_{\text{soft}}^{\text{Var}}$ encoding parts of the program that can be changed. Therefore, mutating a feature or program expression found in a statement that can be changed corresponds to changing the respective SMT formula from $S_{\text{soft}}^{\text{F}}$ or $S_{\text{soft}}^{\text{Var}}$, respectively. The *mutator* unit generates mutated family simulators (mutants) by using a predefined set of syntactic mutations/edits applied to feature and program expressions. Hence, in our repair model, we permit feature and program expressions to be changed but not statements. For example, we allow replacement of `#ifdef` guards (e.g., by applying \neg to features, replacing \wedge/\vee with \vee/\wedge) and right-hand sides of assignments (e.g., by increasing or decreasing a constant, replacing $+/-$ with $-/+$). Thus, the size of the space of mutants depends on the choice of permissible mutations/edits used for repair. The mutants are explored in increasing number of mutations applied to the original family

simulator, so that only minimal sets of mutations are considered. Hence, the search in the space of mutants reduces to searching for an unsatisfiable set of SMT formulas. This search is performed using an iterative generate-and-verify process. The *generator* produces a minimally changed mutant using a SAT solver and the *verifier* checks the bounded-correctness of mutant using an SMT solver. This way, we find a solution with a minimal number of syntactic changes/edits to the original (incorrect) program family. Therefore, the type of errors that can be corrected is determined by the fixed set of syntactic mutations/edits, which can be applied to feature and program expressions. Hence, our approach can make repairs by replacing expressions in `#ifdef`-guards and right-hand sides of assignments with another expressions of the same form, but it cannot make repairs by replacing (adding/deleting) statements (e.g., replace assignment with if statement) or by replacing expressions with another expressions of different form (e.g., replace expression 5 with $x+y$). Both SAT and SMT solvers are used in an incremental way, which means that learned information is passed between successive calls. Since variants in a program family as well as mutated simulators are very similar, their encodings as sets of SMT formulas will have a lot in common. Hence, we can reuse the information that was gathered in checking previous mutated simulators to expedite the solution of the current one. The incremental solving was implemented via the mechanisms called assumptions and guard variables [26].

We have implemented our algorithm for repairing `#ifdef`-based C program families in a prototype tool, called SPLALLREPAIR, which is built on top of the ALLREPAIR tool [50, 51]. The tool uses the CBMC model checker [8] for translating single programs to SMT formulas, as well as the MINICARD [39] and Z3 [11] tools for SAT and SMT solving. We illustrate this approach for automatic repair on a number of C program families from the literature [10, 37, 46, 50, 51], and we report very encouraging results. We compare performances of two versions of our tool, with smaller and bigger sets of possible mutations, as well as with the **Brute-force** approach that repairs all variants from a program family one by one independently.

We summarize the contributions of this paper as follows:

Lifted Algorithm for SPL Repair: We propose a novel lifted algorithm based on variability encoding and syntactic code mutations for repairing program families;

Synthesizing Minimally Repaired SPLs: We automatically compute all minimal repaired program families (minimal in the number of code replacements) that are bounded correct by mutating feature and program expressions;

Implementation and Evaluation: We build a prototype tool for automatically repairing `#ifdef`-based C program families, and present experimental results by evaluating it on a dozen of C benchmarks.

2 Motivating Example

We now present an overview of our approach using a motivating example. Consider the `#ifdef`-based C program family `intro1`, shown in Fig. 2, which uses two Boolean features A and B. They induce a family of four variants defined by the set of configurations $\mathbb{K} = \{A \wedge B, \neg A \wedge B, A \wedge \neg B, \neg A \wedge \neg B\}$. For each configuration, a different variant (single program) can be generated by appropriately resolving `#if` directives. For example, the variant for configuration $(A \wedge B)$ will have both features A and B enabled (set to true or 1), thus yielding the body of `main()`: `int x=0; x=x+2; assert(x≥0); return x`. The variant for $(\neg A \wedge \neg B)$ will have both features A and B disabled (set to false or 0), so it has the following body of `main()`: `int x=0; x=x-2; assert(x≥0); return x`. In such program families, it may

```

int main(){
① int x := 0;
② #if (A) x := x+2; #endif
④ #if ( $\neg A \wedge \neg B$ ) x := x-2; #endif
⑥ assert (x  $\geq$  0);
⑦ return x;
}

```

Figure 2 intro1.

```

int A := [0, 1];
int B := [0, 1];
int main(){
    int x := 0;
    if (A) x := x+2;
    if ( $\neg A \wedge \neg B$ ) x := x-2;
    assert (x  $\geq$  0);
    return x;
}

```

Figure 3 intro2.

```

A0 := [0, 1];
B0 := [0, 1];
int main(){
    x0 := 0;
    g0 := A0;
    x1 := x0+2;
    x2 := g0?x1 : x0;
    g1 :=  $\neg A0 \wedge \neg B0$ ;
    x3 := x2-2;
    x4 := g1?x3 : x2;
    assert (x4  $\geq$  0);
    return x4;
}

```

Figure 4 intro3.

```

Sintro = {
    A0=[0, 1],
    B0=[0, 1],
    x0=0,
    g0=A0,
    x1=x0+2,
    x2=ite(g0,x1,x0),
    g1= $\neg A0 \wedge \neg B0$ ,
    x3=x2-2,
    x4=ite(g1,x3,x2),
     $\neg(x4 \geq 0)$ 
}

```

Figure 5 S_{intro} .

happen that errors (e.g., assertion violations) occur in some variants but not in others. In the `intro1` family, the assertion is valid for variants $(A \wedge B)$, $(A \wedge \neg B)$, $(\neg A \wedge B)$ since the returned value x will be 2, 2, 0, respectively. However, the assertion fails for variant $(\neg A \wedge \neg B)$ since the returned value x will be -2 in this case. The goal is to automatically repair this program family, so that the assertion is valid for all its variants.

If we make mutations only to feature expressions, there are two possible repairs of `intro1` that remedy the feature interaction $(\neg A \wedge \neg B)$ responsible for the fault. First, the feature expression (A) at loc. ② can be replaced with $(\neg A)$, thus making the assertion correct for all variants: the returned value x will be 0 for variants $(A \wedge B)$, $(A \wedge \neg B)$, $(\neg A \wedge B)$; and 2 for $(\neg A \wedge \neg B)$. Second, the feature expression $(\neg A \wedge \neg B)$ at loc. ④ can be replaced with $(A \wedge \neg B)$, thus making the assertion correct for all variants: the returned value x will be 0 for variants $(\neg A \wedge B)$, $(A \wedge \neg B)$, $(\neg A \wedge \neg B)$; and 2 for $(A \wedge B)$. If we make mutations only to program expressions, then one possible repair is the program expression $(x-2)$ at loc. ⑤ to be replaced with $(x+2)$. The above three repairs are all minimal patched mutations obtained by applying only one code mutation to the original program family. Note that the found repairs depend on the sets of mutations applied to feature and program expressions. For example, if we allow mutations of the arithmetic operator $-$ to $*$ and of the integer constant n to 0, we will also find additional minimal repairs that replace the expression $(x-2)$ at loc. ⑤ with $(x*2)$ or $(x-0)$.

Our algorithm for repairing program families goes through four steps. We refer to the running example `intro1` in Fig. 2 to demonstrate the steps.

- (1) We transform the program family to a single program, called family simulator, using variability encoding [30, 56], such that all features are first declared as global variables and non-deterministically initialized to 0 or 1, and then all `#if` directives are transformed into ordinary `if` statements with the same branch condition. For example, the single program `intro2` in Fig. 3 is a simulator for the program family `intro1` in Fig. 2. Features A and B are defined as non-deterministically initialized global variables and two `#if` directives are replaced with `if`-s.
- (2) The simulator is simplified (e.g., branch conditions are replaced with fresh Boolean variables), unwinded by unrolling loops and recursive functions b times, and converted to static single assignment (SSA) form. In the SSA form, time-stamped versions of program variables are created: every time a variable is assigned, the time-stamp is incremented by one and then the variable is renamed; every time a variable is read, it is renamed using the current time-stamp. Thus, the single program `intro3` in Fig. 4 is obtained by simplifying and converting to SSA form the simulator `intro2` in Fig. 3. For example, the `if` condition $(\neg A_0 \wedge \neg B_0)$ is assigned to a fresh Boolean variable g_1 , the first assignment to `x` is replaced by an assignment to x_0 , the second by an assignment to x_1 , etc. We use Φ -assignments to determine which copy of `x` will be used after `if`-s. For example, the Φ -assignment $x_2 := g_0?x_1 : x_0$ means that x_1 is used if g_0 is true, and x_0 is used if g_0 is false.
- (3) The simplified program in SSA form is converted to a program formula. Hence, the program `intro3` in Fig. 4 is converted to a set of SMT formulas S_{intro} shown in Fig. 5, such that the corresponding program formula φ_{intro} is a conjunction of all SMT formulas in S_{intro} . Note that the Φ -assignment $x_2 := g_0?x_1 : x_0$ is converted to the formula $x_2 = \text{ite}(g_0, x_1, x_0)$, which means $(g_0 \wedge x_2 = x_1) \vee (\neg g_0 \wedge x_2 = x_0)$, while `assert(be)` is converted to $(\neg \text{be})$. Therefore, a program is correct (i.e., all assertions in it are valid) iff the corresponding program formula is unsatisfiable.
- (4) By making mutations in the set of SMT formulas, we aim to construct an unsatisfiable program formula and report the corresponding program as repaired. In the running example, if one of the following mutations: $(g_0 = \neg A)$, $(g_1 = A \wedge \neg B)$, or $(x_3 = x_2 + 2)$, is applied to the set of SMT formulas S_{intro} in Fig. 5, we obtain an unsatisfiable program formula. This way, we generate a minimally mutated program family, which contains only one code mutation, that is correct.

3 Background

In this section, we introduce the background concepts used in later developments. We begin with the definition of syntax and semantics of program families. Then, we proceed to introducing the bounded program analysis for translating single programs to SMT formulas.

3.1 Program Families

Let $\mathbb{F} = \{A_1, \dots, A_n\}$ be a finite set of *Boolean features* available in a program family. A *configuration* $k : \mathbb{F} \rightarrow \{\text{true}, \text{false}\}$ is a truth assignment or a *valuation*, which gives a truth value to each feature. If $k(A) = \text{true}$, then feature A is enabled in configuration k , otherwise A is disabled. We assume that only a subset \mathbb{K} of all possible configurations are *valid*. Each configuration $k \in \mathbb{K}$ can also be represented by a formula: $(k(A_1) \cdot A_1 \wedge \dots \wedge k(A_n) \cdot A_n)$, where $\text{true} \cdot A = A$ and $\text{false} \cdot A = \neg A$. We write \mathbb{K} for the set of all valid configurations. We define *feature expressions*, denoted $\text{FeatExp}(\mathbb{F})$, as the set of propositional logic formulas over \mathbb{F} :

$$\theta (\theta \in \text{FeatExp}(\mathbb{F})) ::= \text{true} \mid A \in \mathbb{F} \mid \neg \theta \mid \theta \wedge \theta \mid \theta \vee \theta$$

We consider a simple sequential non-deterministic programming language, in which the program variables $Var = \{x_1, \dots, x_n\}$ are statically allocated and the only data type is the set \mathbb{Z} of mathematical integers. To define program families, a new compile-time conditional statement is introduced: “**#if** (θ) s **#endif**”, such that the statement s will be included in the variant corresponding to configuration $k \in \mathbb{K}$ only if θ is satisfied by k , i.e. $k \models \theta$. The syntax is:

$$\begin{aligned} s (s \in Stm) ::= & \text{skip} \mid x := ae \mid s; s \mid \text{if } (be) \text{ then } s \text{ else } s \mid \text{while } (be) \text{ do } s \mid \\ & \#if (\theta) s \#endif \mid \text{assert}(be) \mid \text{assume}(be) \\ ae (ae \in AExp) ::= & n \mid [n, n'] \mid x \mid ae \oplus ae, \\ be (be \in BExp) ::= & ae \bowtie ae \mid \neg be \mid be \wedge be \mid be \vee be \end{aligned}$$

where $n \in \mathbb{Z}$, $x \in Var$, $\oplus \in \{+, -, *, \%, /\}$, $\bowtie \in \{<, \leq, ==, !=\}$, and integer interval $[n, n']$ denotes a random integer in the interval. Without loss of generality, we assume that a program family P is a sequence of statements followed by a single assertion, whereas a single program p is a sequence of statements without **#if**-s followed by an assertion.

► **Remark 1.** The C preprocessor CPP [32] also uses other compile-time conditional statements that can be desugared and represented only by the **#if** construct we use in this work, e.g. **#if** (θ) s_0 **#else** s_1 **#endif** is translated into **#if** (θ) s_0 **#endif**; **#if** ($\neg\theta$) s_1 **#endif**. Compile-time conditional constructs can also be defined at the level of expressions, e.g. **#if** (θ) ae_0 **#else** ae_1 **#endif**, and they can be translated into compile-time conditional statements by code duplication [32]. We use variability at the level of statements for pedagogical reasons in order to keep the presentation focussed.

A program family is evaluated in two phases. First, the C preprocessor CPP [32] takes a program family s and a configuration $k \in \mathbb{K}$ as inputs, and produces a variant (single program without **#if**-s) corresponding to k as output. Second, the obtained variant is evaluated using the standard single-program semantics [20]. The first phase is specified by the projection function π_k , which is an identity for all basic statements and recursively pre-processes all sub-statements of compound statements. Hence, $\pi_k(\text{skip}) = \text{skip}$ and $\pi_k(s; s') = \pi_k(s); \pi_k(s')$. The most interesting case is “**#if** (θ) s **#endif**”, where the statement s is included in the variant k if $k \models \theta$;¹ otherwise s is excluded from the variant k . That is:

$$\pi_k(\#if (\theta) s \#endif) = \begin{cases} \pi_k(s) & \text{if } k \models \theta \\ \text{skip} & \text{if } k \not\models \theta \end{cases}$$

Given a program family P , the set of all variants derived from P is $\{\pi_k(P) \mid k \in \mathbb{K}\}$.

3.2 Bounded Program Analysis

Unbounded loops with memory allocation are the reason for the undecidability of the assertion verification problem [24]. To avoid undecidability, we impose a bound on the loops by discarding all executions paths in which a loop is iterated more than a pre-determined number of times. That is, we analyze a new bounded program that under-approximates the original program. Using such bounded program, we can build a SMT formula that represents its semantics. We now briefly explain how a pre-processed program without **#if**-s is translated into a set of SMT formulas using the CBMC bounded model checker [8]. We present only the details that are important to understand our algorithm.

¹ Since $k \in \mathbb{K}$ is a valuation function, either $k \models \theta$ holds or $k \not\models \theta$ holds for any θ .

The given pre-processed (single) program undergoes three transformations: simplification, unwinding, and conversion to SSA form. Recall from Section 2 that the simplification ensures that all branch conditions are replaced with fresh Boolean variables, whereas the SSA-form guarantees that each local variable has a single static point of definition. More specifically, in SSA-form each assignment to a variable x is changed into an unique assignment to a new variable x_i . Hence, if variable x has n assignments to it throughout the program, then n new variables x_0 to x_{n-1} are created to replace x . All uses of x are replaced by a use of some x_i . To decide which definition of a variable reaches a particular use after an `if`-statement with the guard g , we add the Φ -assignment $x_k := g?x_i : x_j$ after the `if`. This means that if control reaches the Φ -assignment via the path on which g is true, Φ selects x_i ; otherwise Φ selects x_j . This way, all uses of x after an Φ -assignment $x_k := g?x_i : x_j$ become uses of Φ -assignment x_k until the next assignment of x . The unwinding with bound b means that all `while` loops and recursive functions are unwound b times, so that we consider only so-called *b-bounded paths* that are going through them at most b times. For example, the statement “`while (be) do s`” after unwinding with $b = 2$ will be transformed to:

```
 $g:=be; \text{if } (g) \text{ then } \{s; g:=be; \text{if } (g) \text{ then } \{s; g:=be; \text{assume}(\neg g); \} \}$ 
```

where we use `assume($\neg g$)` to block all paths longer than the bound b . After the above three transformations, in the obtained simplified program all original expressions are right-hand sides (RHSs) of assignments, loops are replaced with `if`-s, and each variable is assigned once. For example, the simplified program `intro3` is obtained from `intro2` by the above three transformations.

The generated simplified program is converted to a set of SMT formulas S as follows. An assignment $x := ae$ is converted to equation formula $x = ae$; a Φ -assignment $x := be?x_1 : x_2$ is converted to formula $x = \text{ite}(be, x_1, x_2)$; an `assume(be)` is converted to formula be ; and an `assert(be)` is converted to formula $\neg be$. A statement that is part of a `while` body may be encoded by several formulas ϕ_1, \dots, ϕ_k in S due to the unwinding. In this case, we remove ϕ_1, \dots, ϕ_k from S , and add instead one conjunctive formula $(\phi_1 \wedge \dots \wedge \phi_k)$ in S . In effect, we obtain that one formula in S encodes a single statement in the original program. For example, the set S_{intro} is obtained from `intro3` by the above conversion.

The obtained set of formulas S is partitioned into three subsets: $S_{\text{soft}}^{\text{Var}}$ that contains all formulas corresponding to statements containing original program expressions, $S_{\text{soft}}^{\text{F}}$ that contains all formulas corresponding to statements containing original feature expressions, and S_{hard} that contains the other formulas corresponding to assertions, assumptions, Φ -assignments, and feature variable-assignments. Since all original program and feature expressions are RHSs of assignments after the simplification phase, all formulas in $S_{\text{soft}}^{\text{Var}}$ and $S_{\text{soft}}^{\text{F}}$ are either single assignment formulas ($x = ae$) or multiple assignment formulas $((x_1 = ae_1) \wedge \dots \wedge (x_k = ae_k))$. For example, the set S_{intro} in Fig. 5 is partitioned as follows:

$$\begin{aligned} S_{\text{soft}}^{\text{Var}} &= \{x_0=0, x_1=x_0+2, x_3=x_2-2\}, \\ S_{\text{soft}}^{\text{F}} &= \{g_0=A_0, g_1=\neg A_0 \wedge \neg B_0\}, \\ S_{\text{hard}} &= \{A_0=[0, 1], B_0=[0, 1], x_2=\text{ite}(g_0, x_1, x_0), x_4=\text{ite}(g_1, x_3, x_2), \neg(x_4 \geq 0)\} \end{aligned}$$

Given a pre-processed (single) program p , the program formula φ_p^b is the conjunction of all formulas in S , where b denotes the unwinding bound used in the transformation phase of p . The formula φ_p^b encodes all possible b -bounded paths in the program p that go through each loop at most b times. We say that a program p is *b-correct* if all assertions in it are valid in all b -bounded paths of p .

► **Proposition 2** ([8]). *A pre-processed (single) program p is b-correct iff φ_p^b is unsatisfiable.*

A satisfying assignment (model) of φ_p^b represents a b -bounded path of p that satisfies all assumptions but violates at least one assertion. In the following, we omit to write p and b in the program formula φ_p^b when they are clear from the context.

Our approach reasons about loops by unrolling them, so it is sensitive to the unrolling bound. We now present an example, where the unrolling bound has impact on the assertion validity.

► **Example 3.** Consider the program:

```
int i:=0, x:=0; while (i<3) do {i:=i+1; x:=x+1; }
```

Suppose that the assertion to be checked is `assert(x≥3)` at the final location. If we use the unrolling bound $b = 2$, we will find that the program is incorrect due to the spurious execution path that runs the `while`-body 2 times. Hence, we will needlessly try to repair this correct program. However, if we use the bound $b \geq 3$, then we will establish that the program is correct and so no repair is needed.

Suppose that the assertion to be checked is `assert(x<3)` at the final location. If we use the unrolling bound $b = 2$, we will find that the program is correct since the assertion is valid for all 2-bounded paths, so no repair will be performed. However, if we use the bound $b \geq 3$, then we will truly establish that the program is incorrect and so a repair is needed.

To enable incremental SMT solving, the program formula φ is instrumented with Boolean variables called *guard variables*. More specifically, a formula $\varphi = \phi_1 \wedge \dots \wedge \phi_n$ is replaced with $\varphi' = (x_1 \implies \phi_1) \wedge \dots \wedge (x_n \implies \phi_n)$, where x_1, \dots, x_n are fresh guard variables. In effect, the formula $(x_i \implies \phi_i)$ can be satisfied by setting x_i to false. Some guard variables called *assumptions* are conjuncted with φ' and passed to an incremental SMT solver. For example, $\varphi' \wedge x_1 \wedge x_2$ is satisfiable iff ϕ_1 and ϕ_2 are satisfiable, since the satisfying assignment will set x_3, \dots, x_n to false thus making $(x_3 \implies \phi_3), \dots, (x_n \implies \phi_n)$ true. Thus, an incremental SMT-solver checking the satisfiability of $\varphi' \wedge x_1 \wedge x_2$ will only check satisfiability of ϕ_1 and ϕ_2 , thus essentially disabling formulas ϕ_3, \dots, ϕ_n .

We will use formulas of the form `AtMost({l1, ..., ln}, k)` (resp., `AtLeast({l1, ..., ln}, k)`) to require that at most (resp., at least) k of the literals l_1, \dots, l_n are true. They are called *Boolean cardinality formulas* encoding that $\sum_{i=1}^n l_i \leq k$ (resp., $\sum_{i=1}^n l_i \geq k$), where l_i is a literal assigned the value 1 if true and the value 0 if false, and $k \in \mathbb{N}$. We will use the MINICARD SAT-solver [39] to check their satisfiability.

4 Lifted Repair Algorithm

In this section, we present our lifted repair algorithm, called SPLALLREPAIR, for repairing program families. We first give a high-level overview of the algorithm, and then describe its components more formally.

High-level Description

The SPLALLREPAIR is given in Algorithm 1. It takes as input a program family P , an unwinding bound b , and a repair size r that limits the search space to only mutated programs with at most r mutations (changes to the original code) applied at once. The algorithm goes through an iterative generate-and-verify procedure, implemented using an interplay between an SAT solver and an SMT solver. In particular, we use an SAT solver in the generate phase to find a mutated program from the search space, whereas we use an SMT solver in the verify phase to check if the mutated program is correct.

Algorithm 1 SPLAllRepair(P, b, r).

Input: Program family P , unwinding bound b , repair size r

Output: Set of solutions Sol

```

1  $p_{sim} := \text{VarEncode}(P)$  ;
2  $(S_{\text{hard}}, S_{\text{soft}}^{\text{Var}}, S_{\text{soft}}^{\mathbb{F}}) := \text{CBMC}(p_{sim}, b)$  ;
3  $(S_1, \dots, S_n) := \text{Mutate}(S_{\text{soft}}^{\text{Var}}, S_{\text{soft}}^{\mathbb{F}})$  ;
4  $(S'_1, \dots, S'_n, V_1, \dots, V_n, V_{\text{orig}}) := \text{InstGuardVars}(S_1, \dots, S_n)$  ;
5  $\varphi_{sim}^b := (\wedge_{s \in S_{\text{hard}}} s) \wedge (\wedge_{s \in S'_1 \cup \dots \cup S'_n} s)$  ;
6  $\varphi := (\wedge_{i=1}^n \text{AtMost}(V_i, 1)) \wedge (\wedge_{i=1}^n \text{AtLeast}(V_i, 1))$  ;
7  $k := 1$ ;  $Sol := \emptyset$  ;
8 while ( $k \leq n$ )  $\wedge$  ( $k \leq r$ ) do
9    $\varphi_k := \varphi \wedge \text{AtLeast}(V_{\text{orig}}, n - k)$  ;
10   $satres, V := \text{SAT}(\varphi_k)$  ;
11  if ( $satres$ ) then
12     $smtres := \text{IncrementalSMT}(\varphi_{sim}^b \wedge \wedge_{v \in V} v)$  ;
13    if ( $\neg smtres$ ) then
14       $Sol := Sol \cup V$  ;
15       $\varphi_k := \varphi_k \wedge (\vee_{v \in V \setminus (V_{\text{orig}})} \neg v)$  ;
16    else
17       $\varphi_k := \varphi_k \wedge (\vee_{v \in V} \neg v)$  ;
18  else
19     $k := k + 1$  ;
20 if ( $\text{Timeout}$ ) then return  $Sol$  ;
21 return  $Sol$ ;
```

The SPLALLREPAIR starts by generating the family simulator p_{sim} using the pre-processor **VarEncode** procedure (line 1). Then, the **CBMC** translation procedure calls the **CBMC** model checker to generate the triple $(S_{\text{hard}}, S_{\text{soft}}^{\text{Var}}, S_{\text{soft}}^{\mathbb{F}})$ of sets of formulas corresponding to p_{sim} as explained in Section 3.2 (line 2). By calling the **Mutate** procedure, we generate all possible mutations S_1, \dots, S_n of formulas in $S_{\text{soft}}^{\text{Var}}$ and $S_{\text{soft}}^{\mathbb{F}}$ (line 3). Here S_i is a set of formulas obtained by mutating some $\phi_i \in S_{\text{soft}}^{\text{Var}} \cup S_{\text{soft}}^{\mathbb{F}}$. Thus, S_1, \dots, S_n correspond to n program locations where an error may occur. Next, we use the **InstGuardVars** procedure to instrument all formulas in S_1, \dots, S_n by fresh guard variables, so that the results are sets of instrumented formulas S'_1, \dots, S'_n and sets of fresh guard variables V_1, \dots, V_n used to guard formulas in S'_1, \dots, S'_n (line 4). Here $S'_i = \{(x \implies \phi) \mid \phi \in S_i, x \text{ is a fresh guard variable}\}$. The set V_{orig} contains guard variables corresponding to original formulas in $S_{\text{soft}}^{\text{Var}}$ and $S_{\text{soft}}^{\mathbb{F}}$. The program formula φ_{sim}^b is then initialized to be the conjunction of all formulas from S_{hard} and all instrumented formulas from $S'_1 \cup \dots \cup S'_n$ (line 5). Subsequently, we search the space of all mutated formulas in increasing size order using the variable k , which is initialized to 1 and increased after each iteration (lines 8–20). In particular, we generate the boolean formula φ_k [13] (line 9) expressing that k guard variables are not original, that is $n - k$ are original (by using $\text{AtLeast}(V_{\text{orig}}, n - k)$), and there is exactly one guard variable selected for each statement in the program (by using $\varphi \equiv \wedge_{i=1}^n \text{AtMost}(V_i, 1) \wedge \wedge_{i=1}^n \text{AtLeast}(V_i, 1)$, line 6). This means that every satisfying assignment of φ_k represents one mutated program formula of size at most k (i.e. with k changes to the original code). The boolean formula φ_k is fed to an SAT solver, which can handle Boolean cardinality formulas, to check its satisfiability. If

φ_k is unsatisfiable, this means that there are no unexplored mutated program formulas of size k so we increase k by one (line 19) and generate a new formula φ_k . Otherwise, if φ_k is satisfiable, we store in a set V all guard variables assigned true in the given satisfying assignment of φ_k (line 10). To check the correctness of the mutated program corresponding to the satisfying assignment V of φ_k , we call an incremental SMT solver to check φ_{sim}^b with all guards in V passed as assumptions (i.e., $\varphi_{sim}^b \wedge \wedge_{v \in V} v$) (line 12). This is the same to checking the conjunction of all formulas in S_{hard} and all soft formulas guarded by variables in V , since all other soft formulas will get satisfied by setting their guard variables to false. Notice that SMT formulas solved consecutively in the iteration are very similar, thus sharing majority of their assumptions and all hard formulas. This means that most of what was learnt in solving the previous formula can be reused to solve the current one. If the result of incremental SMT solving is true, the mutated program is not correct so we block V from further exploration (line 17). Otherwise, we report V as a possible solution (i.e., a repaired program family) and block all supersets of V for further exploration (lines 14,15). The algorithm terminates when either the whole search space of mutated programs is inspected, i.e. all possible combinations of guard variables in n locations are explored as assumptions ($k > n$, line 8), or the subspace of mutated programs with at most r mutations is inspected ($k > r$, line 8), or a time limit is reached (line 20).

► **Example 4.** Let p be a simulator with 4 statements that can be mutated. Let p_1 be a repaired mutant of p consisting of mutating statement 1 with mutation M_1^1 (guard variable v_1^1) and statement 3 with mutation M_3^2 (guard variable v_3^2). Then blocking any superset of this mutation is done by adding the blocking clause $(\neg v_1^1 \vee \neg v_3^2)$ to the Boolean formula φ_k representing the search space of all mutants. This means do not apply either M_1^1 to statement 1 or do not apply M_3^2 to statement 3.

On the other hand, let p_2 be a buggy mutant of p consisting of mutating statement 1 with mutation M_1^2 (guard variable v_1^2) and statement 4 with mutation M_4^2 (guard variable v_4^2). The guards for original statements 2 and 3 are v_2^{orig} and v_3^{orig} . Then the blocking clause $(\neg v_1^2 \vee \neg v_2^{orig} \vee \neg v_3^{orig} \vee \neg v_4^2)$ will be added to prune from the search space exactly the mutant p_2 . Note that smaller blocking clause (with smaller number of literals) will result in a larger set of pruned mutants.

Pre-Processor: VarEncode

The aim of the pre-processor **VarEncode** procedure is to transform an input program family P with sets of features \mathbb{F} and configurations \mathbb{K} into an output pre-processed (single) program without **#if**-s, called family simulator. The set of configurations \mathbb{K} includes all possible combinations of feature values. In the pre-transformation phase, we convert each feature $A \in \mathbb{F}$ into the global variable A non-deterministically initialized to 0 or 1. Let $\mathbb{F} = \{A_1, \dots, A_n\}$ be the set of available *features* in the program family P . We generate the following pre-transformed program:

$$\text{pre-t}(P) \equiv \text{int } A_1 := [0, 1], \dots, A_n := [0, 1]; P$$

We now define a rewrite rule for eliminating **#if**-s from $\text{pre-t}(P)$. Let \mathbb{K} be the set of configurations in the family P that can be equated to a propositional formula $\kappa = \vee_{k \in \mathbb{K}} k$. Note that if \mathbb{K} contains all possible combinations of feature values, then $\kappa \equiv \text{true}$. The rewrite rule replaces **#if**-s with ordinary **if**-s whose guards are strengthened with the feature model κ .

$$\text{#if } (\theta) s \text{ #endif } \rightsquigarrow \text{if } (\theta \wedge \kappa) \text{ then } s \text{ else skip} \quad (\text{R-1})$$

If the current program family being transformed matches the abstract syntax tree node of the shape `#if (θ) s #endif`, then replace it with the RHS of rule (R-1). We write $\text{VarEncode}(P)$ to be the final transformed single program obtained by repeatedly applying rule (R-1) on $\text{pre-t}(P)$ and on its transformed versions until we reach a point at which this rule can no longer be applied.

A memory state $\sigma : \Sigma = \text{Var} \rightarrow \mathbb{Z}$ is a function mapping each program variable to a value. Given a single program p and a memory state σ , we write $\llbracket p \rrbracket \sigma$ for the set of final states that can be derived by executing all terminating paths (computations) of p starting in the input state σ . Note that the result is a set of states since our language is non-deterministic. We define $\llbracket p \rrbracket = \cup_{\sigma \in \mathcal{P}(\Sigma)} \llbracket p \rrbracket \sigma$ to be the set of final states that can be reached by p from any possible input state $\sigma \in \mathcal{P}(\Sigma)$ (where $\mathcal{P}(\Sigma)$ is the powerset of Σ). The following result shows that the set of final states from terminating computations of $\text{VarEncode}(P)$ coincides with the union of final states from terminating computations of all variants derived from the program family P .

► **Proposition 5** ([30]). *For a program family P , $\llbracket \text{VarEncode}(P) \rrbracket = \cup_{k \in \mathbb{K}} \llbracket \pi_k(P) \rrbracket$.*

► **Example 6.** Consider the program family `intro1` in Fig. 2 and its family simulator `intro2≡VarEncode(intro1)` in Fig. 3. The states σ contain only one program variable `x`. Hence, the semantics of all variants of `intro1` is:

$$\begin{aligned} \llbracket \pi_{A \wedge B}(\text{intro1}) \rrbracket &= [x \mapsto 2], \quad \llbracket \pi_{A \wedge \neg B}(\text{intro1}) \rrbracket = [x \mapsto 2] \\ \llbracket \pi_{\neg A \wedge B}(\text{intro1}) \rrbracket &= [x \mapsto 0], \quad \llbracket \pi_{\neg A \wedge \neg B}(\text{intro1}) \rrbracket = [x \mapsto -2] \end{aligned}$$

On the other hand, the semantics of `intro2≡VarEncode(intro1)` is:

$$\llbracket \text{VarEncode}(\text{intro1}) \rrbracket = \{[x \mapsto -2], [x \mapsto 0], [x \mapsto 2]\}$$

Mutate

As explained in Section 3.2, the SMT formulas in $S_{\text{soft}}^{\text{Var}}$ and $S_{\text{soft}}^{\mathbb{F}}$ correspond to statements containing program and feature expressions, so our goal is to repair the given erroneous program family by applying mutations to those formulas. A *mutation* is a replacement of a program/feature expression with another expression of the same type. For example, feature expressions A and $A \wedge B$ can be replaced with $\neg A$ and $(A \vee \neg B)$, while program expressions x and $x + 2$ can be replaced with 0 and $x - 2$. We maintain a fixed list of syntactic mutations for each type of program and feature expressions. Let us assume that mutations M_1, \dots, M_j can be applied to a formula $\phi \in S_{\text{soft}}^{\text{Var}} \cup S_{\text{soft}}^{\mathbb{F}}$. Then, $\text{Mutate}(\phi) = \{\phi, M_1(\phi), \dots, M_j(\phi)\}$. Finally, we have $\text{Mutate}(S_{\text{soft}}^{\text{Var}}, S_{\text{soft}}^{\mathbb{F}}) = \prod_{\phi \in S_{\text{soft}}^{\text{Var}} \cup S_{\text{soft}}^{\mathbb{F}}} \text{Mutate}(\phi)$.

We now present the variability-specific mutations applied to feature expressions: $A \rightarrow \neg A$ (read: feature A is replaced by $\neg A$) and $\neg A \rightarrow A$ for features $A \in \mathbb{F}$, as well as $\{\wedge, \vee\}$ (read: logical operator \wedge can be replaced with \vee , and vice versa).

► **Example 7.** Recall that $S_{\text{soft}}^{\mathbb{F}} = \{g0=A0, g1=\neg A0 \wedge \neg B0\}$ for our running example `intro1`. If we use the variability-specific mutations $A \rightarrow \neg A$, $\neg A \rightarrow A$ for $A \in \mathbb{F}$ and $\{\wedge, \vee\}$, we obtain:

$$\begin{aligned} \text{Mutate}(S_{\text{soft}}^{\mathbb{F}}) = \{g0=A0, g0=\neg A0, g1=\neg A0 \wedge \neg B0, g1=A0 \wedge \neg B0, g1=\neg A0 \wedge B0, \\ g1=A0 \wedge B0, g1=\neg A0 \vee \neg B0, g1=A0 \vee \neg B0, g1=\neg A0 \vee B0, g1=A0 \vee B0\} \end{aligned}$$

Post-Processor: Interpreting results

The solutions obtained by calling the ALLREPAIR tool to repair $\text{VarEncode}(P)$ are interpreted back on the original program family P . Any possible repair for $\text{VarEncode}(P)$, which consists of replacing some feature and program expressions, represents a valid repair for P as well.

This is due to the fact that our transformed program $\text{VarEncode}(P)$ contains all possible paths that may occur in any variant $\pi_k(P)$ for $k \in \mathbb{K}$. A single program (variant) is b -correct if it has no b -bounded path that leads to an assertion failure, while a program family is b -correct if all its variants are b -correct. Therefore, the b -correctness and possible repair of $\text{VarEncode}(P)$ and P are isomorphic (identical).

More formally, by using Propositions 2 and 5, we can prove the following result.

► **Corollary 8.** *Let P and b be a program family and an unwinding bound.*

- (i) $\varphi_{\text{VarEncode}(P)}^b$ is unsatisfiable iff $\forall k \in \mathbb{K}. \pi_k(P)$ is b -correct iff P is b -correct.
- (ii) $\varphi_{\text{VarEncode}(P)}^b$ is satisfiable iff $\exists k \in \mathbb{K}. \pi_k(P)$ is not b -correct iff P is not b -correct.

Correctness

We first use Corollary 8 to show the b -correctness of the SPLALLREPAIR algorithm (where b is the unwinding bound). That is, every solution returned by SPLALLREPAIR is minimal repaired program family (b -soundness), and every minimal repaired program family with respect to mutations we apply is eventually returned by SPLALLREPAIR (b -relative completeness). Our algorithm explores all mutated programs in increasing size order starting with size 1. Every returned solution is minimally repaired due to the fact that it would have been blocked by another smaller solution in a previous iteration. Therefore, the b -correctness (b -soundness and b -relative completeness) of SPLALLREPAIR follows from the b -correctness of ALLREPAIR shown in [50] and Corollary 8 (i.e., the fact that $\text{VarEncode}(P)$ and P are isomorphic with respect to b -correctness).

The SPLALLREPAIR always terminates, as there are only finitely many mutations that can be applied to any type of (feature and program) expressions so the algorithm enumerates all possible mutated programs (simulators) until it finds the minimal repaired ones if any. This way, we have proved the following result.

► **Theorem 9.** *The algorithm $\text{SPLAllRepair}(P, b, r)$ is b -bounded correct and terminates.*

5 Evaluation

We now evaluate our approach for mutation-based lifted repair of SPLs. We show that our approach can efficiently repair various interesting `#ifdef`-based C program families, and we compare the runtime performances and precision of two versions of our algorithm, with smaller and bigger sets of mutations, as well as with the `Brute-force` approach that repairs all variants of a program family one by one independently.

Implementation

We have implemented our lifted repair algorithm SPLALLREPAIR in a prototype tool, which is built on top of the ALLREPAIR tool [50, 51] for repairing single programs. The pre-processor `VarEncode` procedure is implemented in Java, while the translation and mutation procedures (`CBMC` and `Mutate` in Algorihtm 1) are implemented by modifying the CBMC model checker [8] written in C++, where variability-specific mutations are defined. Moreover, we have experimented by defining various mutations to other types of program expressions (see below). The repair phase is implemented by calling the ALLREPAIR tool [50] written in Python. We also call the MINICARD SAT solver [39] and the Z3 SMT solver [11]. The altered CBMC (plus $\sim 1K$ LOC) takes as input a family simulator, and generates a `gsmt2` file containing SMT formulas for all possible mutations of the corresponding statements in the input program. The ALLREPAIR ($\sim 2K$ LOC) takes as input a `gsmt2` file, generates formulas for SAT and SMT solving, and handles all calls to them.

The tool accepts programs written in C with `#ifdef/#if` directives. It uses three main parameters: *mutation level* that defines the kind of mutations that will be applied to feature and program expressions; *unwinding bound b* that shows how many times loops and recursive functions will be inlined; and *repair size r* that specifies how many mutations will be applied at most to buggy programs. We use two mutation levels: *level 1* contains simpler mutations that are often sufficient for repairment, while *level 2* contains all possible mutations we apply. For each type of feature and program expression, the list of syntactic mutations/edits in level 1 and level 2 is given below:

type of exp.	level 1	level 2
arithmetic op.	{+, -}, {*%, ÷}	{+, -, *, %, ÷}
relational op.	{<, ≤}, {>, ≥}, {==, !=}	{<, ≤, >, ≥, ==, !=}
logical op.	{&&, }	{&&, }
bit-wise op.	{>>, <<}, {&, , ^}	{>>, <<, &, , ^}
program vars		$x \rightarrow 0, x \rightarrow -x$
integer constants		$n \rightarrow n+1, n \rightarrow n-1, n \rightarrow -n, n \rightarrow 0$
feature vars	$A \rightarrow \neg A, \neg A \rightarrow A$	$A \rightarrow \neg A, \neg A \rightarrow A$

For example, for arithmetic operators in mutation level 1 we have two sets $\{+, -\}$ and $\{*%, ÷\}$, which means that $+$ is replaced with $-$ and vice versa, and $*, %, ÷$ can be replaced with each other. On the other hand, in mutation level 2 we have one set $\{+, -, *, %, ÷\}$, which means that any arithmetic operator from the set can be replaced with any other. Mutations on feature variables $A \in \mathbb{F}$ in both levels include negations of feature variables ($A \rightarrow \neg A, \neg A \rightarrow A$), whereas for program variables $x \in Var$ in level 2 we have mutations for replacing them with 0 ($x \rightarrow 0$) and changing the sign ($x \rightarrow -x$). Integer constants $n \in \mathbb{Z}$ in mutation level 2 can be increased by one, decreased by one, minused, or replaced with 0.

Experimental setup and Benchmarks

Experiments are run on 64-bit Intel®CoreTM i7-1165G7 CPU@2.80GHz, VM Ubuntu 22.04.3 LTS, with 8 GB memory. We use a timeout value of 400 sec. The implementation, benchmarks, and all obtained results are available from: <https://zenodo.org/records/11179373>. For the aim of evaluation, we ran: (1) our tool with mutation level 1, denoted SPLALLREPAIR₁; (2) our tool with mutation level 2, denoted SPLALLREPAIR₂; and (3) the **Brute-force** approach that uses a preprocessor to generate all variants of a program family and then applies the single-program repair tool ALLREPAIR to each individual variant independently.

The evaluation is performed on a dozen of C programs: two warming-up examples (`intro1` in Fig. 2 and `feat-inter` in Fig. 6); four commonly known algorithms (`feat_power` in Fig. 7, `factorial` in Fig. 8, `sum` in Fig. 9 and `sum_mton` in Fig. 10); `Codeflaws` [53], `TCAS` [29], and `Qclose` [10] benchmarks that are widely used for evaluating program repair tools [10, 37, 46, 50, 51]; as well as `MinePump` system [38] from the `product-lines` category of SV-COMP 2024 (<https://sv-comp.sosy-lab.org/2024>) that is often used to assess product-line verification in the SPL community [4, 9, 56, 55]. `Codeflaws` consists of programs taken from buggy user submissions to the programming contest site Codeforces (<http://codeforces.com>). For each program, there is a correct reference version and several buggy versions. Traffic Alert and Collision Avoidance System (`TCAS`) represents an aircraft collision detection system used by all US commercial aircrafts. The `TCAS` benchmark suite consists of a reference (correct) implementation and 41 faulty versions. In our experiments, we use 10 faulty versions that can be repaired using the mutations we apply in our approach. The

    while (#if (A) (i < x) #else (i ≤ x) #endif){
        res = mult(res, i);
        i++;
    }
    return res;
}
int mult(int x, int y){
    int res = 0;
    for (int i = 1; i ≤ y; i++)
        #if (B) res -= x; #else res += x; #endif
    return res;
}

```

Qclose benchmarks are used for evaluating the **Qclose** program repair tool [10], which consist of a reference (correct) implementation and several faulty versions for each programming task. In the case of **Codeflaws**, **TCAS**, and **Qclose**, we have selected several faulty versions of each benchmark and we have created a buggy program family out of them. For example, we use **tcas_v3** and **tcas_v12** (resp., **tcas_v16** and **tcas_v17**) to create the **tcas_spl1** (resp., **tcas_spl2**) program family. Then, we use assertions to check the equivalence of the results returned by the program family and the reference (correct) version (for example, see **main()** of **factorial** in Fig. 8). Note that the correct version is marked so that it will not be mutated. The **MinePump** SPL system contains 730 LOC and six independent optional features: **start**, **stop**, **methaneAlarm**, **methaneQuery**, **lowWaterSensor**, **highWaterSensor**. When activated, the controller should switch on the pump when the water level is high, but only if there is no methane in the mine. We consider two specifications of the **MinePump** system encoded as assertions in SV-COMP 2024: **MinePump_spec1** checks whether the pump is not running if the level of methane is critical; and **MinePump_spec3** checks whether the pump is running if the level of water is high. Table 1 presents characteristics of the benchmarks, such as: the file name (Benchmark), the number of features $|F|$ (note that $|K| = 2^{|F|}$), and the lines of code (LOC).

```
int sum(int n){
    assume(n ≥ 1);
    int sum := 0, i := 0;
    #if (A) i := 1; #endif
    while(i < n) {
        #if (B) sum+=i;
        #else sum-=i; #endif
        i++;
    }
    assert(sum==n*(n+1)/2);
    return sum;
}
```

```
int sum_mton(int n, int m){
    assume(n ≥ 1&&m ≥ 1);
    #if (A) assume(n ≥ m);
    #else assume(m ≥ n); #endif
    int sum := 0;
    #if (A) int i := n;
    #else int i := m; #endif
    while(#if (A) (i ≤ n)#else (i ≤ m) #endif)
    {
        sum:=sum-i;
        i++; }
    #if (A) assert(sum==(n*(n+1)-m*(m-1))/2);
    #else assert(sum==(m*(m+1)-n*(n-1))/2);
    #endif
    return sum; }
```

Figure 10 sum_mton.

Examples

We now present several of our examples in detail. Consider the program family `feat-inter` in Fig. 6. The error occurs due to the feature interaction ($\neg A \wedge B \wedge C$). In particular, the variant ($\neg A \wedge B \wedge C$) is: `int x=0; x=x-2; assert(x≥0 && x<4)`. So the assertion fails since `x` has value -2 at the assertion location. The simplest fix from mutation level 1, which replaces `x:=x-2` with `x:=x+2`, does not work as it introduces a new error in other variants. In this case, the feature interaction ($A \wedge B \wedge C$) causes the assertion failure since the value of `x` will be 4 at the assertion location for variant ($A \wedge B \wedge C$). Therefore, SPLALLREPAIR₁ reports that no repair is found by searching the space of 7 mutants in 0.254 sec. However, if we consider mutations of level 2 then SPLALLREPAIR₂ successfully finds a repair, which replaces `x:=x-2` with `x:=x-0`, by searching the space of 25 mutants in 0.315 sec. On the other hand, the `Brute-force` approach applies mutations to all faulty variants independently. As the only faulty variant is ($\neg A \wedge B \wedge C$), it will report the repair that replaces `x:=x-2` with `x:=x+2`. This is a correct repair for the variant ($\neg A \wedge B \wedge C$), but not for the entire family. This example shows that sometimes the `Brute-force` approach may not report correct results due to the feature interaction.

The program family `feat_power` in Fig. 7 should find the third power of `n` when feature `A` is enabled and the fourth power of `n` when `A` is disabled. SPLALLREPAIR₁ suggests fixes in 0.722 sec that replace the feature expression ($\neg A$) with (`A`) when initializing variable `i` and replace `while`-guard (`i < 3`) with (`i ≤ 3`). The `Brute-force` finds that variant (`A`) is correct, but variant ($\neg A$) is not correct and no fix is suggested as integer constants cannot be mutated in level 1. Some possible repairs of variant ($\neg A$) in level 2 will make variant (`A`) incorrect. For example, changing the `while`-guard to (`i ≤ 3`) will make variant (`A`) incorrect since it is initialized to 0 so it will return the fourth power of `n` instead of the third.

The program `factorial` in Fig. 8 contains two implementations of the factorial function: a correct one, called `fact_correct`, and a buggy one, called `fact`, that represents a program family with four variants. The assertion requires that the results returned from each variant of `fact` are equivalent with the result returned from `fact_correct`. We do not apply mutations to `fact_correct`, but only to the program family `fact`. All three approaches suggest fixes that replace the `while`-guard (`i < x`) with (`i ≤ x`) and the assignment `res-=x` with `res+=x`.

MinePump_spec3	6	730	✓	39	291.0	✗	-	timeout	✓	-	timeout

Consider the program family `sum` in Fig. 9, which computes the sum of all integers from 0 to a given input integer `n`. The specification indicates that given a positive input `n` ($n \geq 1$), the output represented by the variable `sum` is $n*(n+1)/2$. The body of `sum` is implemented in an iterative fashion. There are two features `A` and `B` that enable different initializations of `i` and different updates of `sum`. Let us consider mutations of level 1. If the repair size is 1 (i.e., only one original expression can be mutated), our tool cannot find a repair by searching the space of 7 mutants in 0.321 sec. However, if the repair size is 2, then SPLALLREPAIR₁ suggests a fix that replaces the `while`-guard (`i < n`) with (`i ≤ n`) and the assignment `sum-=i` with `sum+=i`. The search space contains 17 mutants and the tool explores it in 0.376 sec. The Brute-force approach reports a correct repair in 1.147 sec.

The program family `sum_mton` in Fig. 10 computes the sum $m + (m + 1) + \dots + n$ when feature `A` is enabled and ($n \geq m$), and the sum $n + (n + 1) + \dots + m$ when feature `A` is disabled and ($m \geq n$). The corresponding specifications assert that the returned value `sum` is equal to $(n * (n + 1) - m * (m - 1))/2$ when `A` is on and $(m * (m + 1) - n * (n - 1))/2$ when `A` is off. The programmer has made two mistakes: when initializing variable `i` and when updating variable `sum` in the `while`-body. SPLALLREPAIR₁ suggests fixes in 0.770 sec that replace the feature expression (`A`) with ($\neg A$) when initializing variable `i` and replace `sum:=sum-i` with `sum:=sum+i` when updating `sum`. However, the Brute-force cannot fix any of the two variants since mutating variable `n` (resp., `m`) to other variable `m` (resp., `n`) is not allowed.

Performance

Table 1 shows performance results of running SPLALLREPAIR₁, SPLALLREPAIR₂, and the Brute-force approach on the given benchmarks. We use mutation level 1 for Brute-force. Note that the Brute-force approach calls translation, mutation, and repair procedures for each variant separately, whereas SPLALLREPAIR₁ and SPLALLREPAIR₂ call these procedures only once per program family. Moreover, the Brute-force approach can only

Table 2 Performance results of SPLALLREPAIR₁ for different values of the unwinding bound $b = 2, 5, 8$. All times in sec.

Benchmarks	$b = 2$		$b = 5$		$b = 8$	
	Fix	Time	Fix	Time	Fix	Time
feat_power	✗	0.254	✓	0.722	✓	0.978

sum	✗	0.304	✓	0.376	✓	0.456
sum_mton	✗	0.589	✓	0.770	✓	0.922
651-A-Codelflaws	✓	1.814	✓	3.394	✓	6.828

find repairs by mutating program expressions. The default values for unwinding bound is $b = 5$ and for repair size is $r = 1$. However, for some benchmarks whose repaired versions contain more than one code mutation, we use the minimal value of repair size r that allows one approach to find a correct solution. For example, we use repair size $r = 2$ for `sum`. For each approach, there are three columns: “Fix” that specifies with ✓ (resp., ✗) whether the given approach finds (resp., does not find) a correct repair for a given benchmark; “Space” that specifies how many mutants have been inspected; and “Time” that specifies the total time (in seconds) needed for the given tasks to be performed.

From Table 1, we can see that SPLALLREPAIR₁ and SPLALLREPAIR₂ combined outperform the **Brute-force** approach with respect to both repairability and runtime. In particular, SPLALLREPAIR₂ fully repairs 12 benchmarks, which is better than 8 full correct repairs reported by SPLALLREPAIR₁ and 4 full correct repairs reported by the **Brute-force** approach that use the same mutations of level 1 (see also Discussion below). Note that SPLALLREPAIR₂ and the **Brute-force** timeout after 400 sec for the MinePump system. Hence, they report only a partial list of possible repairs, denoted by ✓. On the other hand, SPLALLREPAIR₁ achieves time speed-ups compared to **Brute-force** when report the same results, that range from 1.2 to 4 times. If we compare SPLALLREPAIR₁ and SPLALLREPAIR₂, we can see that there is a trade-off between repairability and runtime. That is, SPLALLREPAIR₂ is more precise (12 vs. 8 fixes) but slower (from 1.2 to 42 times slow-down when report the same results) compared to SPLALLREPAIR₁.

Table 2 shows performance results of running SPLALLREPAIR₁ on a selected set of benchmarks for different unwinding bounds b . Recall that our approach reasons about loops by unrolling (unwinding) them, so it is sensitive to the chosen unwinding bound. By choosing larger bounds b , we will obtain more precise results (more genuine repairs), but we will also obtain longer SMT formulas and slower speeds of the repairing tasks. We can see that the running times of all repairing tasks grow with the number of bound b . This is due to the fact that longer SMT formulas are generated, which need more time to be verified. Of course, we will also obtain more precise results for bigger values of b , and less precise results (i.e., some genuine repairs will not be reported) for smaller values of b . Hence, there is a precision/speed tradeoff when choosing the unwinding bound b . We obtain similar results for SPLALLREPAIR₂ and the **Brute-force**.

Discussion

In summary, our experiments demonstrate that our tool outperforms the **Brute-force** approach, and moreover it can be used for repairing various SPLs with different sizes of LOC, configuration space, and mutation space. Although SPLALLREPAIR₁ and **Brute-force**

have similar precision (8 vs. 4 fixes) due to the use of same sets of mutations, there is still a difference in the quality of the reported results. As we argued before, SPLALLREPAIR₁ and SPLALLREPAIR₂ report repaired program families obtained by fixing both feature and program expressions, whereas **Brute-force** only reports the repaired variants obtained by fixing program expressions. Hence, the results from **Brute-force** have to be analyzed by the user to produce information comparable to that returned by SPLALLREPAIR₁ and SPLALLREPAIR₂ in the form of repaired program families. Moreover, the fixes of individual variants may cause errors in other variants as evidenced by **feat-inter** and **feat_power**.

The main bottleneck for real-world SPLs, such as **MinePump** with 730 LOC and 6 features, is the huge space of mutants. The problem is that the search space of mutants grows very rapidly as the number of changeable expressions (statements) included in S_{soft} grows. For example, the space of mutants for **MinePump** is $\sim 10^{12}$ for mutation level 1 and $\sim 10^{34}$ for mutation level 2. Hence, to explore even the sub-space of mutants with only 1 edit ($r = 1$) we need around 300 sec for SPLALLREPAIR₁ and >400 sec (timeout) for SPLALLREPAIR₂. One way to address this problem is to use variability fault localization [5, 47], which will first identify feature and program expressions relevant for a variability bug, so that the SPL repair algorithm will apply mutations only to those expressions. This way, we will significantly reduce the space of all mutants without dropping any potentially correct mutant, and so we will improve the performance of the SPLALLREPAIR algorithm.

The runtime performance results confirm that our lifted (family-based) repair algorithm is indeed effective and especially so for large values of $|F|$ and $|K| = 2^{|F|}$. That is, the focus of lifted repair algorithm is to combat the configuration space explosion of SPLs, not their LOC or mutation space sizes. As an experiment, we took **feat-inter**, and we have gradually added optional features into it by conjoining them to the presence conditions of **#if**-s. For $|F| = 3$, SPLALLREPAIR₁ achieves speed-up of 8.3 times compared to **Brute-force**, whereas for $|F| = 4$ and $|F| = 5$ we observe speed-ups of 14.7 and 26.7 times, respectively. The key for those speed-ups is the linear growth of the running times of SPLALLREPAIR₁ with the number of features $|F|$ compared to the exponential growth of the running times of **Brute-force** with $|F|$.

Finally, the evaluation shows that for bigger values of the unwinding bound b , we obtain repairing tasks with slower runtime speed, but reporting more precise results.

6 Related Work

We divide our discussion of related work into two categories: lifted SPL analysis and program repair.

Lifted SPL analysis

Formal analysis and verification of program families have been a topic of considerable research in recent times. The challenge is to develop efficient techniques that work directly on program families, rather than on single programs. Various lifted techniques have been introduced that lift existing single-program analysis techniques to work on the level of program families. Some examples are lifted syntax checking [27, 34], lifted type checking [7, 33], lifted static analysis [6, 30, 15, 20, 55], lifted model checking [9, 16, 25], etc. There are two main lifted techniques: to develop dedicated lifted (family-based) algorithms and tools (e.g. [9, 7, 6, 20]); or to use specific simulators and variability encodings which transform program families into single programs that can be analyzed by the standard single-program analysis tools. The two approaches have different strengths and weaknesses. The advantage of the dedicated

lifted algorithms is that precise (conclusive) results are reported for every variant, but the disadvantage is that their implementation and maintenance can be labor intensive and expensive. For example, CBMC [8] is prominent (single-system) software model checker that contains many optimization algorithms, which are result of more than two decades research in advanced formal verification. Adapting and implementing all these algorithms in the context of lifted software model checking would require an enormous amount of work. Moreover, the performance of dedicated lifted algorithms still heavily depends on the size and complexity of the configuration space of the analyzed SPL.

On the other hand, the approaches based on variability encoding [30, 56] generate a family simulator that simulates the behaviour of all variants in an SPL. They re-use existing tools from single-program world, but some precision may be lost when interpreting the obtained results. The work [56] defines variability encoding on the top of TYPECHEF parser [34] for C and Java SPLs, while the work [30] defines variability encoding on the top of SUPERC parser [27] for C SPLs. The results of variability encoding have been applied to testing [35], software model checking [4], formal verification [30], and theorem proving [54] of SPLs. In this work, we pursue this line of research by presenting a lifted repair algorithm that is based on variability encoding of program families and an existing single-program mutation-based repair algorithm ALLREPAIR [50, 51].

Program repair

Automated program repair has been extensively examined in software engineering as a way to efficiently maintain software systems [28, 37, 40, 42, 45, 46, 48, 50, 51]. These works aim to repair the buggy program, so that the transformed program does not exhibit any faults. Most of them use test suits as the only specification, so the correctness of a candidate is checked by running all tests in the test suite against it. They iteratively generate a candidate from the repair search space and check its validity by testing. Some examples are GENPROG [28], RsREPAIR [48], SPR [40]. The main problem of all testing-based approaches is the generation of overfitting repairs that pass all the test cases, but they break some untested required functionality of correct programs. This happens when the test suites do not cover all the functionality of a program.

In contrast to testing-based approaches, our work belongs to the category of repair tools that use formal techniques to guide the repair process. Several techniques, such as SEMFIX [45] and ANGELIX [42], use symbolic execution to find a repair constraint and then generate a correct fix based on it. Similarly to our work, Könighofer et al. [37] also use assertions as formal specifications, but instead of mutations they use on-the-fly concolic execution (a variant of symbolic execution that uses both symbolic and concrete input values) and templates (linear expressions of program variables with unknown coefficients) as repairs. The solutions for unknown coefficients are found by SMT solving, thus discovering the repaired program. The MAPLE tool [46] utilizes a formal verification system to locate buggy expressions, which are again replaced with templates in which the unknown coefficients are determined using constraint solving. The work [36] uses a deductive synthesis framework for repairing recursive functional programs with respect to specifications expressed in the form of pre- and post-conditions.

Finally, our approach is inspired by Rothenberg and Grumberg [50, 51] that have developed the ALLREPAIR tool for automatic program repair based on code mutations. In this paper, we pursue this line of work by applying it in a new context of SPL repair, which is done by taking into account all specific characteristics of SPLs. This way, we broaden the space of programs that can be repaired.

The QLOSE tool [10] introduces a quantitative program repair algorithm that finds the “optimal” solutions by taking into account multiple quantitative objectives, such as the number of syntactic edits and semantic changes in program behaviours/executions. The work [41] proposes a semantic program repair technique that performs counterexample-guided inductive repair loop via symbolic execution. In this work, we currently find a solution with minimal number of syntactic changes to the original program family. The semantics of the program family is encoded as an SMT formula that is mutated and checked for correctness by an SMT solver. In the future, we plan to investigate some semantics-based learning techniques that will use the counterexamples returned by the SMT solver to guide the algorithm towards finding faster solutions.

Automated program repair has often been combined with fault localization. Fault localization [31, 17] is a technique for automatically generating concise error explanations in the form of locations/statements relevant for a given error that describe why the error has occurred. The works [12, 49, 51] use fault localization to narrow down the repair search space, followed by applying program repair. Firstly, fault localization suggests locations in the erroneous program that might be the cause of the error. Subsequently, the program repair attempts to change only those locations detected by the fault localization in order to eliminate the error. This way, the original program repair procedure is speeded up without incurring any precision loss. Recently, variability fault localization in buggy SPL systems has also been a subject of research [5, 44, 47]. They use spectrum-based fault localization (SBFL) metric [1] to calculate the suspiciousness scores for localizing variability bugs at the level of features [5] and statements [44, 47] based on the test information (program spectra). We can combine the variability fault localization and our variability-aware repair method to additionally prune the search space of mutants, thus improving the performances of our approach.

Program repair is also related to program sketching [52], where a program with missing parts (holes) has to be completed in such a way that a given specification is satisfied. One of the earliest and widely-known approach to solve the sketching problem is the SKETCH tool [52], which uses SAT-based counterexample-guided inductive synthesis. It iteratively performs SAT queries to find integer constants for the holes so that the resulting program is correct on all possible inputs. The works [19, 21] introduce the FAMILYSKETCHER tool that solves the sketching problem by using a lifted static analysis based on abstract interpretation. The key idea is that all possible sketch realizations represent a program family, and so the sketch search space is explored via an efficient lifted analysis of program families, which uses a specifically designed decision tree abstract domain. The FAMILYSKETCHER also generates an optimal solution to the sketching problem with respect to the number of execution steps to termination. Furthermore, the approach [18] uses abstract static analysis and logical abduction to solve the generalized program sketching problem where the missing holes can be replaced with arbitrary expressions, not only with integer constants as in the case of SKETCH and FAMILYSKETCHER tools.

7 Conclusion

In this paper, we have introduced an automated SPL repair framework using variability encoding, bounded model checking and cooperation between SAT and SMT solvers. More specifically, we utilize the CBMC bounded model checker to translate the family simulator of a program family to a program formula. By checking the satisfiability of the program formula using an SMT solver, we verify the correctness of the given program family. Then, each

formula corresponding to a buggy (feature or program) expression is replaced by a mutated patch, to create a new SMT formula that is again checked for satisfiability. To ensure that only minimally mutated programs are considered, we call a SAT solver. By experiments we have shown that our prototype tool can discover interesting patches for various buggy SPLs.

The huge space of mutants can be a bottleneck when dealing with real-world SPLs that have high sizes of LOCs and features. To overcome this problem, we can consider different techniques for pruning the search space of all possible mutations in the future. One possibility is to use variability fault localization [5, 47], which will find statements relevant for the variability bug. The formulas corresponding to all other statements will be included in S_{hard} and so no mutations will be applied to them. By mutating only statements relevant for the bug, we will significantly reduce the space of all mutants, thus speeding up the SPL repair method without any precision loss.

Abstract

Object-oriented programming languages typically allow mutation of objects, but pure methods are common too. There is great interest in recognizing which methods are pure, because it eases analysis of program behavior and allows modifying the program without changing its behavior. The roDOT calculus is a formal calculus extending DOT with reference mutability. In this paper, we explore purity conditions in roDOT and pose a SEF guarantee, by which the type system guarantees that methods of certain types are side-effect free. We use the idea from ReIm to detect pure methods by argument types. Applying this idea to roDOT required just a few changes to the type system, but necessitated re-working a significant part of the soundness proof. In addition, we state a transformation guarantee, which states that in a roDOT program, calls to SEF methods can be safely reordered without changing the outcome of the program. We proved type soundness of the updated roDOT calculus, using multiple layers of typing judgments. We proved the SEF guarantee by applying the Immutability guarantee, and the transformation guarantee by applying the SEF guarantee within a framework for reasoning about safe transformations of roDOT programs. All proofs are mechanized in Coq.

1 Introduction

A feature common to many object-oriented programming languages is that execution of a method can have important side effects such as creating new objects on the heap or modifying (mutating) existing objects. For example, a setter method modifies a field of the receiving object. Such effects are also the reason why, in general, execution of a method cannot be treated as evaluation of a function in a mathematical sense, because every call of a method with possible side effects can produce different results.

13:2 Pure Methods for roDOT

That being said, many methods in object-oriented programs are actually designed as side-effect-free and meant to work like pure mathematical functions, producing the same result on each invocation. An example of such methods are getters, or generally, computations based solely on the arguments passed into the method. Creating methods without side effects is also often considered to be a good practice, because it reduces hidden dependencies, and these methods can be used more freely without the fear of unwanted interaction of their effects. For example, the program code fragment `val x = computeX() ; val y = computeY()`, which involves two side-effect-free methods, can be transformed to `val y = computeY() ; val x = computeX()` by swapping the order of method calls without any observable change in the program behavior and semantics. Writing side-effect-free methods also enables a greater degree of parallelization (concurrency) and, in general, makes it easier to understand the program behavior. Therefore, the issue of purity is relevant to most mainstream object-oriented programming languages, such as Java, C++, C# and Scala.

However, in common programming languages, pure functions and methods with effects are typically unified under a single concept of a method, and there is no way to express, check and make use of method purity at the language level. The idea that a method is pure can be expressed using an annotation (see, e.g., Checker Framework [14, 10] and Code Contracts [15]), but one must look into the documentation of such an annotation for the exact meaning of purity, and there may be limited possibilities of checking automatically whether the annotation is applied properly.

In the context of Java, ReIm [19] introduced annotations with a formal meaning, which give rise to a type system that allows to recognize side-effect-free methods using the types of their parameters – if all parameters of a method, including the receiver, have read-only types, the method cannot get hold of a writeable reference to an existing object, so it is necessarily side-effect free. The advantage of this general approach, based on the usage of static type systems for reasoning about purity and side-effect freedom, is the possibility to prove soundness and consistency of such annotations.

Scala favours a functional programming style, so Scala programs are likely to contain more methods (than Java programs) that can be identified as side-effect-free. Our main objective is to design a type system that guarantees side effect freedom for Scala methods and supports advanced language features present in Scala.

Previous formalization efforts for Scala resulted in the Dependent Object Types (DOT) calculus [2], which captures the essence of Scala’s type system. However, the original DOT calculus does not model mutation of objects, so purity cannot be addressed there, but some variants that do allow mutation have been developed. roDOT [12] is an existing core calculus for Scala with reference mutability. It has mutable fields and a type system feature to distinguish read-only and mutable references. An important rationale behind the design of roDOT, when compared to other possible approaches, is to use existing features of Scala, including its rich type system, as much as possible rather than introducing new forms of types only for reference mutability, to ease adoption of such a type system into the Scala language. In particular, roDOT expresses the mutability of a reference using a specially designated type member in the type of that reference. The type system of roDOT also provides an *immutability guarantee*: an object can only be mutated if there is a path of mutable references to it from the code being executed.

In this paper, we extend the core roDOT calculus from [12] with the concept of side-effect-free methods. Before going into details, we want to emphasize that it was not possible to simply adapt ReIm [19] from Java, because of several challenges specific to Scala and roDOT that we discuss below. However, we use the idea proposed by the authors of ReIm that side-effect-free methods are recognized based on the types of their parameters.

The general concept of purity is, in addition to (1) side-effect-freedom, sometimes understood to comprise more properties: (2) determinism – returning the same value for the same arguments [14], and (3) termination. In this paper, we focus only on the side-effect-free (SEF) property. We will just mention that in regards to determinism, mutable DOT calculi including roDOT have semantics that is deterministic except for instantiation of objects.

Within the context of roDOT, we look at the SEF property from three different perspectives – what a SEF method does, how it can be recognized using the type system, and how it can be used in programs. We define SEF methods in roDOT as those that do not modify any objects that existed on the heap before the method was called.

As the main result of this paper, we prove the *side-effect-free guarantee* (SEF guarantee), which says that methods with read-only parameters do not modify existing objects.

One important related challenge is that in order to state and prove the SEF guarantee, we needed a way to test whether a given type is read-only. As we will explain, this is not possible in the existing (original) roDOT type system from [12]. Therefore, one of our contributions is an extension of roDOT that makes it possible to recognize read-only types.

Another challenge was defining the SEF guarantee formally and proving it in a calculus that supports a mutable heap (like roDOT). The roDOT operational semantics says that fresh heap addresses are chosen during method execution. Therefore, after calling a SEF method, these heap addresses can be different, yet the heap still has the same overall structure. We formally define a concept of similarity of heaps in roDOT to describe this relation. We prove the SEF guarantee by simulating the execution of a SEF method with a similar execution, where writeable references are removed, and by applying roDOT's immutability guarantee.

Finally, as a corollary of the SEF guarantee, we state and prove a guarantee of safety of a particular code transformation. The transformation guarantee states that swapping two calls to SEF methods anywhere in a program does not affect the result of its execution.

Formalizing safe program transformations has to deal with specific issues, such as mixing of program code and values together on the program heap, or the heap similarity mentioned above. In order to deal with these issues, we design a general framework for reasoning about safe transformations in roDOT. The framework provides a general way to define program transformations, defines what properties a safe program transformation must have, and provides a general theorem about lifting the safety of transformation from execution of a small piece of code to execution of the whole program. Within this framework, we define the specific transformation of swapping two calls of SEF methods. We prove the transformation guarantee using the SEF guarantee and the lifting theorem.

We mechanized all of our formal results, in particular the soundness proof of the extended roDOT calculus and the SEF guarantee, in Coq to enable future formal reasoning to build on them. Note that the soundness of the original roDOT calculus was proved by hand in [12]. We have made our formalization in Coq public as an artifact for this paper.

1.1 Contribution

In summary, the main contributions of this paper are the following:

- a modification of the original roDOT calculus that makes it possible to test whether a type is read-only, which is necessary to state and prove the SEF guarantee;
- a formal definition of side-effect-free methods in the context of roDOT, statement and proof of the SEF guarantee;

- a general framework for defining transformations of roDOT programs and proving that some of them are safe in that they do not change the result of program execution, statement and proof of a transformation guarantee, which states that re-ordering calls to SEF methods is safe in that sense;
- the first mechanization of roDOT and its immutability guarantee, with addition of the SEF and transformation guarantees, and all the proofs in Coq – provided as an artifact.

1.2 Outline

The paper is organized as follows. Section 2 gives an overview of the roDOT calculus, which has been mechanized in Coq and within which we define the SEF condition. Section 3 discusses the definition of pure and SEF methods, looking at several variants. It defines the SEF guarantee and identifies necessary changes to the roDOT type system in order for the guarantee to work. In Section 4 we describe the changes to the calculus in more detail, and discuss a new proof of type soundness of the calculus. In Section 5, we describe how we proved the SEF guarantee, and in Section 6 we define and prove the transformation guarantee within a framework for safe transformations. An appendix containing full definitions and more detailed discussion is available in the extended version of this paper [13].

2 Background – The roDOT calculus

In this section, we present the summary of the roDOT calculus [12], which we use as the baseline for this work. The DOT calculus [2, 33, 30] is a formal calculus, designed to formalize the essence of the types of the Scala programming language. In the basic versions of the DOT calculus, objects have read-only fields (so the objects are immutable), but there are also several versions that allow changing values of the fields of objects (mutation).

The roDOT calculus [12] evolved from DOT with mutable fields. The goal was to extend DOT with the ability to control mutation of objects using the type system, while using the existing features of the DOT calculus, dependent types.

In roDOT, write access to a field is controlled by a reference mutability permission. It is based on an idea of a reference capability represented by a special type member M . A reference can only be used to mutate an object if the type of the reference includes this capability, in the form of a type member declaration $\{M : \perp\ldots\perp\}$. Thanks to that, we can refer to the mutability of a variable x using type selection $x.M$.

Without this capability, the field can only be read, but with it, the field can also be written to. The permission applies transitively, in the sense that reading from a read-only reference always produces read-only references.

2.1 Syntax and typing

The syntax of terms and types in roDOT is in Figure 1. It uses the A-normal form [36] of terms from DOT. To avoid ambiguity, if a variable is used in the position of a term, it is marked as vx . Unlike other versions, the roDOT calculus does not have λ values, but methods are a kind of object member (and cannot be reassigned), so there is a more explicit relationship of a method, the containing object and the reference used to call the method. Objects are represented by the $\nu(s : R)d$ constructor, appearing as literals in the programs and as items on the heap (R is the type of the object and d is a list of member definitions).

When typing the program or a part of it, free variables are assigned a type in a typing context Γ . There are several kinds of variables. *Abstract variables* are variables bound in terms such as let-in terms and method definitions. When the program executes, objects are

Variable	Type
$x ::= z, s, r$	
$ y \mid w$	location, reference
$t ::=$	Term
$ vx \mid x_1.m\,x_2$	variable, method call
$ \text{let } z = t_1 \text{ in } t_2$	let
$ \text{let } z = \nu(s : T)d \text{ in } t$	let-literal
$ x.a \mid x_1.a := x_2$	read, write
$d ::= d_1 \wedge d_2$	Definition
$ \{a = x\} \mid \{A(r) = T\}$	field, type
$ \{m(z, r) = t\}$	method
$\rho ::= \cdot \mid \rho, w \rightarrow y$	Environment
$T ::=$	
$ \top \mid \perp \mid \mathsf{N}$	top, bottom, read-only \perp
$ \mu(s : T) \mid x_1.B(x_2)$	recursive, selection
$ \{a : T_1..T_2\} \mid \{B(r) : T_1..T_2\}$	field, type decl.
$ \{m(z : T_1, r : T_3) : T_2\}$	method
$ T_1 \wedge T_2 \mid T_1 \vee T_2$	intersection, union
$B ::=$	Type member name
$ A \mid \mathsf{M}$	ordinary, mutability
$\sigma ::= \cdot \mid \text{let } z = \square \text{ in } t :: \sigma$	Stack
$\Sigma ::= \cdot \mid \Sigma, y \rightarrow d$	Heap
$c ::= \langle t; \sigma; \rho; \Sigma \rangle$	Configuration

■ **Figure 1** roDOT syntax.

 \end{array}$$

■ **Figure 2** Selected rules for typing and reduction in roDOT.

created on the heap, and variables referring to concrete objects on the heap are substituted in place of the abstract variables. Each object on the heap has a unique location y and one or more references w . In an object on the heap, the values of fields are locations of other objects. In terms, only references may appear. The kind of the variable has no effect on execution or typing. In roDOT, references are a separate concept from locations in order to allow references to the same object to have different types (specifically, different mutabilities). While the run-time stack and focus of execution work with references that have their own mutabilities, the heap only works with locations, and mutability is determined by field types.

The types form a lattice, with the top, bottom, union and intersection types. Objects can contain multiple members – fields, methods and type members. Types of objects are formed by intersection of individual declaration types for each member.

The type members $\{A : T..T\}$ specify lower and upper bounds, and they introduce a new dependent type $x.A$ that has a subtyping relationship with those bounds. This is relevant because roDOT uses a type member for mutability. The ability to create dependent types in this manner is the defining feature of the DOT calculus.

The declarations of an object’s members are wrapped in a recursive type, so several declarations in one object type can reference each other, using a member type selection $s.A$ involving the self-reference s . An example of a type of an object without mutability is $\mu(s : \{A : T..T\} \wedge \{a : s.A..s.A\} \wedge \{m(r : T, z : T) : T\})$. An object of this type has a type member A with bounds T , a field a with a self-referential type $s.A$, and a method m .

In roDOT, dependent types are also used to express the mutability of a reference, by selecting the special type member M . When accessing an object through a reference which does not have this capability, for example $\{a : T..T\}$, the field can only be read. With it, for example $\{a : T..T\} \wedge \{M : \perp..\perp\}$, the field can also be written to.

In the declaration of the type member M , the lower bound is always \perp , and the upper bound determines the mutability. If the upper bound is also \perp , it means the reference is mutable. Otherwise, it is read-only. This way, mutable references are subtypes of read-only references, so a mutable reference can be used anywhere a read-only reference is expected, but not vice versa. We will use M_T as a shorthand for the type member declaration $\{M : \perp..T\}$, or just M when the bound is not important. The mutability of a reference applies to the whole object – a mutable reference allows writing to all fields.

An example of a type of an object with a type member A , a field a , method m and a mutability declaration is $\mu(s : \{A : T..T\} \wedge \{a : T..T\} \wedge \{m(r : T, z : T) : T\}) \wedge \{M : \perp..\perp\}$.

A declaration of a method allows specifying a type of the receiving reference $r : T$, which can be more precise than the type of the recursive self parameter s in the defining object. This allows the type of the method to require that the receiver be writeable, or allow it to be read-only. It is similar to the ability to annotate the type of `this` parameter in Java, used by the Checker Framework [18, 9]. For this reason, every method in roDOT has two parameters: a normal parameter z and the receiver r , which is a reference to the object containing the method, like `this` in Scala. In roDOT, the type of r can be dependent on z . The parameter r is special in how it gets its type, but in terms of semantics, behaves the same as z .

Several rules in roDOT need a read-only version of a type. For that, there are two type-level operations: $T \mathbf{ro} U$ means that U is a readonly version of T , $T \mathbf{mu} U$ means that U is a mutability bound of type T (rules are shown in Figure 11 in the appendix). A special type N is defined to be the read-only version of the least type in the subtyping lattice, \perp .

The typing rules (selected in Figure 2, full set in Figures 8 to 12 in the appendix) describe correctly formed programs. In addition to the typing context Γ , which assigns types to variables, the left side of the typing judgment includes an environment ρ that connects references in the terms to locations of objects on the heap.

The write term, typed by TT-Write, is guarded by a check of the mutability permission on the receiving reference. The premise $\Gamma; \rho \vdash x : \{M : \perp..\perp\}$ ensures that only mutable references can be used for writing.

Reading a field, typed by TT-Read, is always possible, but the type of the result is changed to read-only if the source reference is read-only. This type operation is called viewpoint adaptation, and ensures that read-onlyness is transitive, which is required for the immutability guarantee of roDOT and for our SEF guarantee. This is achieved by taking a read-only version of the field’s type, and adding a mutability that is a union of the mutabilities of the source reference and of the field type. For example, if a reference w has type $\{a : T_1..\mu(s : \dots) \wedge M_U\}$, then the term $w.a$ has type $\mu(s : \dots) \wedge M_{w.a \vee U}$.

With the **vis** judgment (Figure 9 in the appendix), roDOT hides captured variables in methods – to access a value from outside, it must be stored in a field of the containing object, so viewpoint adaptation applies to it.

Variables appearing in terms and definitions have types given by the typing and subtyping rules in Figures 9 and 10 in the appendix. Selected rules are shown in Figure 2: ST-Met is a subtyping rule for method declarations. The part highlighted in grey is not part of roDOT, but our modification, which we will describe in Section 4.2. Rules ST-Or and ST-Dist are examples of subtyping rules for union types, which are relevant in Section 4.1.

2.2 Semantics

The operational semantics of roDOT is defined as a small step semantics, with machine configurations (Figure 1) consisting of a term in the focus of execution t , a stack σ , a heap Σ and an environment ρ . The environment ρ maps references to locations and the heap Σ maps locations to objects. The stack σ is used to evaluate terms of the form $\text{let } z = t_1 \text{ in } t_2$. The stack is a list of frames of the form $\text{let } z = \square \text{ in } t_2$, where \square represents t_1 while it is being evaluated in the focus of execution. When t_1 is evaluated to a value, that value is substituted for the square in the top frame of the stack, and the t_2 from that frame then becomes the new focus of execution.

Execution starts with the program, an empty stack, empty heap and an empty environment, and proceeds by steps defined in Figure 13 in the appendix, until it reaches an answer configuration, which has an empty stack and the focus of execution is a single variable. During execution, new items are added to the heap and the environment (there is no garbage collection). Calling a method copies its body to the focus of execution, while the receiver and argument are substituted.

The semantics is generally deterministic – there is no way to express a nondeterministic choice. However, there is one source of non-determinism: locations of objects on the heap. Allocating objects must be regarded as a non-deterministic operation because even if the new objects are initially equal, they may take on different values due to subsequent mutation.

2.3 Properties

The roDOT calculus has the type soundness property (Theorem 1, Theorem 7 in [12]) – a term that has a type in an empty context can be executed and either reduces to an answer, or executes indefinitely. DOT and roDOT do not include explicit checks for error conditions, but trying to access (read, write or call) a non-existing member of an object is an error. In such a case, a reduction step is not defined and the execution “gets stuck”. The soundness theorem guarantees this does not happen for typed programs.

► Theorem 1 (Type Soundness).

If $\vdash t_0 : T$, $\left| \begin{array}{l} \text{The initial term } t_0 \text{ is well typed,} \\ \text{then either } \exists w, j, \Sigma, \rho: \langle t_0; \cdot; \cdot; \cdot \rangle \xrightarrow{j} \langle vw; \cdot; \rho; \Sigma \rangle, \\ \text{or } \forall j: \exists t_j, \sigma_j, \Sigma_j, \rho_j: \langle t_0; \cdot; \cdot; \cdot \rangle \xrightarrow{j} \langle t_j; \sigma_j; \rho_j; \Sigma_j \rangle. \end{array} \right.$
then execution terminates in j steps with answer w ,
or continues indefinitely.

Type soundness and other properties are based on the fact that during execution, the type of the configuration is preserved. Rules for typing a machine configuration are in Figure 14 in the appendix. As the program executes and new objects are added to the heap, new locations and reference variables are used to refer to the objects. To give the configurations a type, these variables are added to the typing context. Their type is the type of the object, and has a fixed form – it is a recursive type containing declarations of all the object’s members, intersected with a declaration of mutability. A typing context that only contains types of this form is called an *inert context*. Under an inert context, stronger claims can be made about types of variables [30], and it plays an important role in the proof of soundness.

$$\begin{array}{c}
 \frac{\Gamma \vdash \langle t; \sigma; \rho; \Sigma \rangle \text{ mreach } y_1}{y_1 \rightarrow \dots_1 \{a = y_2\} \dots_2 \in \Sigma} \\
 \frac{\Gamma; \rho \vdash y_1 : \{a : \perp \dots \{M(r) : \perp \dots \perp\}\}}{\Gamma \vdash \langle t; \sigma; \rho; \Sigma \rangle \text{ mreach } y_2} \text{ (Rea-Fld)} \quad \frac{t \text{ tfree } w \vee \sigma \text{ tfree } w}{w \rightarrow y \in \rho} \\
 \frac{\Gamma; \rho \vdash w : \{M(r) : \perp \dots \perp\}}{\Gamma \vdash \langle t; \sigma; \rho; \Sigma \rangle \text{ mreach } y} \text{ (Rea-Term)}
 \end{array}$$

Figure 3 roDOT mutable reachable references.

The essential property of roDOT is the immutability guarantee (Theorem 2, Theorem 9 in [12]): in order for an object to be mutated, a writeable reference to it must exist, or it must be possible to reach it by a path of writeable fields, starting from a writeable reference – the object must be mutably reachable, defined formally in Figure 3.

► **Theorem 2 (Immutability Guarantee).**

If $y \rightarrow d \in \Sigma_1$ and $\Gamma \vdash \langle t_1; \sigma_1; \rho_1; \Sigma_1 \rangle : T$,
and $\langle t_1; \sigma_1; \rho_1; \Sigma_1 \rangle \xrightarrow{k} \langle t_2; \sigma_2; \rho_2; \Sigma_2 \rangle$,
then either $y \rightarrow d \in \Sigma_2$,
or $\Gamma \vdash \langle t_1; \sigma_1; \rho_1; \Sigma_1 \rangle \text{ mreach } y$.

For an object at some point during well-typed execution,
at any later point,
either the object does not change,
or it was reachable by mutable references.

3 Method Purity for roDOT

Here we informally define the meaning of side-effect freedom in roDOT, and informally state the main results of this paper: the SEF guarantee and the transformation guarantee.

We structure our work around an observation that (in any programming language or calculus), we can look at side-effect freedom from different perspectives:

1. (Static) Recognize which methods are SEF statically at compile time, using types.
2. (Runtime) Define what events can (or cannot) happen when a SEF method is executed.
3. (Usage) Differentiate SEF methods from general methods based on how they can be safely used in programs.

For each of these perspectives, we will state a *SEF condition*, each giving a different definition of SEF methods in roDOT. First we do it informally in this section, and then formalize the definitions in the following sections. The guarantees then form connections between different SEF conditions.

3.1 Runtime SEF condition

Saying that a method is side-effect-free is informally understood as saying that the execution of the method will not perform any actions that are considered to be side effects. This view corresponds to the second perspective on our list.

This perspective is most directly related to the semantics. In roDOT, this means looking at the small step semantics, defining the beginning and end of execution of a method, and defining the SEF condition in terms of the state of execution or the steps performed between the beginning and the end. When looking at the effects caused by method execution, the only relevant part of the machine configuration is the heap (the focus of execution is the part being evaluated, the stack cannot be changed, and the mapping from references to locations is only relevant for typing). The heap can only be modified by two kinds of execution steps: instantiation of an object and writing a value to a field of an object on the heap.

The condition of side-effect-freedom can be stated in multiple versions of varying strength. In the strictest sense, we could say that a SEF method cannot have any effect on the heap at all, meaning no instantiations and no writes. That would, however, be overly restrictive, as object instantiation is one of the basic operations in object-oriented programming. It is therefore usually (such as in [34, 38, 19, 14]) allowed that a SEF method can instantiate new objects, and also write to the fields of those newly instantiated objects. In turn, the only forbidden action is writing to fields of previously existing objects.

Another choice in the definition is when the change to the heap is detected, which leads to different answers to questions such as: (a) Is it allowed to write to a field of an existing object, if the value written is the same as the current value so the object does not actually change? (b) Is it allowed to write to a field of an existing object, if the field is restored to the previous value before the end of the method execution? We choose to allow (a) but not (b), so our definition observes the state of the heap at every moment during the execution of the method. Allowing (b) would lead to a weaker condition, which would check the state of the heap only at the end of the method call. Forbidding (a) would lead to a stronger condition, defined in terms of allowed steps of execution rather than in terms of the state.

► **Informal statement of Definition 15** (Run-time SEF condition, in Section 5.1). An execution of a method is side-effect free, when at every step of execution until returning from the method, the heap contains all the objects from the start of execution in an unchanged state.

3.2 Static SEF condition

The static perspective (the first in our list) is useful because it provides a way to check that a method is SEF by looking at the code. We must, however, accept that statically, it will not be possible to recognize all methods that are pure from the second (and third) perspective.

In ReIm [19], SEF methods are recognized by the mutability of the parameters. roDOT uses the same notion of transitive read-only references, therefore it should be possible to use an analogous condition in roDOT.

► **Informal statement of Definition 11** (static SEF condition). A method has a SEF type, if both its parameter and its receiver parameter have read-only types.

This condition will be formally defined in Section 4.1. Example 3 and Example 4 illustrate its ability to recognize SEF methods.

► **Example 3.** A getter defined as $\{m_{get}(r, z) = z.a\}$ can be typed with $\{m_{get}(r : \top, z : \{a : \top..\top\} : \top)\}$. Both \top and $\{a : \top..\top\}$ are read-only types, and therefore the getter is SEF.

► **Example 4.** The method m_{sef} defined by $\{m_{sef}(r, z_a) = (\text{let } x = \nu(r_o : R_o) \dots \text{in } z_a.m_a x)\}$ calls a method of its argument, passing a newly allocated object to it. This method has type $\{m_{sef}(r : \top, z_a : T_z) : \top\}$, where $T_z = \{m_a(r : \top, z : \mu(r_o : R_o) \wedge \{\mathbf{M} : \perp..\perp\}) : \top\}$. By Definition 11, m_{sef} is SEF, because it has read-only parameters, even though it calls m_a , which may mutate the heap.

Example 5 shows how viewpoint adaptation transitively ensures that read-only parameters cannot be used to modify existing objects. Example 6 shows how a dependent type can change whether the method is SEF or possibly not.

► **Example 5.** The method defined by $\{m_{va}(r, z) = (\text{let } x = z.a \text{ in } x.b := r)\}$ mutates an object stored in a field of the argument z , and therefore is not SEF. This method cannot be typed with a read-only type for the parameter z , because even if the field a has a mutable type, by viewpoint adaptation of fields in roDOT, the variable x would also have a read-only type, so the subsequent write would not be allowed.

► **Example 6.** A method with a type $\{m_{dep}(r : \top, z_a : \{a : \top..\top\} \wedge x.A) : \top\}$ has a parameter with a type dependent on the variable x , which can decide the mutability. This method is recognized as SEF only in contexts where $N <: x.A$. When $x.A <: M_\perp$, then the method can (indirectly) mutate the argument.

3.3 SEF guarantee

For the **SEF guarantee** (Theorem 16), we want to be able to claim that a method is SEF based on the type of the method declaration. The SEF guarantee makes the connection from the first to the second perspective.

► **Informal statement of Theorem 16** (SEF guarantee, in Section 5.2). Let c_1 be a well-typed machine configuration just prior to executing a method call step $w_1.mw_2$. If, by typing of the receiving reference w_1 , the method m has a SEF type, then the execution of the method will be side-effect free.

3.4 Using pure methods in roDOT

Finally, the third perspective shows why SEF methods are useful. It is, however, a view from outside of the method, and does not tell us how to construct a SEF method or check it.

The practical use of a type system with SEF methods comes when it allows us to look at the code, and based on what we see (from the first perspective) gives us a guarantee about its behavior (second perspective) and how it can be used (the third perspective). An example of this is allowing safe transformations of the program, which can be applied at coding time using IDE-provided code transformations, or at compile time as optimizations. For example, calls to SEF methods can be safely reordered.

To keep the problem simple, we will look at one particular case of such reordering: swapping two calls to SEF methods. With SEF methods, the code $x1.m1(); x2.m2()$ is equivalent $x2.m2(); x1.m1()$.

► **Informal definition** (Call-swapping transformation of programs). A program t_1 is transformed into t_2 by SEF call-swapping, when the programs are the same except in one place, where t_1 calls two methods in succession, but t_2 calls them in the opposite order. Furthermore, within the contexts of typing these method calls, both methods have the same read-only types, and allow both programs to be typed in the same manner.

► **Example 7.** A chain of calls $\text{let } x_1 = x_{o1}.m_1x_{a1} \text{ in let } x_2 = x_{o2}.m_2x_{a2} \text{ in } t$, can be transformed by call swapping into $\text{let } x_2 = x_{o2}.m_2x_{a2} \text{ in let } x_1 = x_{o1}.m_1x_{a1} \text{ in } t$.

The static condition from the first perspective is already a part of the definition of the transformation. The transformation guarantee then states that this transformation is safe – it does not change the behavior of the program. By that, the guarantee connects the static condition (first perspective) with the call-swapping transformation (third perspective). We use the run-time condition (second perspective) as a connecting step between them in the proof of this guarantee.

► **Informal statement of Theorem 27.** The call-swapping transformation is safe, in the sense that if for any programs t_1 and t_2 related by this transformation, provided that t_1 terminates with an answer c_1 , then t_2 also terminates with an answer c_2 , which is the same as c_1 , except for certain unavoidable differences in variable names and in method bodies.

The formal definition of the transformation, formal statement of the transformation guarantee and an outline of its proof are provided in Section 6.

4 Recognizing SEF methods by type in modified roDOT

In this section, we formalize the static SEF condition in roDOT given informally in Section 3.2. Although the notion of read-only types, used by this condition, was already defined in roDOT, we identify issues with that definition in regards to this new use.

We fix them by updating the calculus with small changes, which comprise adding one new subtyping rule and one type splitting rule, and one restriction added to the method subtyping rule. The updated calculus is neither a subset nor a superset of the original, so it is necessary to update the proof of soundness and the immutability guarantee, which were proven by hand for the original roDOT [12]. The soundness proof followed the scheme from [30] and uses an auxiliary definition of invertible typing, which allows doing proofs by induction on the typing of variables. This is possible thanks to eliminating possible cycles in the derivation, by forcing the derivation to follow the syntactic structure of the target type.

One of the new subtyping rules, however, breaks this soundness proof, because it introduces new possibilities to derive types in cycles, which cannot be repaired by simply handling additional cases in the original proof. In the presence of cycles, we cannot use the straightforward inductive hypothesis to prove properties necessary for type safety, because a derivation for typing a variable can involve derivations of arbitrarily complex types.

We implemented a new proof based on a different auxiliary typing definition, which avoids cycles by forcing the derivation to arrive at the target type by adding type constructors in a fixed order (for example, all unions in the type are handled before intersections). Compared to the original invertible typing, which was single typing judgment with many rules, the new approach leads to a definition in several layers, where each layer has a small number of typing rules. We call this set of judgments *layered typing*. In layered typing, we re-prove important properties of invertible typing, so that the new definition fits into the rest of the existing soundness proof, and also prove new properties required for the SEF guarantee.

The rest of this section is structured as follows: in Section 4.1, we formalize static SEF condition, and discuss the meaning of read-only types in roDOT. In Section 4.2, we propose small changes to the roDOT calculus to make definitions work for the SEF guarantee. We give a short overview of the structure of the original soundness proof for roDOT, and show how this proof breaks with the new changes. In Section 4.3, we describe the new layered typing that replaces invertible typing in the updated proof and show its important properties.

4.1 Static SEF condition in roDOT

In the **SEF guarantee** (Theorem 16), we claim that a method is SEF based on the type of the method declaration. Our SEF guarantee follows the approach of ReIm [19] and requires the parameters to have read-only types.

4.1.1 Read-only types in roDOT

The check whether a type is read-only was also present in roDOT, but it had a limited purpose – to ensure that recursive types are read-only in VT-RecI (Figure 9 in the appendix). It was not based on subtyping, but rather on the relation **ro**, which makes a read-only version of a type using a syntax-based type splitting.

This definition did not guarantee that all supertypes of a read-only type are also read-only. As we will explain in Section 4.1.3, this would be a critical problem for the SEF guarantee.

We solve this problem by using a different notion of read-only types, based on subtyping with the “read-only bottom” type **N**.

The purpose of N in the original roDOT was to be the read-only version of the type \perp for defining the **ro** relation. Because the bottom type \perp is a subtype of all types, it is inherently mutable. For that reason, the type N was added and made a lower bound of read-only types. That allows us to define read-only types as supertypes of N .

► **Definition 8** (Read-only types). *A type T is read-only, if $\Gamma; \rho \vdash \mathsf{N} <: T$.*

With Definition 8 settled, we discovered a few problems related to read-only types, which would not allow us to state the SEF guarantee in the original roDOT.

Our proof of the SEF guarantee, specifically Lemma 19 in Section 5.4, relies on the idea that if a reference has some read-only type, then any other reference to the same object has that type too. Note that because of subsumption, a variable of a mutable type also has the corresponding read-only types. This essentially means that in any place where a reference is used by virtue of its read-only type, it can be replaced with a read-only version of that reference. With the new Definition 8 of read-only types, this can be stated as:

► **Lemma 9** (Read-only types are shared by all references). *If $\Gamma \sim \rho$ and $\Gamma; \rho \vdash y : T$ and $\Gamma; \rho \vdash \mathsf{N} <: T$, then $\Gamma; \rho \vdash w : T$ for any w such that $\rho(w) = y$.*

This key lemma, however, does not hold in the original roDOT, because of union types.

Union types were not a part of DOT, but were added to roDOT in order to be used to define viewpoint adaptation (union types are already a part of Scala’s type system), along with the subtyping rules ST-Or, ST-Or1, ST-Or2, ST-Dist, which are shown in Figure 10 in the appendix. However, using unions, it is possible to construct a type that is a supertype of both N and a mutability declaration:

► **Example[†] 10** (In the original roDOT, counter-example to Lemma 9). Let $T_{\text{am}} := \{a : T_a\} \vee \mathcal{M}_{\perp}$ be a union of some field declaration with a declaration of mutability, and $T_{\text{bm}} := \{b : T_b\} \wedge \mathcal{M}_{\perp}$ be a type of a writeable reference to some other field b .

The type T_{am} is not mutable, because it is not a subtype of \mathcal{M}_{\perp} . It is read-only, because $\Gamma \vdash \mathsf{N} <: T_{\text{am}}$, by the rules of subtyping of union types and by rule ST-N-Fld (Figure 10 in the appendix).

Let y_1 be a location of type T_{bm} , and w_2 be a reference to y_1 with type $T_b := \{b : T_{\text{bm}}\}$. By subtyping of unions and intersections, $\Gamma \vdash T_{\text{bm}} <: T_{\text{am}}$, so by subsumption, y_1 has type T_{am} . By Lemma 9, w_2 should have also type T_{am} , but in the original roDOT, it does not.

Example[†] 10 is marked with the [†] sign, which we use in this chapter to identify properties of the original roDOT from prior work, in contrast to the modified roDOT in this paper.

We observe that the read-only type T_{am} in this counter-example is a union of disjoint declarations, so it does not allow accessing the field a_{am} , or any other member. Therefore, T_{am} is no more useful for typing programs than \top . In order to make Lemma 9 work, we decided to extend the type system with new subtyping rules to make types like this equivalent to \top . These changes will be described in Section 4.2.

4.1.2 The SEF condition

A method is statically SEF if the types of its receiver and parameters are read-only according to Definition 8 i.e., they are supertypes of N . Thanks to subsumption and subtyping of method types, the type $\{m(z : \mathsf{N}, r : \mathsf{N}) : \top\}$ is a type bound for methods named m and requires that both the argument and receiver have read-only types.

► **Definition 11** (Static SEF condition). *A method is statically SEF if it has a type $\{m(z : \mathsf{N}, r : \mathsf{N}) : \top\}$*

$$\frac{\Gamma; \rho \vdash N <: T}{\Gamma; \rho \vdash T \text{ ro } T} (\text{TS-N}) \quad \frac{}{\Gamma; \rho \vdash \top <: N \vee \{M(r) : T_1..T_2\}} (\text{ST-NM})$$

■ **Figure 4** New rules for roDOT.

In Section 5, we will show that this condition works because a method must access all objects through the argument or the receiver (capturing values is modeled using fields of the receiver), so the method will not be able to get a writeable reference to any existing object.

4.1.3 Subtyping of method types

In order for the SEF guarantee (Theorem 16) to work with Definition 11, it is critical that all subtypes of a SEF method type are also SEF. The reason is at the site of a method call, the observed static type of the method is a supertype of the actual type of the method within its containing object, so this is needed to make the connection from the SEF type at a call site to the SEF type of the actual method.

That is why Definition 8 needs to be based on subtyping, so that all supertypes of read-only types are read-only (method types are contravariant in their parameter types).

Still, the type system required one more change related to a possible dependency between the types of method parameters. In roDOT, the type of the receiver r can be a dependent type referring to the other parameter z of the method. If, however, the receiver type depended on the mutability of z , then while typing the body of the method, it would be possible to derive that z is mutable, even if its type is read-only in the sense of Definition 8. If r has the type $\{A : z.M..\perp\}$, one can use the typing rules ST-SelL and ST-SelU (Figure 10 in the appendix) to derive $z.M <: \perp$. The change to the rules TT-Call and ST-Met in Figure 2 prevents this issue by disallowing using method types where the receiver depends on the mutability of the parameter.

4.2 The updated roDOT calculus

In the previous section, we defined the static SEF condition, but identified several reasons why this definition would not work as intended in roDOT as-is. We fix these issues by changes to the roDOT calculus, which amount to two new and one modified typing rule:

- A new subtyping rule ST-NM (Figure 4) is added, which makes the union of a mutability declaration and the read-only lower bound N a top-like type (the other direction of subtyping was already a part of the type system).
- A new rule TS-N (Figure 4) is added to type splitting, making it so that all types that are read-only by Definition 8 are unaffected by the splitting operation.
- The typing rule TT-Call and subtyping rule ST-Met have a new premise (shown highlighted in Figure 2), which disallows introducing a dependency between the receiver type and the parameter in method subtyping. This fixes the problem described in Section 4.1.3.

The new rule ST-NM fixes the counter-example to Lemma 9, because now we have $\Gamma; \rho \vdash \top <: T_{am}$, derived from $\Gamma; \rho \vdash \top <: N \vee M_\top$ and $\Gamma; \rho \vdash N <: \{a : T_a\}$. By subsumption and $\Gamma; \rho \vdash w_2 : \top$, that also means that $\Gamma; \rho \vdash w_2 : T_{am}$.

Additionally, we can now improve the type splitting relation $\vdash \text{ ro }$, by extending it with a new rule TS-N, shown in Figure 4. With that, the condition in VT-RecI (Figure 9 in the appendix) that recursive types are read-only, $\Gamma; \rho \vdash T \text{ ro } T$, becomes equivalent to Definition 8:

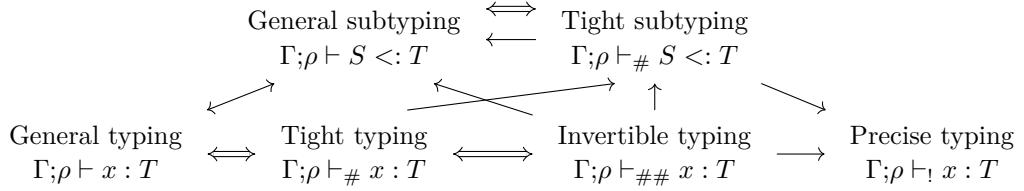

Figure 5 Dependencies (\rightarrow) and equivalences (\leftrightarrow) between definitions of typing in roDOT.

► **Lemma 12** (Read-only types). $\Gamma; \rho \vdash N <: T \Leftrightarrow \Gamma; \rho \vdash T \text{ ro } T$.

4.2.1 Updating the safety proof

The changes described above require updating the type safety proof of the calculus, to show that the changes did not allow invalid programs to be typed. The new subtyping rule ST-NM has a significant effect on the soundness proof, because it makes it possible to derive many additional union types, such as the now top-like type $M \vee N$.

The proof of soundness of roDOT before these changes followed the structure of the proof of DOT [30]. The core part of this proof is to show that if a reference w has some declaration type D (such as a field $\{a : T\}$), then the type associated with w in the typing context Γ is an object type containing D or a more precise declaration of the same member. That means, for $\Gamma; \rho \vdash w : D$, where D is a declaration type, because the types in Γ correspond to the object on the heap ($\Gamma \sim \Sigma$), the actual object referred to by w must contain a corresponding member definition in Σ , and therefore it is safe to access that member.

The proof was based on two alternative definitions of typing for variables – tight typing and invertible typing. Figure 5 shows the relations between the different versions of typing.

Tight typing is used as an intermediate step in equivalence of general and invertible typing. It is very similar to general typing – it has the same rules, except that subtyping rules involving selection types (ST-SelL and ST-SelU in Figure 10 in the appendix) use precise typing, a simpler version of variable typing, which does not have subsumption.

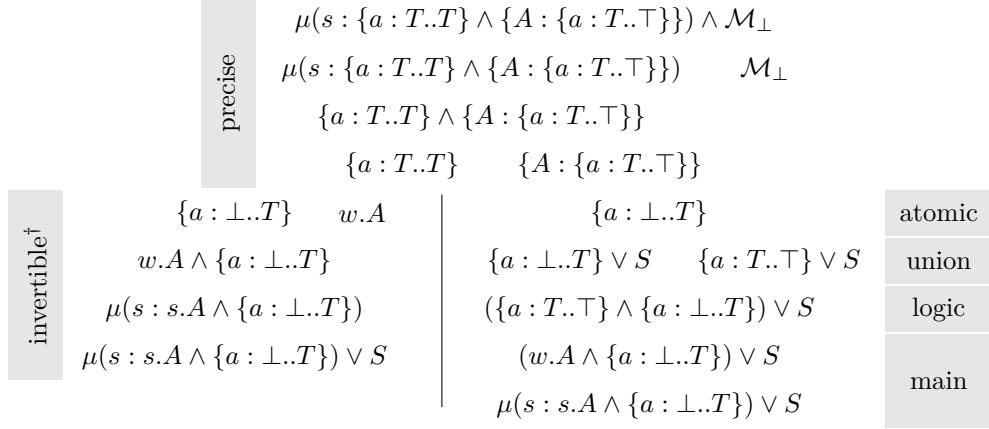

Updating tight typing for our modified rules is straightforward – we apply the same changes as to general typing, and the proof of equivalence between general and tight typing still works. However, we will show that updating invertible typing poses a challenge, as it cannot be easily extended with the additional rules.

4.2.2 Invertible Typing[†]

The main utility of invertible typing was providing a simple path of derivation of a variable's type, starting from the type given to it by the typing context, and ending with a type that was used to access a member at some particular point in the program. This direct path then allowed induction-based proofs of properties of the typing relation.

This task would be especially hindered if the typing rules allowed cycles in the derivation, which would allow the derivation to go through unnecessarily complicated types. For example, with general typing, it is possible to derive $\Gamma \vdash x : T$ from $\Gamma \vdash x : T \wedge T$ and vice versa. Therefore, a derivation of type T can start with $\Gamma \vdash x : T$, go through arbitrarily complicated types such as $(T \wedge T) \wedge T$, and come back to T . This inhibits arguments by induction on the derivation of a general typing.

Invertible typing in DOT prevented this by ensuring that the derivation closely follows the syntactic structure of the target type.

■ **Figure 6** Example derivation of a type by invertible typing (left) and layered typing (right). Assuming that a variable w has the type $\mu(s : \{a : T..T\} \wedge \{A : \{a : T..\top\}\}) \wedge \mathcal{M}_\perp$ in the typing context, w has all the types shown here, ordered from types that are simple to derive at the top, to more complex derivations, which make use of derivations above. S is an arbitrary type.

The original roDOT adopted the invertible typing from DOT [30], where it has two layers, which we present using an example derivation of a type for a variable w in Figure 6.

The first layer, **precise typing**, only derives types by deconstructing the type of the variable given by the typing context. For each reference w , its type in the typing context is an intersection of a mutability declaration with a recursive type containing an intersection of declarations. Precise typing allows opening this recursive type and extracting the declarations from the intersection, but does not support subtyping. The top of Figure 6 shows individual steps of this process.

The second layer, **invertible typing[†]**, combines both variable typing and subtyping into a single layer. In DOT and the original roDOT, it has fewer rules than general typing and subtyping, because it only has rules that construct the target type syntactically “bottom-up”, such as closing recursive types (akin to VT-RecI), or deriving intersection and union types. Thus the derivations of invertible typing are unambiguously guided by the syntax of the target type. The left side of Figure 6 shows individual steps of this process in building up the type $\mu(s : s.A \wedge \{a : \perp..T\}) \vee S$ for w .

As per Figure 5, invertible typing was equivalent to tight typing. That required invertible typing to be closed under tight subtyping (Lemma[†] 13).

► **Lemma[†] 13** (In original roDOT, invertible typing is closed under subtyping).

If $\Gamma; \rho \vdash_{\#} x : T_1$, and $\Gamma; \rho \vdash_{\#} T_1 <: T_2$, where $\Gamma \sim \rho$, then $\Gamma; \rho \vdash_{\#} x : T_2$.

The addition of ST-NM, together with the rules ST-Or and ST-Dist (Figure 2), breaks this. In Lemma[†] 13, the case for ST-Or relies on case analysis of deriving union types (Lemma[†] 14).

► **Lemma[†] 14** (In original roDOT, typing with union types can be inverted).

If $\Gamma; \rho \vdash_{\#} x : T_3 \vee T_4$, then either $\Gamma; \rho \vdash_{\#} x : T_3$ or $\Gamma; \rho \vdash_{\#} x : T_4$.

However, the rule ST-NM adds new ways of deriving union types such as $N \vee M_\perp$, and the distributivity rule ST-Dist actually allows deriving arbitrarily large types of the form $T_N \vee T_M$, where the two parts can consist of arbitrary intersections and unions of various types that contain N and M somewhere within them.

For example, with the variables from Example[†] 10, we have $\Gamma; \rho \vdash w_2 : \{a : T_a\} \vee M_{\perp}$, but $\Gamma; \rho \not\vdash w_2 : \{a : T_a\}$ and $\Gamma; \rho \not\vdash w_2 : M_{\perp}$. Such a type cannot be derived in a syntactically bottom-up manner that invertible typing is based on. Rather than trying to fix invertible typing by adding complicated rules, we replace it by a new auxiliary typing judgment, which derives types in different way.

4.3 Layered Typing

In *layered typing*, we avoid the need for Lemma[†] 14 by organizing the derivation of a type not bottom-up, but by handling different type constructors in separate layers of typing judgments. All union type constructors are derived before intersection types, recursive types and type selections. Additionally, we derive union types on two layers:

First, the *basic layer* derives the newly top-like types possible by the rule ST-NM. Because intersections, recursive types and selections are out of the picture at this layer, these types have a simple form of possibly nested union types, where one of the sides contains N and the other M , where M is a declaration $\{M : \perp..T\}$ for some bound T . We will write that as $\vdash N \triangleleft T_N$ and $\vdash M \triangleleft T_M$. Second, the *union layer* derives types possible by the rules ST-Or1 and ST-Or2, allowing nesting a known type of w in a union with any other type. This way, the layers retain the information about how a union type has been derived and those cases can be handled separately when inverting the derivation.

Intersection types can be handled in analogy to how any logical formula can be derived by starting from conjunctive normal form (CNF) and pushing conjunctions down. Any type constructed from a mixture of union and intersection types can be derived by starting from an intersection of union types and pushing the intersections down.

The *logic layer* sitting above the union layer can derive any mixture of unions and intersections using the LTL-And rule shown in Figure 7. It takes derivations of two types that may have some parts in common but differ in one place. The common part C^{\vee} is a syntactical context which combines the argument into a union with other types. For example, we can write the two types $\{a_1 : T_1\} \vee \{a_2 : T_2\}$ and $\{a_1 : T_1\} \vee M_{\perp}$ as $C^{\vee}[\{a_2 : T_2\}]$ and $C^{\vee}[M_{\perp}]$. If we view these two types as an intersection, then the rule pushes the intersection down to the place where the two types differ. In the example derivation on the right of Figure 6, we derived two union types on the union layer. (The type $\{a : T..T\}$ was derived on the previous layer and S is an arbitrary type.) On the logic layer, we combined them into one type, pushing the intersection down to the left.

The rest of the type constructors are handled either below the basic layer or above the logic layer. Subtyping between declarations is handled in an *atomic layer* positioned before the basic layer. This layer only deals with types that are single declarations.

Recursive types of the form $\mu(s : T)$ and selection types can “wrap around” or replace any part of the derived type (in general typing by VT-RecI and ST-SelL, Figures 9 and 10 in the appendix), which may both appear under unions and intersections, and also contain them within. Therefore, they are handled above the logic layer in a final, *main layer*. In the rule LTM-Sel in Figure 7, the syntactic context $C^{\wedge\vee}$ can consist of a mixture of unions and intersections. The rules have premises that correspond to conditions in the relevant rules of tight typing. For example, in Figure 6, the left side of the union is wrapped under a recursive type in the last step.

The layers are summarized in Table 1, showing the relevant type constructors and the connection to rules of general typing. Selected rules are shown in Figure 7; full definitions are in Figures 15–19 in the appendix.

■ **Table 1** The layers of layered typing.

Typing layer	Relevant type constructors	Relevant rules
Atomic layer	$\{a : T..U\}, \{A : T..U\}, \{m(S, T) : U\}$	ST-Met, ST-Fld, ST-Typ
Basic layer	$N \vee M$	ST-NM
Union layer	$T, T \vee U$	ST-Or1, ST-Or2, ST-Top
Logic layer	$T \wedge U$	ST-Dist, ST-And, VT-AndI
Main layer	$\mu(s : T), x.A$	VT-RecI, ST-SelL, ST-N-Rec

$$\frac{\Gamma; \rho \vdash_1 x : C^\vee[T_1] \quad \Gamma; \rho \vdash_1 x : C^\vee[T_2]}{\Gamma; \rho \vdash_1 x : C^\vee[T_1 \wedge T_2]} \text{(LTL-And)} \quad \frac{\Gamma; \rho \vdash_m x : C^{\wedge\vee}[[v_3/r]T_1] \quad \Gamma \vdash_! v_2 : \{B(r) : T_1..T_2\}}{\Gamma; \rho \vdash_m x : C^{\wedge\vee}[v_2.B(v_3)]} \text{(LTM-Sel)}$$

■ **Figure 7** Selected rules of layered typing.

- Typing on the **atomic layer** ($\Gamma; \rho \vdash_a x : T$) only gives variables single declaration types – the declarations derived by precise typing, and their supertypes (subtyping rules between declarations are handled here).
- The **basic layer** ($\Gamma; \rho \vdash_b x : T$) additionally gives all variables top-like types of the form $T_N \vee T_M$ and $T_M \vee T_N$, where $\vdash N \triangleleft T_N$ and $\vdash M \triangleleft T_M$.
- The **union layer** ($\Gamma; \rho \vdash_u x : T$) handles \top and unions of known and arbitrary types.
- The **logic layer** ($\Gamma; \rho \vdash_l x : T$) handles intersections and distributivity. The rule LTL-And takes two types, preserves their common part, and combines the differing parts using an intersection type – pushing the intersection down from the top to its target place.
- The **main layer** ($\Gamma; \rho \vdash_m x : T$) closes recursive types and handles type selections.

For layered typing, we also proved the following properties:

- If a location has a declaration type by layered typing, then it also has a declaration type by precise typing, with the same or tighter bounds. This property has three variants, for field, type and method declarations.
- Layered typing is equivalent to general typing. As in the original proof, we use tight typing as a step between general and layered typing, and separately prove both directions of equivalence between tight and layered typing (Lemma 31 and Lemma 37 in the appendix).
- We also use layered typing to prove Lemma 9 – if a location has some read-only type in layered typing, then all references to that location have that type too.

With these properties, the safety proof from roDOT, with invertible typing replaced by the new layered typing definition, works as a safety proof of the updated calculus. Formal statements of these and other selected properties are given in Section A.3 in the appendix.

5 The SEF Guarantee

In Section 3.3, we informally stated the SEF guarantee, which provides the connection between a static typing condition (Definition 11) and run-time behavior of the method.

In this section, we present the formal definitions of the run-time SEF condition (Definition 15 in Section 5.1) and the SEF guarantee (Section 5.2). We then outline the proof of the guarantee (Section 5.3) and discuss some details of the proof (Section 5.4).

5.1 The run-time SEF condition

We informally stated the run-time SEF condition in Section 3.1, where we mentioned that several possible versions of such a condition could be defined. In our approach, we allow a pure method to create new objects and to modify just these new objects, which are under full control of the method.

The main SEF condition is that the method must not modify any **existing objects** that are already on the heap when the method starts executing. We can state such a condition in three variants, depending on the way in which it is checked that an object was not modified. Here we will use the variant that guarantees that existing objects on the heap do not change. In such a case, we say that a given execution of a method, starting from a method call start and reaching method call end in k steps, has the Sef-I property (Definition 15). The other possible variants are stated as Definition 42 and Definition 43 in the appendix.

► **Definition 15 (Sef-I).** A method execution $\langle w_1.m\ w_2; \sigma; \rho_1; \Sigma_1 \rangle \xrightarrow{k} \langle vw_3; \sigma; \rho_2; \Sigma_2 \rangle$ is Sef-I when for every $j \leq k$ and $\langle w_1.m\ w_2; \sigma; \rho_1; \Sigma_1 \rangle \xrightarrow{j} \langle t_3; \sigma_3; \rho_3; \Sigma_3 \rangle$, Σ_1 is a prefix of Σ_3 .

5.1.1 Method call limits

Because we are defining a condition on what can happen while a method is executing, we need to understand what it means in roDOT that a method starts and ends its execution.

In roDOT, a method is called by a term $w_1.m\ w_2$. A *method call start* is a configuration of the form $\langle w_1.m\ w_2; \sigma; \rho_1; \Sigma_1 \rangle$, where w_1 is the receiver, m is the called method, w_2 is the argument, σ is the *continuation stack*, and Σ_1 is the *existing heap* (the environment ρ_1 does not have a special significance here).

The execution proceeds by replacing the call term $w_1.m\ w_2$ with the body of the method. Then, the body is executed. Unless there is an infinite loop, the body of the method will eventually evaluate to a single value. The machine will reach a configuration $\langle vw_3; \sigma; \rho_2; \Sigma_2 \rangle$, where w_3 is the result of the call and σ is the same stack as at the method call start.

The **first** such configuration after a method call start is the corresponding *method call end*. Another such configuration could possibly occur later in a completely unrelated way, but only the first such configuration is the method call end.

When a method call end is reached, the execution will either terminate, or proceed by popping a frame from the stack.

5.2 The SEF guarantee

The SEF guarantee, informally stated in Section 3.3, says that a SEF method does not modify existing objects in the heap during its execution. Theorem 16 is based on Definition 15, and speaks about the state of the heap at every point during the call. It is not the strongest possible purity guarantee, because this allows writing the value that already is in the field. On the other hand, it does not allow the value of fields to be changed and then changed back.

► **Theorem 16.** Let the configuration $c_1 := \langle w_1.m\ w_2; \sigma_1; \rho_1; \Sigma_1 \rangle$ be well-typed in a context Γ . Further assume that $\Gamma \vdash w_1 : \{m(z : \mathbb{N})(r : \mathbb{N}) : \top\}$. Then for any k steps of execution:

1. Either the method call has finished executing. There is $j < k$ for which $c_1 \xrightarrow{j} \langle vw_3; \sigma_1; -; - \rangle$.
2. Or, the method call has not finished executing and in this period existing objects in the heap are unchanged. For each $c_1 \xrightarrow{k} c_2$, all heap locations in c_1 also exist in c_2 and moreover they are unchanged in c_2 .

5.3 Overview of the proof

The SEF guarantee talks about objects not being modified during the execution of methods, based on the mutability of method parameters. We base our proof of the SEF guarantee on the immutability guarantee (IG, Theorem 2), which states that individual objects can only be modified through mutable references. This guarantee was proven for roDOT [12] and is included in our mechanization in Coq.

However, the immutability guarantee cannot be applied at the start of the method, because there may be many mutable references to objects on the heap. Also, IG guarantees immutability until the end of execution of the whole program, but the SEF guarantee only until the end of the method.

These differences can be bridged by taking the machine configuration at the method start, and constructing a different configuration that will execute the same way until the end of the method, but removing the parts that prevent the IG from applying.

First, note that the stack is not relevant to how the method executes and stays the same from the method start until its end. We therefore remove this stack entirely, and get an execution isolated from the rest of the program. This execution proceeds through the same steps, but stops at the method end. By removing the stack, we rid the configuration of any references to objects that might be used after the method call returns. If we apply the IG to this configuration, it will guarantee that objects are not modified until the end of the method, exactly what is needed for the SEF guarantee.

Removing the stack is not enough for the IG to apply though, because a SEF method can be called with arguments that are mutable references. We do not want to prevent that from happening, because even when a method is SEF, it can be useful to pass mutable references to the method and have it return one of these references with its mutability intact.

What is special about a SEF method is that (because of its declared parameter types) it cannot use the mutability during its execution. Therefore, when called with mutable arguments, it should execute in exactly the same way as if called with read-only arguments.

So the second modification to the configuration after removing the stack is to change the mutability of the arguments to read-only. That way, the alternative configuration contains no writeable references, and IG guarantees that no objects that were on the heap at the start will be modified. Still, this alternative configuration executes the same steps as the original, meaning the original method execution also does not modify any existing object on the heap.

5.4 Proof of the SEF Guarantee

The strategy of the proof of Theorem 16 is to focus on the second case of the SEF guarantee by using the immutability guarantee to show the theorem for a configuration c_2 obtained by temporarily truncating the stack of c_1 from Theorem 16.

► **Lemma 17** (SEF guarantee without stack). *For c_1 satisfying the conditions of Theorem 16, let $c'_1 := \langle w_1.m\ w_2; \cdot; \rho_1; \Sigma_1 \rangle$. If $c'_1 \mapsto^n c'_2$ for some n and c'_2 , then the heap of c'_2 contains all objects of c'_1 without modification.*

It is easy to prove the full SEF theorem with this result for c'_1 . The premise of the immutability guarantee is that c'_1 is well-typed in some context Γ_2 and there are no mutably reachable objects in c'_1 with respect to the typing of Γ_2 . Clearly c'_1 is well typed in the original context Γ . But for the part about mutably reachable objects, we cannot just take Γ as Γ_2 because for this, Γ_2 must assign read-only types to w_i . Even though we have $(r : \mathbb{N})$ in the typing $\Gamma \vdash w_1 : \{m(z : \mathbb{N})(r : \mathbb{N}) : \top\}$, this does not necessarily mean $\Gamma(w_1)$ is a read-only type. For example, w_1 might be mutable in Γ but m might not make use of its mutability. Therefore, instead of using Γ as Γ_2 , we construct Γ_2 and show that c'_1 is well-typed in Γ_2 like so:

1. *Reference elimination.* Remove bindings for w_i from Γ and replace all occurrences of w_i with the corresponding location y_i in both Γ and c'_1 .
2. *Read-only weakening.* Add back bindings for w_i , where the new type bound to w_i is the type bound to y_i except with the mutable part set to read-only.

We do this instead of changing the types of w_i , because we only know that w_i are used in a read-only way in the focus, while on the heap, w_i might be used as a part of dependent types referring to their mutability. Changing their types would break the typing of the heap.

The second step is essential, because only references can be read-only, while locations always have mutable types. The references w_i are added in the same order as in the original context, to ensure that types in the typing context only refer to preceding variables in case the types are dependent. The two steps above correspond to the following two lemmas.

► **Lemma 18** (Reference elimination). *Let c_1 and Γ satisfy the conditions of Theorem 16, and $\rho_1[w_i] = y_i$. Define Γ' as the context obtained from Γ by first removing bindings for w_i and then replacing w_i with y_i . Define ρ' as the environment obtained from ρ_1 by removing bindings for w_i . Then the term $y_1.m\ y_2$ is well-typed under $\Gamma'; \rho'$ and we have heap correspondence $\Gamma'; \rho' \sim [y_i/w_i]_i \Sigma_1$.*

Proof. Because w_i is a reference to y_i , types assigned to y_i and w_i by Γ differ only by mutability, and y_i has a mutable type. So $\Gamma(y_i)$ is a subtype of $\Gamma(w_i)$, and the result follows by substitutivity. ◀

► **Lemma 19** (Read-only weakening). *Let c_1 and Γ satisfy the conditions of Theorem 16, and y_1, y_2 be such that $\rho_1[w_i] = y_i$. Then there is a context Γ_2 binding w_i to read-only types such that the configuration $c''_1 := \langle w_1.m\ w_2; \cdot; \rho_1; [y_i/w_i]_i \Sigma_1 \rangle$, is well-typed in Γ_2 (formally $\Gamma_2 \vdash c''_1 : \top$).*

By Lemma 19 along with the immutability guarantee, we have SEF established for $c''_1 := \langle w_1.m\ w_2; \cdot; \rho_1; [y_i/w_i]_i \Sigma_1 \rangle$. However, we need SEF in particular for the configuration $c'_1 := \langle w_1.m\ w_2; \cdot; \rho_1; \Sigma_1 \rangle$ in Lemma 17, where there is no substitution $[y_i/w_i]_i$ in the heap. Nevertheless, this substitution can be ignored in the sense that execution can only change fields of objects, but in roDOT, fields always store locations while w_i are references. (When a reference is assigned to a field, the corresponding location is stored, in order to make the field type determine the mutability of the stored value.) Because c'_1 and c''_1 are the same everywhere except for $[y_i/w_i]_i$ on the heap, the SEF property of c''_1 can be carried over to c'_1 . The first part of carrying the SEF property over to c'_1 is to relate each k -th step of execution starting from c''_1 and the k -th step of execution starting from c'_1 . We need to show that the two executions are almost the same, except some specific variables that appear in the machine configuration can differ. In particular, the references w_i can be replaced by the locations y_i . Additionally, the locations and references of newly created objects can differ, because variable names are not assigned deterministically.

For that reason, we define the *similarity* relation, which formalizes structural equivalence of syntactic elements such as terms, objects or whole configurations that differ only in names of variables. It relates two such elements using a *renaming* relation over variables. A formal definition of similarity and its basic properties is given in Section A.5 in the appendix.

Similarity has two important properties with respect to program execution: (1) it is preserved by reduction, and (2) if a machine configuration can reduce, then all similar configurations can reduce too (and the results are similar). That means that if we start with two similar configurations, where the execution of one reaches an answer state, then the execution of the other will reach a similar answer state. With this definition of similarity, Lemma 20 formalises the idea that c''_1 is similar to c'_1 up to renaming w_i to y_i :

► **Lemma 20** (Similarity for eliminated references). *Let c'_1 satisfy the conditions of Lemma 17 and c''_1 the conditions of Lemma 19. Then $c'_1 \xrightarrow{(w_1,y_1),(w_2,y_2)} c''_1$.*

The final part of carrying over the SEF property to c'_1 is to recognize that reduction only changes values of fields (while the structure of the object, methods and type members are immutable).

► **Definition 21** (Objects identical except fields). *For objects o_1 and o_2 , we write $o_1 \xrightarrow{fld} o_2$ to mean they are identical except for possibly the values of fields.*

► **Lemma 22** (Reduction only changes fields). *If $\langle -; -; -; \Sigma \rangle \mapsto^n \langle -; -; -; \Sigma' \rangle$ and y is a location in Σ , then $\Sigma(y) \xrightarrow{fld} \Sigma'(y)$.*

And with this, we can finish the proof of Theorem 16.

Proof. By classical reasoning, assume the condition 1 is false so that the goal is to prove the condition 2. That is, assume that there is no $j < k$ such that the top-most frame of c_1 is popped after execution by j steps: $c_1 \mapsto^j \langle vw_3; -; -; \Sigma_2 \rangle$. Then, the sequence of reductions $c_1 \mapsto \dots \mapsto c_2$ corresponds to a sequence of reductions $c'_1 \mapsto \dots \mapsto c'_2$ because even though c'_1 has no awaiting frames, there are no frame pops in this execution sequence by the current assumption. By Lemma 17, the condition 2 follows. ◀

6 Transformations

In Section 3.4, we informally stated the transformation guarantee, which connects the static SEF condition with a practical application – that calls to SEF methods can be safely swapped.

Defining the call-swapping and the guarantee in a formal way requires dealing with several technicalities particular to the roDOT calculus (or DOT calculi in general). In order to separate the common problems from the specific case of swapping calls, we build a general framework in which various transformations of roDOT programs can be defined and proven safe. We instantiate it here only with the call swapping transformation, but it could represent the general part of a proof of safety for other transformations, such as reordering field reads or removing dead code.

In Section 6.1, we present the framework for defining and reasoning about safe program transformations in roDOT and similar calculi, including a general Theorem 25 about safety of transformations. In Section 6.2, we define the transformation that swaps two calls to methods that are statically determined to be side-effect free (Definition 26) and state the transformation guarantee.

6.1 Transformation framework

The framework defines a general form for roDOT program transformations, defines the precise meaning of a *safe transformation* that “does not affect the behavior of the program”, and provides a way of proving this property, while helping to deal with common technical issues of DOT formalizations.

Our general approach is to define a transformation that applies to an initial program, and prove it safe by showing that if the original and transformed program are executed side-by-side, they will either eventually reach the “same” answer, or both not terminate.

In the initial program, a transformation, such as swapping calls, can be located anywhere, including inside a body of a method of an object literal, such as $\text{let } x = \nu(r : R)\{m(r, z) = t_m\} \text{ in } t_2$. We must consider that in roDOT, terms are in A-normal form, and that a term can

have multiple different types. Also code (terms) and values (objects) are mixed with each other during execution of a program – the program contains object literals, and methods on the heap contain program code.

During execution, objects are created on the heap, including copies of the code of their methods, which can be affected by the transformation. It would be too restrictive to require that a transformed program produce the exact same output value as the original program since the output value may be an object that may contain the transformed code. To facilitate this, we define each transformation using a local relation which relates two terms that differ only locally, and the framework provides lifting operators, which allow this transformation to occur anywhere in a program or in a machine configuration.

The general safety Theorem 25 is based on executing the two programs and observing that the intermediate states are also related by the transformation (lifted to whole configurations and allowed to occur at multiple places), except the moments when the directly affected part of the program is executing. When the two answers are reached, they will be similar except that bodies of methods on the heap may differ as the transformation permits.

A more detailed description of the framework design and its definitions are given in Section A.7 in the appendix. The following text describes the most important parts.

6.1.1 Transformations of roDOT programs in general

A transformation of a program is defined as a binary relation on terms – the original program and the transformed one. For example, the call-swapping transformation is defined as a relation that relates a program containing two method calls with a program that only differs in the order of those calls.

Because the safety of the transformation depends on typing information, we define the transformation as a binary relation between triples: the term, its type and a typing context. This generalizes to other syntactic elements – stacks, heaps and machine configurations, though for each kind of element, the exact meaning of “typing context” and “type” may differ. For terms, the typing context is actually paired with a runtime environment $\Gamma; \rho$.

► **Definition 23** (Transformation). *A transformation τ is a relation between triples consisting of typing contexts $\Gamma_{1,2}$, types $T_{1,2}$ and typeable elements $X_{1,2}$. We write $\langle \Gamma_1 \vdash X_1 : T_1 \rangle \rightarrow_\tau \langle \Gamma_2 \vdash X_2 : T_2 \rangle$ and say that X_1 is transformed into X_2 .*

Like any binary relation, transformations can be symmetric, reflexive or transitive, and we can construct transformations using iteration, composition, union and inversion.

Additionally, a transformation is *type-safe*, if the syntactic elements on both sides are correctly typed under the respective contexts. Another useful property of a transformation is being *type-identical*, where both the types and typing contexts are the same on both sides.

To facilitate the possibility of the transformation being located anywhere in a term, it is useful to define the transformation in two steps: (1) A *local transformation*, which only allows swapping calls at the root of the term. (2) A lifting operator $\text{lift } \tau$ which takes a local transformation τ and allows it to be located at one place anywhere in a term.

Such a local transformation of a term can be further lifted by $\text{cfg } \tau$ to a whole run-time configuration, where τ applies at exactly one place in the focus of execution, in the stack or on the heap. To allow multiple occurrences, we can apply the iteration operator to the lifted transformation. Having a definition that only allows one occurrence is useful in the proof of Theorem 25 in Section A.7.4 in the appendix, where we want to look at each occurrence individually. More details about lifting are in Section A.7.3; the definitions of the lifting operators are shown in Figure 23 and Figure 24.

6.1.2 Safe transformations

The definition of a safe transformation must allow the answers of the two programs to contain different variable names and allow for the fact that the transformation can occur in the heap of the program answer, possibly at multiple places. Therefore a local transformation is safe if execution of the transformed program reaches answers related by an iteration of this transformation. To deal with non-deterministic location names, the transformation is in union with a *similarity transformation* \approx , which allows one-to-one variable renaming.

► **Definition 24** (Safe transformation). *A transformation τ is safe if $\langle \Gamma_1 \vdash c_1 : T \rangle \rightarrow_\tau \langle \Gamma_2 \vdash c_2 : T \rangle$ and $c_1 \rightarrow^k c_3$, where c_3 is an answer typed as $\Gamma_3 \vdash c_3 : T$, implies that there exist c_4 , Γ_4 and j such that $c_2 \rightarrow^j c_4$, $\Gamma_4 \vdash c_4 : T$ and $\langle \Gamma_3 \vdash c_3 : T \rangle \rightarrow_{(\tau \cup \approx)^*} \langle \Gamma_4 \vdash c_4 : T \rangle$.*

Thanks to being able to define a transformation by applying a general lifting to a local transformation, the safety proof of such a transformation can be also divided into a theorem that will apply to any local transformation with certain local properties, and then proving those local properties for the particular local transformation.

This approach makes it possible to state the call-swapping guarantee presented here (Theorem 27), or analogous guarantees for other local transformations.

Theorem 25 states that if a local term transformation does not change typing of the term, is compatible with properties such as weakening, narrowing and substitution, does not change whether the term is an answer or not, and if execution of just the transformed term will eventually reach similar configurations, then transforming a program by this transformation anywhere will not change its result. Full definitions of the premises are in Section A.7 in the appendix as Definitions 49, 50, 52, 56 and 54.

► **Theorem 25** (General safety for local transformations). *If τ is a transformation that is type-identical, type-safe, compatible with weakening, narrowing and substitution, preserves answers, and eventually reduces to similarity, then $(cfg \tau \cup \approx)^*$ is safe.*

6.2 The call-swapping transformation

The specific transformation guarantee that we want to achieve should state that swapping two calls will not change the outcome of the program, in the sense of Definition 24.

Call-swapping is defined as a local transformation that transforms one program containing two successive calls into another program in which the calls are swapped. Due to the A-normal form of terms, two successive calls in the program have the form $\text{let } x_{c1} = x_{o1}.m_1x_{a1} \text{ in let } x_{c2} = x_{o2}.m_2x_{a2} \text{ in } t$. In the transformation, the two calls $x_{o1}.m_1x_{a1}$ and $x_{o2}.m_2x_{a2}$ appear in the opposite order, but the continuation t is the same.

The transformation is only safe if both the methods are SEF, so it has several typing premises, analogous to the ones of Theorem 16 in Section 5.2.

► **Definition 26** (Local call swapping). *The local call-swapping transformation csw is a transformation of terms that relates $\langle \Gamma \vdash \text{let } x_{c1} = x_{o1}.m_1x_{a1} \text{ in let } x_{c2} = x_{o2}.m_2x_{a2} \text{ in } t : T \rangle \rightarrow_{csw} \langle \Gamma \vdash \text{let } x_{c2} = x_{o2}.m_2x_{a2} \text{ in let } x_{c1} = x_{o1}.m_1x_{a1} \text{ in } t : T \rangle$ when*

- $x_{c1,2}$ are distinct from $x_{a1,2}$ and $x_{o1,2}$,
- $\Gamma \vdash x_{o1}.m_1x_{a1} : T_{c1}$, $\Gamma \vdash x_{o2}.m_2x_{a2} : T_{c2}$, and $\Gamma, x_{c1} : T_{c1}, x_{c2} : T_{c2} \vdash t : T$,
- $\Gamma \vdash x_{o1} : \{m_1(r_1 : \mathbb{N}, z_1 : T_{a1}) : \top\}$, and $\Gamma \vdash x_{o2} : \{m_2(r_2 : \mathbb{N}, z_2 : T_{a2}) : \top\}$,
- $\Gamma \vdash x_{a1} : T_{a1}$, and $\Gamma \vdash x_{a2} : T_{a2}$,
- $\Gamma \vdash \mathbb{N} <: T_{a1}$, and $\Gamma \vdash \mathbb{N} <: T_{a2}$.

As the final form of the transformation guarantee, we apply Definition 24 to Definition 26, and specialize the theorem to initial programs. The proof is given in Section A.8 in the appendix.

► **Theorem 27** (Transformation guarantee). *If $\langle \vdash t_1 : T \rangle \rightarrow_{lift\ csw} \langle \vdash t_2 : T \rangle$ and $\langle t_1 ; \cdot ; \cdot ; \cdot \rangle \rightarrow^k c_3$, where c_3 is an answer typed as $\Gamma_3 \vdash c_3 : T$, then there exists c_4 , Γ_4 and j such that $\langle t_2 ; \cdot ; \cdot ; \cdot \rangle \rightarrow^j c_4$, c_4 is an answer typed as $\Gamma_4 \vdash c_4 : T$ and $\langle \Gamma_3 \vdash c_3 : T \rangle \rightarrow_{(cfg\ csw \cup \approx)^*} \langle \Gamma_4 \vdash c_4 : T \rangle$.*

7 Related work

Since the topic of this work includes both the DOT calculus and method purity, here we discuss previous work related to these concepts. Prior to this work, many variants of the DOT calculus were published, some including mechanized proofs. Also the issue of purity in object-oriented languages is of great research interest, and it is approached from different angles of automation and precision. We give details about the existing work in the following subsections. As far as we know, our work is the first one to consider the issue of purity within a DOT calculus.

7.1 Mechanizations of DOT calculi

The first appearance of a DOT calculus [3] did not include a proof of soundness, but was followed by several versions with proofs in Coq [33, 30] and Iris [17]. In particular, WadlerFest DOT [2], thanks to its simplicity and its proof of soundness based on invertible typing [30], was used as a baseline for numerous extensions [32, 22, 31, 23], including roDOT. While objects are immutable in WadlerFest DOT, it was extended to support mutation using mutable slots in Mutable WadlerFest DOT [32], and more directly by allowing changing values of fields in kDOT [22]. A simplified version [21] with mutable fields, but without the specific kDOT feature of constructors, was used as a base for the mechanization of roDOT.

The differences between the mechanization of roDOT and those of previous DOT calculi mainly stem from the differences in how roDOT handles variables – namely, typing of variables and terms being separated from each other, using different definitions of typing contexts to support variable hiding, using the runtime environment to map references to locations, and using typing information in its definition of operational semantics.

The mechanization of roDOT includes a feature to ease further extensions to the calculus. The definitions and theorems are parameterized by a “typing mode”, which allows selecting type system features that are supported. Using this feature, our proofs work for roDOT both with and without the changes described in this paper.

7.2 Purity in other languages

Purity in programming is such an important concept that in many languages, functions are pure by default. This approach is typically associated with functional programming, but an object-oriented system can also be pure [1] when the objects are immutable. That is also the case in the basic DOT calculus.

In pure functional languages, effects must typically be explicitly declared in the program using monadic types. This style of programming has been shown to be as powerful as other styles and is used in practical programming languages such as Haskell.

Regarding purity in object oriented languages with mutable fields, many publications [37, 34, 38, 40, 6, 16, 29] focus on Java and languages with similar type systems, such as C#. For Scala, a type system for purity was developed, but not based on the DOT calculus [35].

When approached from a practical standpoint, the definition of purity in these languages has to include considerations other than modification of object fields, such as accessing global variables or synchronization. This leads to different definitions of purity. The term “pure” is sometimes used to mean the same as “side-effect-free”, without requiring determinism.

Observational purity [25, 5] is a weaker property that allows side effects as long as they are not observable from certain parts of the code. This definition is based on classes and access control, features which are not modeled in DOT calculi.

Purity is of great use to program verification and specification frameworks, where it enables inserting run-time checks without changing behavior, and allows more precise analysis. Code Contracts [15], JML [20] and Checker Framework [14] allow annotating a method as pure. Code Contracts do not check that this annotation is correctly applied, and JML and Checker Framework use simpler checks, where pure methods are not allowed to call impure methods. Checker Framework uses the fact that side-effect free methods do not invalidate flow-sensitive types of local variables.

To avoid imposing an annotation burden on the programmer, purity can be inferred by automatic program analysis [26, 34], and side-effect analysis can be used for program optimization [11].

ReIm [19] provides both a type system for reference mutability and a way to automatically infer mutability types. It can therefore automatically find pure methods, which have all parameters read-only. We adopted this way of recognizing pure methods by parameter types for roDOT in this work. While in ReIm, mutability is attached to parameter types as a qualifier in the style of the Checker Framework, roDOT uses the special member type M to include the mutability in the parameter type using intersection types. In ReIm, mutability qualifiers are subjected to qualifier polymorphism and viewpoint adaptation. roDOT can express the equivalent of polymorphic qualifiers using dependent types and implements viewpoint adaptation using union and intersection types [12].

7.3 Capability and Effect Systems

There are other ways to express the permitted side-effects of functions using types, which have been developed in recent work on formal type systems.

The principle of **capabilities** [28, 27] is to require every operation that can have a side effect to take an extra value, called a capability, as a parameter. Then, if some function or method does not have the capability value corresponding to a particular effect, we can conclude that it does not perform that effect. Capabilities are well suited for coarse-grained effects, such as performing input/output in general or accessing some specific file, where a single capability value can guard a set of related operations. To apply such an approach to reasoning about a fine-grained effect such as writing to a field of a specific object, we would need large numbers of such capability values, one new capability value for each existing object. For each reference passed to a parameter or stored in a field, a corresponding capability would need to be passed or stored, thus multiplying the number of parameters and fields.

Wyvern's effect system [24] expresses possible effects by type members of objects. That is syntactically similar to how roDOT represents mutability, but the meaning of the type members is different. In roDOT, the type member of an object reference defines the bounds on the mutability of the reference, the knowledge about whether a reference may be used for mutation, in the type of that reference. In contrast, in Wyvern, the effect member represents

a permission to perform an effect, such as `file.Write`, where the effect can be independent of the object that contains the effect member. Thus, Wyvern effect members are more similar to the capability-based approach.

Another successful direction is to use types to express sets of possible variables captured or aliased by values in the program. **Capture Types** [7] follow from a capability based approach, and enable reasoning about where capability values may be stored in the heap or captured in closures, in order to more precisely reason about where effects may occur. **Reachability Types** [4] annotate the type of an expression with a set of variables, which are values that are possibly reachable from the result of that expression. This can be used in conjunction with effect qualifiers as in Graph IR [8], where a function type declares a set of variables that can be read or written, describing the possible effects in a fine-grained way. The types can also be extended to support qualifier polymorphism [39]. This work is defined in the context of a higher order functional formalism, whereas roDOT is an object-oriented calculus. Also, both Wyvern and Reachability Types express effects using new constructs added to the type system, while roDOT aims to encode mutability using the existing DOT constructs of dependent types, unions and intersections.

8 Conclusion

To conclude, our paper confirms that the reference mutability system provided by roDOT can be mechanically proven sound, and with a few changes can be used to guarantee side-effect freedom of methods, and to justify safe transformations of programs.

The Performance Effects of Virtual-Machine Instruction Pointer Updates

M. Anton Ertl   

TU Wien, Austria

Bernd Paysan

net2o, Munich, Germany

Abstract

How much performance do VM instruction-pointer (IP) updates cost and how much benefit do we get from optimizing them away? Two decades ago it had little effect on the hardware of the day, but on recent hardware the dependence chain of IP updates can become the critical path on processors with out-of-order execution. In particular, this happens if the VM instructions are light-weight and the application programs are loop-dominated. The present work presents several ways of reducing or eliminating the dependence chains from IP updates, either by breaking the dependence chains with the *loop* optimization or by reducing the number of IP updates (the *c* and *ci* optimizations) or their latency (the *b* optimization). Some benchmarks see speedups from these optimizations by factors > 2 on most recent cores, while other benchmarks and older cores see more modest results, often in the speedup ranges 1.1–1.3.

1 Introduction

Interpreters are a popular approach for implementing programming languages. Their benefits are simplicity of implementation, portability, and fast edit-run cycles. While they cannot compete in execution performance with JIT compilers or ahead-of-time compilers, a fast interpreter is not that far away: e.g., with the IP update optimizations of the present work, Gforth has similar performance to the SwiftForth JIT compiler and to gcc -O0 (see Section 6).

This paper uses Gforth as an example high-performance interpreter. Gforth implements a virtual machine (VM) and uses several previously published techniques for achieving high performance (see Section 2), most notably dynamic superinstructions (aka selective inlining) with replication and stack caching.

At the start of this work, every VM instruction in Gforth performed a VM instruction-pointer (IP) update [3]. It turns out that these IP updates (both the increments for ordinary instructions and the loads for taken branches) form a critical dependence path that limits the execution performance of many programs on modern processors.

We introduce a collection of optimizations for reducing these dependences: The loop optimization (*l*) breaks dependency chains in loops (Section 4.1). Optimization *c* combines the IP updates of VM instructions that do not need an up-to-date IP (Section 4.2); the immediate optimization (*i*) avoids the need for an up-to-date IP for VM instructions with immediate operands (Section 4.3); The branch optimization (*b*) optimizes VM branches by replacing loads with (lower-latency) adds (Section 4.4).

Section 2 explains the interpreter performance techniques necessary to understand the present work. Section 3 explains how data dependences influence the performance of modern processors. Section 4 describes the optimizations and shows an example of their application; the novel *loop* (Section 4.1), *immediate* (Section 4.3), and *branch* (Section 4.4) optimizations are among the main contributions of this work. Section 5 describes the measurement setup. The other main contribution of this work is in the empirical evaluation of the optimizations (Section 6). Finally, we discuss the applicability to other languages (Section 7), how to get the source code (Section 8) and related work (Section 9).

1.1 Why Gforth? Is this paper relevant for other languages?

You may wonder why we use Gforth and whether our results are relevant for other languages and their VMs.

We chose Gforth in the present work because it already implemented a number of techniques for increasing performance, in particular dynamic superinstructions and stack caching. As a result, Gforth’s VM executes so few real-machine instructions per VM instruction that the dependences formed from IP updates become a bottleneck on certain programs.

We think that our IP update optimizations are also applicable to other VMs, but it depends on the VM, its implementation, and the characteristics of programs that are run on it how big the benefits will be. For a longer discussion, see Section 7.

2 Interpreter performance techniques

This section provides an overview of the performance techniques as far as necessary for understanding the IP update optimization, with literature references.

2.1 Virtual machines

Most interpreted programming language implementations compile the source code with a simple compiler into an intermediate code that represents the source program as a sequence of instructions of a virtual machine (VM) that is designed as both an easy target for the compiler and for easy (and ideally efficient) interpreted implementation of this code. Some well-known virtual machines, such as the Java Virtual Machine [15] and WebAssembly [12] also serve as program interchange formats, but in the present paper we focus on the role of virtual machines for execution in fast interpreters.

For our running example, we use Gforth’s VM. Gforth is an implementation of the programming language Forth, a low-level (address arithmetic etc.) stack-based programming language.

Our running example is the inner loop of the siev benchmark:

```
do
  0 i c!
  dup +loop
```

We look only at the body of the loop, i.e., without the `do`. In Gforth’s VM, the body looks as follows:

```

loophead: lit
  0
  i
  c!
  dup
  (+loop)
  loophead

```

Each line occupies one machine word, and *slanted blue* lines are immediate operands of the preceding VM instruction.

An interpreter for VM code keeps a pointer to the current VM instruction (the IP) around and uses it for finding immediate operands of the VM instruction and for finding the next VM instruction. In case of a VM-level direct branch instruction like `(+loop)`, the immediate operand is the branch target and if the branch is taken, the IP is set to the value of the immediate operand.

That's all you need to understand the optimization in the paper in the abstract, but to round out the picture, the rest of this section describes what these VM instructions do.

This Forth code corresponds to the following C code:

```

do {
  *p = 0;
  p += prime;
} while (p<pend)

```

Gforth's VM is stack-based and is relatively close to the Forth source code, with the following exceptions: Gforth compiles the number 0 to the VM instruction `lit` with the immediate operand `0`, and it compiles `+loop` to the VM instruction `(+loop)` with an immediate operand: the address of the VM instruction that `(+loop)` jumps to unless it exits the loop.

`lit` pushes its immediate operand on the data stack (or stack, for short). `i` pushes the current counter of the `do...+loop` counted loop on the stack (in this loop the counter contains the address corresponding to `p` in the C fragment). `c!` (pronounced “c-store”) stores the second item on the stack to the byte pointed to by the address on the top-of-stack (TOS), popping both stack items. `dup` pushes another copy of the current top-of-stack value on the stack; this value corresponds to `prime` in the C program.

`(+loop)` pops the top-of-stack and adds it to the loop counter and checks for loop termination.¹ If another iteration is merited, `(+loop)` performs a VM-level jump to `loophead`.

2.2 Switch dispatch

A common way to implement an interpreter in C is to use a big switch statement along the lines of:

¹ As you will see in the assembly code later, this check is more complex than one would expect from the C code. The reason is that `+loop` is specified to support circular arithmetic and both positive and negative increments, which complicates the termination condition. For details see <https://forth-standard.org/standard/core/PlusLOOP>.

14.4 The Performance Effects of Virtual-Machine Instruction Pointer Updates

```

for (;;) {
    switch (*ip) {
        case dup: dsp[0] = tos; dsp--; ip++; break;
        case lit:  dsp[0] = tos; dsp--; tos = ip[1]; ip+=2; break;
        ....
    }
}

```

In this example the data stack is represented by having the top-of-stack in a local variable `tos`, and the remainder of the data stack is in memory, and the local variable `dsp` points to where the top-of-stack would reside if it were in memory. IP is also kept in a local variable `ip`. We will use the same names for registers in assembly code shown below.

This scheme has a relatively high overhead of getting from one VM instruction implementation to the next. For `lit` with switch dispatch `gcc -O2` produces the following code for RISC-V (the destination register (if any) is leftmost):

```

.L2:          #switch code
    ld      a4,0(ip)   # a4=*ip
    slli   a5,a4,2     # a5=a4*4 #for indexing
    add    a5,a6,a5     # a5=a6+a5 #table start in a6
    bgtu  a4,a7,.L17   # if a4>a7 goto default #bounds check
    lw     a2,0(a5)     # a2 = *a5 #load from table
    jr    a2             # indirect branch to a2

.L6:          #lit code
    sd      tos,0(dsp)  # dsp[0] = tos
    ld      tos,8(ip)   # tos = ip[1]
    addi   dsp,dsp,-8   # dsp--
    addi   ip,ip,16     # ip += 2
    j     .L2            # back to switch code

```

Figure 1 shows the data structures involved in switch dispatch. The VM instructions are represented as integers that are used as indexes into the switch table. We use 8-byte VM-code slots for the code above.

The *payload* consists of only 3 RISC-V instructions in this case, whereas the dispatch overhead is 8 instructions.

Gforth has never implemented switch dispatch, and instead went directly for threaded code.

2.3 Threaded code

Threaded code [1] reduces the dispatch overhead by representing each VM instruction directly as the address of the machine code that implements it. This means that each instruction occupies one machine word (8 bytes on a 64-bit machine) and immediate operands are usually represented by one or more machine words. This concept results in the following code for `lit`:

```

sd      tos,0(dsp) # dsp[0] = tos
ld      tos,0(ip)   # tos = ip[0]
addi   dsp,dsp,-8 # dsp--
addi   ip,ip,16     # ip += 2
ld      a4,-8(ip)  # a4 = ip[-1] #address of next VM inst
jr    a4            # jump to next VM inst

```

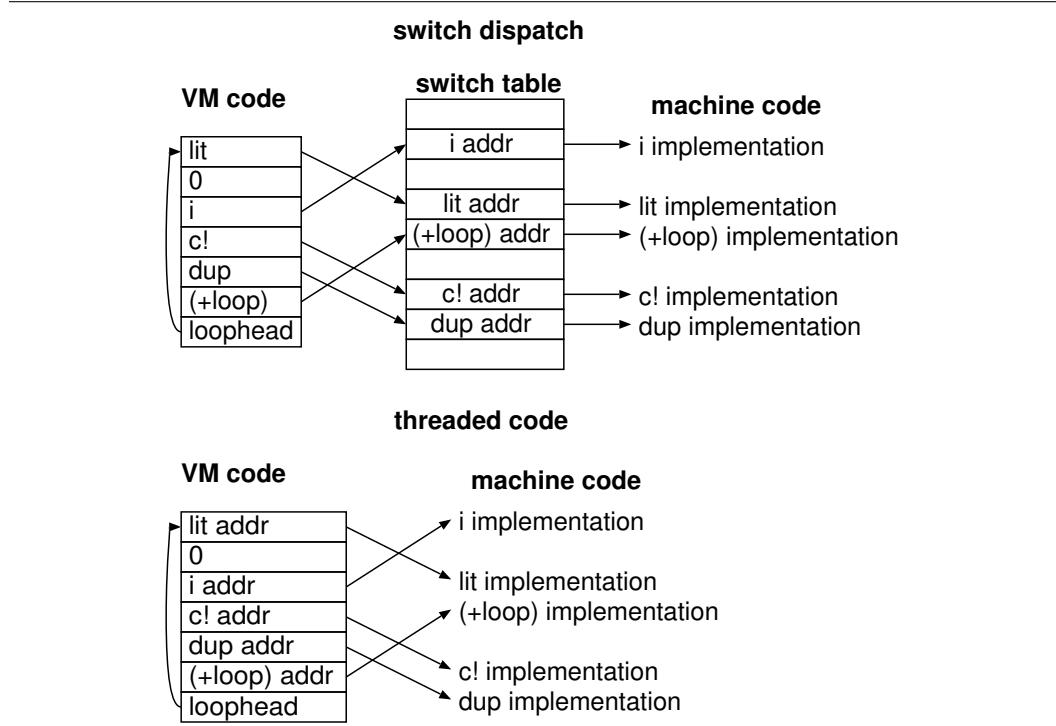

Figure 1 Switch dispatch vs. threaded code.

The dispatch code is inlined here and consists of 3 RISC-V instructions.

Figure 1 shows how the two schemes get from the VM code to the corresponding machine code. In both schemes ip points to the VM code, and immediate operands are accessed through ip. VM control flow is performed by setting ip to something other than the next VM instruction.

One practical consideration is how to implement threaded code in an architecture independent language. Fortunately it is possible by using the labels-as-value extension of GNU C, which has been implemented by at least gcc, clang, tcc, and icc.

2.4 Selective inlining and dynamic superinstructions

One can eliminate more of the dispatch: While generating VM code, copy (real-)machine code snippets from the interpreter to a separate memory area, thus concatenating these snippets (Fig. 2); the threaded-code addresses then point to this newly generated real-machine code rather than the originals as in normal threaded code.

This technique has first been outlined as *memcpy method* by Rossi and Sivalingham [20], and later explored in depth as *selective inlining* by Piumarta and Riccardi [17]. Ertl and Gregg combined it with replication [4] for better branch prediction. They call the result of the concatenation *dynamic superinstructions*, because, like static superinstructions [18, 8, 2] they combine a sequence of n VM instructions with n dispatches into something with only one dispatch.

In our example (Fig. 2), each VM instruction except the last one ((+loop), which is a VM-level branch) just continues with the next one, so the machine code of the next one can be concatenated to the machine code of the dynamic superinstruction. The (+loop) may

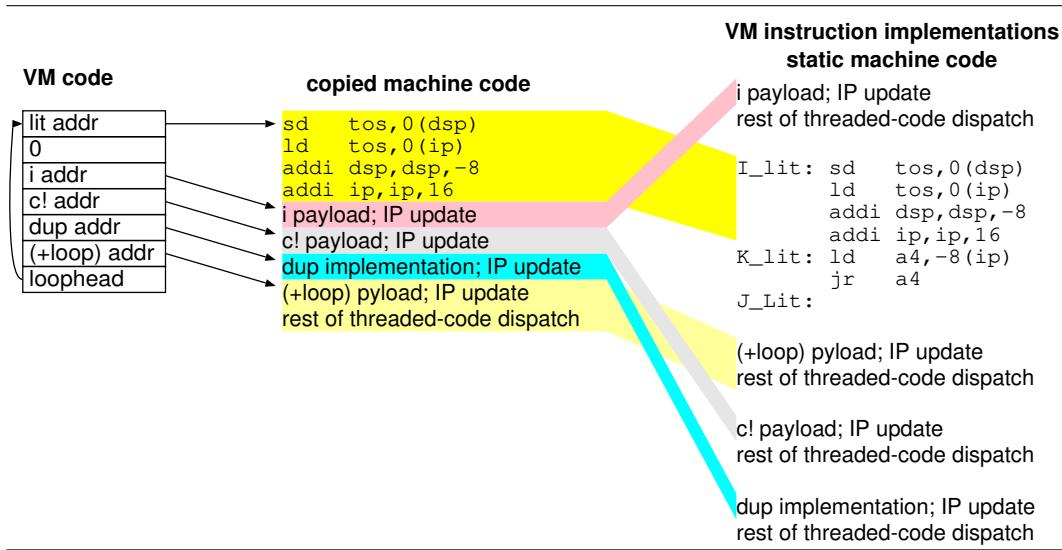

Figure 2 Concatenating machine-code snippets to further reduce the dispatch overhead.

set `ip` to something other than the next instruction, so for `(+loop)` and other control-flow VM instructions the whole code including the rest of a threaded-code dispatch is appended in order for the control-flow change to take effect at run-time; such an instruction therefore ends a dynamic superinstruction.

Gforth copies the machine code snippets at the same time as when it generates VM code for newly compiled source code. Gforth does not save the machine code in its images, so its image loader copies the machine code snippets for the VM code it loads.

This technique has provided a big performance boost to Gforth across many different CPUs, typically by a factor of 2 over threaded code (see Fig. 10). One may balk at the prospect of directly manipulating machine code, but the advantage of starting with an interpreter is that Gforth can always fall back to threaded code if conditions seem adverse (and this normally works automatically).

One may wonder if the result is not already a JIT compiler, and in certain respects it is. But for the language implementor it is an extension of a threaded-code interpreter: Each implementation of a VM instruction just gets labels before and after the “rest of threaded-code dispatch” part, and when a VM instruction is generated, it also copies the memory containing the machine code for the VM instruction (using the labels to know the boundaries), and lets the threaded-code word point to the copy (instead of the original). The only amount of machine-specific code are a few lines to synchronize the I-cache to the D-cache, and GNU C provides `__builtin__clear_cache` for that purpose. And when the conditions for dynamic code generation are not met, the system just falls back to plain threaded code, overall or on a per-VM-instruction basis (e.g., for code that contains a relative reference to an address outside the code snippet at hand). By contrast, a typical JIT compiler needs much more machine-specific work.

2.5 Multi-representation stack caching

The Gforth baseline also uses an optimization called multi-representation stack caching. This optimization reduces only the machine instructions in the payload, so you only need to read this section if you want to understand the payload of our running example, too.

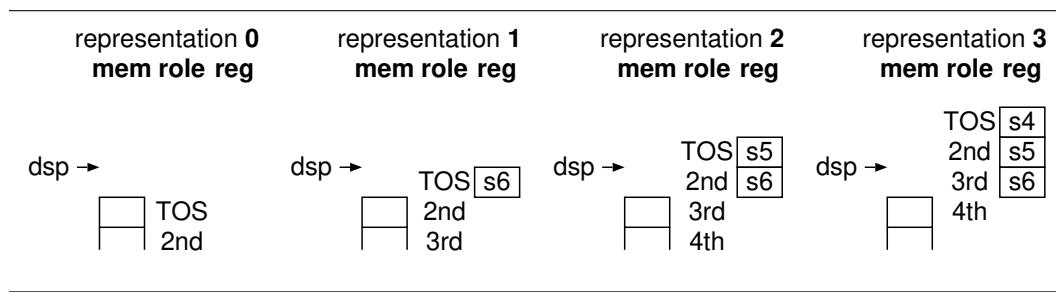

Figure 3 Four data-stack representations used by Gforth on RISC-V.

Figure 3 shows different representations of the data stack. Representation 0 keeps 0 stack items in registers, i.e., all stack items in memory. A representation with all stack items in memory is often seen in the literature (usually with the stack pointer pointing to the top-of-stack, but that is just a difference in the offsets used for the memory accesses).

The examples shown earlier use representation 1, and this is also used by Gforth when it falls back to threaded code. The advantage of this representation can be seen for `dup` which does one load and two stores with representation 0, but just one store with representation 1.

By switching between representations Gforth further reduces the stack handling effort. E.g., our running example starts in representation 1 (Gforth always uses this at the start of a basic block) with the VM instruction `lit`. By choosing the `lit` implementation that ends in representation 2 (i.e., `lit 1 → 2`), the payload of `lit` in this case is reduced to

`ld s5,8(ip)`

The old top-of-stack stays in `s6` (and becomes the 2nd stack element), and the new top-of-stack is pushed by setting `s5` (the new top-of-stack) to the immediate operand.

This eliminates a memory access to the data stack as well as an update of `dsp`. If you take a closer look at Fig. 4, you do not find any memory access to the data stack nor any data-stack pointer update, so in this case data-stack caching works perfectly.

Ertl and Gregg [5, 7] discuss multi-representation stack caching in more detail.

3 Understanding performance

This section describes how program characteristics influence the performance on processors with out-of-order (OoO) execution, and in particular, it discusses the role of instruction pointer updates in interpreters with dynamic superinstructions. OoO processors have dominated general-purpose computers in this century, and are now advancing towards smaller systems. E.g., the Raspberry Pi switched to OoO cores with the Raspberry Pi 4 in 2019 and the Compute Module 4 in 2020.

3.1 ... on modern CPUs ...

Starting from an empty pipeline, the front end of an OoO processor fetches and decodes instructions as directed by the branch predictor, possibly running far ahead of execution. An instruction is then executed as soon as all its inputs are available and an appropriate functional unit is available.

If a branch is mispredicted, fetch, decode, and execution at first continue along the (mis-)predicted path, but the results are not committed. When the correct direction or branch target is determined by executing the appropriate conditional or indirect branch instruction, the front end is redirected to fetch, decode and eventually execute from the correct path.

This description indicates the ways in which program characteristics influence performance:

As long as mispredictions are rare, if there are enough independent instructions, execution will be limited by the resources, either by the program needing too many of a particular functional unit (e.g., a matrix multiply program will exercise load and store units and the FP multiply-add a lot), or by the width of the decoder and/or the retirement unit.

On the other hand, if there are lots of dependences between instructions and the processor offers enough resources, the dependences will determine the performance: an instruction that depends on another instruction i on the critical dependence path will wait in the processor's buffers until i produces a result. After prefetching for a while, all these not-yet ready instructions will fill the processor's buffers and the processor's front end has to wait until more buffers become ready by finishing an instruction on the critical path.

In the branch misprediction case, the misprediction penalty is influenced by the kind of dependences between instructions: If there is a short dependence path to the predicted branch instruction, the misprediction can be resolved early. However, if the mispredicted branch depends on an instruction in the critical dependence path, the misprediction will not be discovered until the instructions leading to the branch have been executed; only then can the correct path be fetched and decoded, so such a misprediction incurs a bigger misprediction penalty. By contrast, in case of a correct prediction, the long latency until the prediction is confirmed does not hurt, except for occupying some buffers for longer.

3.2 ... in fast interpreters

In an interpreter, there is the resource consumption and dependences inherent in the interpreted program (i.e., also present if the program is compiled to real-machine code), but there is also the overhead of the interpreter:

In particular, every VM interpreter updates the VM instruction pointer (IP), in order to access immediate VM data through it, and to access the next VM instruction (or next dynamic superinstruction). In straight-line code, this results in one addition per executed VM instruction, with a latency of one cycle on most processors. For a VM-level absolute branch (as used in Gforth), the new VM instruction pointer has to be loaded, with a latency of 3–5 cycles on recent OoO processors; if the VM-level branch is relative, the loaded value has to be added to the instruction pointer, costing an additional cycle.

A VM-level return instruction breaks the IP dependence chain of the callee, because it loads the new VM instruction pointer from the saved return address. This continues the dependence chain of the caller, but the callee's chain of IP updates ends with the return.

VM interpreters also have other overheads: A stack-based VM like that of Gforth has dependence chains through stack-pointer updates, and these dependence chains are not broken by returns. Moreover, they keep most stack items in memory with the resulting store-to-load latency: 4–7 cycles in many processors, but 0 cycles in several recent processors like Zen 3 and Tiger Lake.² However, stack caching (see Section 2.5) reduces these overheads substantially.

² <https://www.complang.tuwien.ac.at/anton/memdep/>

For a register-based VM, the VM register accesses are usually implemented through real-machine memory accesses, which increases the resource consumption substantially. On older processors there is also the latency cost of store-to-load forwarding, but the significance of this cost depends on the dependence patterns of the interpreted program.

Previous work did not consider VM instruction-pointer updates to have much effect. Ertl and Gregg [4] wrote:

One thing that we have not implemented is eliminating the increments of the VM instruction pointers along with the rest of the instruction dispatch in dynamic superinstructions. However, by using static superinstructions in addition dynamic superinstructions and replication we also reduce these increments (in addition to other optimizations); looking at the results from that, eliminating only the increments probably does not have much effect.

For a long time our thinking was that other dependencies would dominate over VM instruction-pointer updates, and that, with processors becoming wider (being able to execute more instructions per cycle), instruction-pointer updates would become even less relevant. However, for a number of benchmarks this is wrong (see Section 6).

4 Instruction-pointer update optimization

This section discusses four mostly independent optimizations. We implemented these optimizations in Gforth, and discuss them in this context, but they can also be applied to implementations of other languages.

4.1 Loops

This optimization breaks the IP dependence chains on loop-back edges. In typical VM instruction sets, the loop-back branch takes the target address as an immediate operand (e.g., in Fig. 4 the immediate operand **loophead** following the VM branch instruction (`+loop`)).

With the *loop* optimization, the loop-back address is stored on the return stack on entering the loop, and the loop-back branch then takes its address from there (the **bold green** instruction in Fig. 4). Because it does not need to access the VM instruction pointer to do that, this breaks the dependence chain.

In Forth the return stack is a stack that contains return addresses and counted-loop parameters. In general, the loop-back address can be stored on any stack or in a VM register; the important part for the *loop* optimization is that this address must be readable by the loop-back instruction without requiring an IP access, so one cannot use a VM register whose number is given as immediate operand.

Unfortunately, the design of Forth makes it difficult to apply this optimization to general loops, so we only apply it to counted loops in the present work.

However, if you are designing a virtual machine for a programming language, it may be worthwhile to design it in a way that makes it possible to store the loop-back address somewhere on entry to the loop, and to load it from there on the loop-back branch without accessing the IP.

The loop optimization has very little effect on the instruction count and other dependences, and can therefore be used to see the performance effect of breaking the IP dependence chains independent of, e.g., the effect of reducing the number of executed instructions. In Fig. 9 we see speedups by a factor of 2 on some benchmarks, showing that the IP-update dependence chain really is the bottleneck for these benchmarks.

14:10 The Performance Effects of Virtual-Machine Instruction Pointer Updates

VM code		<i>unoptimized</i>	<i>l</i>	<i>c</i>	<i>ci</i>	<i>cib</i>

Figure 4 The inner loop of the benchmark `siev` in Gforth’s VM code, and the corresponding RISC-V code produced by Gforth without optimization and with various IP-update optimizations: *l* optimizes loops, *c* combines IP updates, *i* optimizes immediate operands, *b* optimizes branches. 1 → 2 etc. indicates a stack representation change (see Section 2.5). For instructions with destination registers, the destination is leftmost. The instruction that starts a new IP dependence chain (in the loop) is **bold green**. Instructions that continue IP update dependence chains are **slanted red**. Some register names have been changed for ease of understanding: ip is the VM instruction pointer, rp is the return-stack pointer. s6, s5, s4 contain stack elements (see Fig. 3).

While it is possible to combine this optimization with the others, we think that the combination of the others is effective enough in reducing the IP dependence chain, and that adding the *loop* optimization would not help once the other optimizations are performed. However, we consider the *loop* optimization to be an alternative that requires less effort.

You can see the result in column *l* of Fig. 4. The decisive difference is that the ***ld a2,-8(ip)*** in (+loop) in *unoptimized*, *c*, *ci* loads the branch target from VM code using the IP, while the ***ld ip,16(rp)*** loads the branch target from the return stack (using rp).

We implemented a prototype of this optimization in Gforth by adding 89 lines.

4.2 Combining instruction-pointer updates

There are VM instructions where the payload of the implementation does not read the IP and therefore does not need an up-to-date IP. In our running example `i`, `c!` and `dup` do not need an up-to-date IP.

Therefore the IP update can be left away. When there is finally a reason for an up-to-date IP, all the updates can be combined into one addition of a larger constant.

Columns *unoptimized*³ and *c* of Fig. 4 illustrate this. In *unoptimized* every VM instruction has its own IP update; in *c*, `lit` has an IP update, because it loads its immediate operand 0 in the VM code through `ip`. The next three VM instructions `i`, `c!` and `dup` don't need an up-to-date IP, so `c` eliminates their IP updates. Finally, `(+loop)` needs an up-to-date IP in order to load its immediate operand `loophead` (the loop-back address) from the VM code, so Gforth's compiler inserts an IP update by 40 covering all VM instructions `i...(+loop)` (inclusive), the same as the sum of the corresponding IP updates in *unoptimized*.

The optimization itself is trivial: The code generator just keeps track of where IP actually points to, and when an up-to-date IP is needed, it inserts the appropriate update.

One not quite trivial part, however, is: When is an up-to-date IP needed?

Superblock end: The next VM instruction is the target of a VM jump. Because the IP may be used afterwards, we have to synchronize the IPs coming from different paths at this point, and we do it by letting it point to the first VM instruction in the new superblock.

Calls: VM instructions like `call` and `execute` (an indirect call) also require an up-to-date IP: calls save the IP (which points to the next instruction at that point) as return address, and after returning execution continues at that address. The routine invoked by `execute` finishes with a threaded-code dispatch, which needs an up-to-date IP.

Non-relocatable VM instruction: When the machine code for a VM instruction is not relocatable (typically because there is a call to a C function in the machine code), this code cannot be used in a dynamic superinstruction. Instead, this code is called through a threaded-code dispatch (which uses IP), and this code then updates the IP and makes another threaded-code dispatch for continuing execution after this VM instruction.

Immediate operands: The IP is used when accessing immediate operands of VM instructions.

One particular case of this optimization is VM instructions like Gforth's `;s` which returns from a definition. It does not need an up-to-date IP beforehand, and it branches elsewhere (returning to the caller at the VM level), so there is no need to update the IP afterwards, and we suppress such an update.

The other not quite trivial part is how to generate the machine code in the dynamic superinstruction framework for which the actual machine code that is copied around is just an opaque code snippet.

The first question is how to separate the IP update that is part of every VM instruction implementation (as part of the threaded-code dispatch) so that we can copy the machine code without the IP update.

Because the IP needs to be up-to-date in front of some VM instructions, we put the IP update at the start of each VM-instruction implementation, resulting in the following template:

```
I_inst:
    update ip
L_inst:
    non-dispatch code
K_inst:
    rest of dispatch
J_inst:
```

³ This column shows the code for a Gforth version that includes ip-update optimizations but has them disabled; this means that it uses the same register allocation and instruction schedule as the various optimized variants, which makes it easy to compare with the other columns.

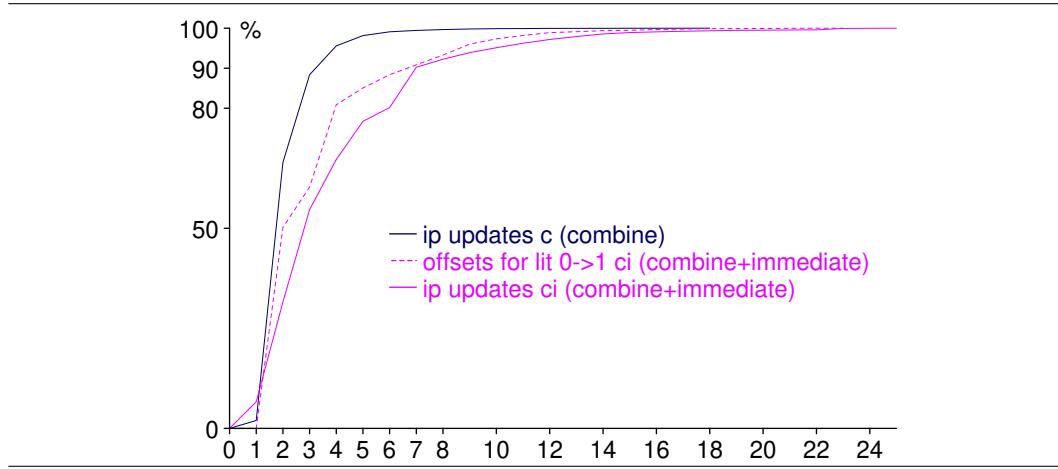

Figure 5 Proportion of IP updates or `lit 0->1` offsets with distances less than a given number of machine words in Gforth’s image (static counts).

If the resulting code is relocatable and code for the VM instruction *inst* should be generated, the code generator first generates an appropriate IP update if necessary (but normally does not use the update between `I_inst` and `L_inst` for that). Then it copies the code between `L_inst` and `K_inst`.

The code generator needs code snippets for different amounts of IP updating, because it cannot just patch a constant into a template for IP-updating (the code generator does not know anything about the internal structure of the machine code). Instead, we added code snippets for IP updates for a range of values (by 1–23 machine words) to the C source code of Gforth, and the code generator selects the right one, or (for IP updates > 23 words) generates a sequence of IP updates.

Figure 5 shows that if we have IP update code snippets for updates by 1–6 machine words, 99% of the cases statically occurring in the Gforth image can be performed with one instruction, so for Gforth limiting the IP upates to this range would be good enough as long as VM instructions with immediate operands (Section 4.3) are not optimized as well.

These data are somewhat specific to the Gforth VM, so if you want to minimize the number of IP update code snippets, you should do your own measurements. As Fig. 5 shows, a major reason for IP updates is VM instructions with immediate operands. VMs that use local-variable accesses more than Gforth and specify the local with an immediate operand will have shorter sequences between IP updates, which makes *c* alone less beneficial, but means that even fewer IP update code snippets cover nearly all occurring distances with one IP update.

4.3 Immediate operands

VM instructions with immediate operands are relatively frequent. We can eliminate this reason for requiring an up-to-date IP in most cases: We introduce additional variants of the most frequent VM instructions with immediate operands.⁴ These additional variants access their immediate operand at an offset (1–23 machine words in our experimental implementation) from where their base variant accesses the immediate operand, thus allowing the actual IP to point 1–23 machine words in front of to up-to-date IP.

⁴ `lit`, `call`, `?branch`, `lit@`, `branch`, `(loop)`, `lit-perform`, `lit+`, `does-xt`

When the code generator has to compile such a VM instruction, if the difference between the actual and the up-to-date IP is within the offset range of the variants, the code generator copies the code of the appropriate variant, and no IP update needs to be generated.

In Fig. 4, column *ci* shows how combining IP updates is enhanced by this immediate-operand optimization: The first VM instruction is `lit`, and in *c* it needs an IP update; in *ci*, a variant of `lit` that accesses its immediate operand at `ip+8` instead of `ip-8` (an offset of 2 machine words) is used, so there is no need to update IP.

However, `(+loop)` is a VM instruction that does not have such variants, so the code generator updates the IP at the start of `(+loop)`.

While it is not obvious from this example, this extension contributes a lot to the effectiveness of combining IP updates: In the Gforth image, the number of static IP updates is reduced by a factor of 5; the dynamic reduction in our benchmarks usually a factor < 2 compared to the reduction from *c* alone (see Fig. 8).

Figure 5 shows that IP updates by 1–16 machine words are sufficient for performing (without resorting to sequences of adds) 99% of the remaining IP updates statically occurring in the Gforth image. It also shows that for the most frequent VM instruction with a literal, `lit` in its stack caching variant $0 \rightarrow 1$, 99% of the IP offsets are in the range 2–13 (machine words).

The relevance of these numbers is as follows: The compilation time of the VM implementation increases with the number of VM instruction implementation variants, so we only want to add additional variants when a benefit is expected. This is particularly relevant for instructions with immediate operands, because there are a number of them, and stack caching multiplies the numbers.

E.g., we selected only 9 VM instructions with immediate operands; stack caching increases this to 15 variants, and having 24 subvariants with different offsets for each variant results in a total of 360 implementations of these 9 VM instructions. We did not use additional variants for other VM instructions with immediate operands (e.g., `(+loop)`) to avoid increasing the compilation time of the interpreter too much. For the same budget of 360 implementations, it might have been a little better to use a smaller offset range and to have offset-variants of more VM instructions.

Another way to deal with this problem is to eliminate immediate operands by introducing versions of VM instructions for specific immediate operands. E.g., Gforth has a general VM instruction `@local#` with an immediate operand *n* for pushing the value of local variable *n* onto the stack, but it also has `@local0`, which fetches the local variable 0 without needing an immediate operand. To increase the benefits from IP update optimization, we added more such variants to Gforth.⁵

These optimizations also shift the balance in VM design towards splitting one VM instruction into several, especially if it means that an unoptimized VM instruction with a literal operand can be replaced with an optimized one. E.g., we have replaced the general case of `@local# n` (i.e., cases not covered by specialized variants like `@local0`) in Gforth by the sequence `lit n; @localn` where `@localn` takes *n* from a register representing the top of the data stack (pushed there by `lit`). The resulting code is often better than for `@local#`:

⁵ In the mainline, not in the variants used for the empirical results of the present work. The benchmarks used for the present work don't use local variables much, so we don't expect that this would make a significant difference.

unsplit			split		
@local#	0 → 1	<i>addi ip,ip,88</i>	lit	0 → 1	
64		ld a5,-8(ip)	64		ld s6,80(ip)
		add a5,a5,lp	@localn	1 → 1	add a5,s6,lp
		ld s6,0(a5)			ld s6,0(a5)

In this code *lp* is a register containing Gforth's locals pointer.

4.4 Branches

When executing VM instructions, every taken VM branch that loads the target address from the VM code (such as `(+loop)` in Fig. 4) performs an IP-dependent load, and thus extends the IP dependence chain with the load latency (3–5 cycles on modern processors). Even with the *ci* optimizations, these loads can mean that IP updates are still the critical dependence path in branch-heavy code like the `siev` benchmark.

However, branches are often to nearby targets, which inspires the following idea: If the target is nearby, set the IP to the target, and then execute a branch-to-IP variant of the branch; i.e., if the branch is taken, it just needs to perform a threaded-code dispatch to branch to where the IP currently points to. If the branch is not taken, execution just continues after the branch, taking the changed IP into account.

To implement this, we have extended the code snippets for updating the IP to increment the IP by -24–23 machine words. Only one branch-to-IP variant is needed for each branch, so we implemented this additional variant for all branches where the ordinary variant just takes the target address as immediate operand; there are branches in Gforth with an additional immediate operand, and we cannot apply this optimization to those branches; fortunately, they are rarely used.

You can see an example in column *cib* in Fig. 4. Thanks to the *ci* part of the optimization, there is no IP update for the *lit*, so when Gforth's code generator reaches the `(+loop)`, the actual IP is still at the start of the loop. The code generator determines that the target is nearby, and proceeds to insert an IP update for setting IP to the branch target. Because the actual IP already points to the target location, the IP update would be by 0 bytes, and no code is generated for that, an ideal outcome; in the general case you would see one or more IP update instructions at this point. Next, the code generator appends the code of the `(+loop)` variant for the branch optimization; note that this code does not contain the instructions *ld a2,-8(ip)* and *mv ip,a2* for modifying the IP; it expects that the IP already contains the right value for taking the branch.

In our experiments, we considered the target to be nearby, if it can be reached with one IP update for conditional forward branches, or if it can be reached with three IP updates for unconditional branches and conditional backwards branches. This assumes that backwards branches are usually taken, and also takes into consideration that on the fall-through path IP update for the branch might require a followup correction.

We did this for the following reasons: For unconditional branches, three IP updates have a smaller or the same latency as a load. In case of conditional branches, a backwards branch is a loop branch and therefore probably taken.

For the conditional forward branch, a classical rule-of-thumb says that not-taken is more likely. If we use the original branch instruction instead of the branch-to-IP variant, the not-taken path may work without IP update; with the branch-to-IP variant, we incur the IP update for setting the target in either case, and in the not-taken case we may need another IP update because of an instruction with an immediate operand in the code before the branch target. One could reduce the latter cost by introducing variants of instructions with immediate operands with negative offsets, but that also has its costs.

Another idea that we have not implemented (yet) is to have IP update variants with larger granularity. E.g. have IP update variants for $-16, -15, -14, \dots, 14, 15$ machine words and then $-272, \dots, -80, -48, 47, 79, 111, \dots, 271$ machine words. This would allow to compose IP updates by $-288\dots286$ machine words by concatenating two code snippets (typically with one instruction each) using only 47 IP-update variants (the same number currently used in Gforth).

We do not present empirical data for branch distances, because they depend strongly on the programming language usage (large or small routines), the VM design (e.g, already the splitting of VM instructions discussed in Section 4.3 changes the distances), and on compiler features such as tail call optimization, inlining or jump-to-jump optimization. So you will have to do your own measurements to see the distribution of distances for your VM.

For Gforth, Fig. 9 shows speedups from *cb* over *c* or from *cib* over *ci* on most benchmarks (exceptions: brainless, cd16sim, sha512), so even the $-24\dots23$ machine-word range of IP-update variants provides some benefit for this VM.

We implemented *cib* in Gforth by inserting 864 lines and deleting 316 lines.

5 Evaluation setup

5.1 Systems

We present measurements for the versions described in Section 4. As *baseline* we use a Gforth version without any IP-update optimization work. We branched a variant from that that contains only the loop optimization, and a variant that contains all new optimizations developed in the present work, selectable individually (however, the loop optimization does not work with *cib* at the moment). The Gforth variants we measured are:

baseline The Gforth version we started from. This is the numerator in the factors shown in the speedup and instruction factor graphs. The variants/system for the specific bar is the denominator.

unoptimized The version that contains all optimizations developed in the present work, but with the optimizations turned off. While in the baseline the IP update of a VM instruction is anywhere in its code, the IP update is at the start in *unoptimized* (so the IP-update optimizations can eliminate it or replace it). We show this variant in some figures to see whether the code changes had some additional effect (and to isolate this effect, if any).

baseline+loop opt This variant adds VM instruction variants for the loop optimization (see Section 4.1) and uses these for counted loops instead of the variant that loads the branch target from the VM code.

unopt+loop opt This uses the same executable as the *unoptimized* variant, but for counted loops it uses the VM instructions that perform the loop optimization.

c: combine IP updates This uses the same executable as *unoptimized*, but enables combining IP updates (Section 4.2).

ci: c+immediate opt Like *c*, but also enables the optimization of VM instructions with immediate operands (Section 4.3).

cb: c+branch opt Like *c*, but also enables the optimization of short VM branches (Section 4.2).

cib: ci+branch opt Like *ci*, but also enables the optimization of short VM branches.

Program	Author	Description	Lines	Characteristics
bench-gc	Anton Ertl	Garbage Collector	1155	calls
brainless	David Kuehling	Chess	3648	calls, app

sha512	Marcel Hendrix	Cryptography	538	counted loops, huge body

Figure 6 Benchmark programs used.

Evaluating b alone would also have been interesting, but we left it away for time and space reasons. However, you can see the effect of b by comparing the results of c with cb and of ci with cib .

In addition, for Fig. 10 we compare with the following systems/compilers.

PFE is an interpreted Forth system written in C that uses one C function per VM instruction implementation. PFE is designed to rely on explicit register allocation (a GCC extension) for performance, but unfortunately, for AMD64 no explicit register definitions have been added yet. We use PFE-0.33.71.

Gforth threaded code only This is the baseline Gforth with the option `--no-dynamic`, which means that it falls back to using plain threaded code (Section 2.3); this option also disables stack caching.

SwiftForth, VFX Forth Two commercial Forth systems with JIT compilers. We measured SwiftForth x64-Linux 4.0.0-RC87 and VFX Forth 64 5.43.

gcc-12 Various optimization options for GCC 12.2. Manually written C code for four of the benchmarks is available and was used for generating these results. The C programs were linked statically so that the binaries could also run on machines with older glibc implementations. For gcc the results do not include the compile time (unlike for the Forth systems).

We compiled the three Gforth branches with gcc-12.2 on Debian 12 for AMD64 and with gcc-10.2 on Debian 11 on ARM A64 and statically linked them so they would run on the other platforms we used. All variants use stack caching with 0–3 registers.

5.2 Benchmarks

We use the benchmarks shown in Fig. 6. The first five are from the appbench suite of Forth benchmarks⁶; they are substantial programs and therefore are probably more representative of significant Forth applications and idiomatic Forth usage than the other benchmarks.

The next five are small benchmarks that come with Gforth: **siev** is based on the Byte Sieve by Gilbreath, but we use Bernd Paysan’s Forth version and Al Aburto’s C version.

Figure 7 Microarchitectures measured and shown in Section 6. The year shows when the CPU we measured was released. Some of the microarchitectures were released earlier in different CPUs. “P” stands for performance core, “E” for (power or die area) efficiency core.

bubble and **matrix** are based on Hennessy’s Stanford integer benchmarks (in C), and have been translated to Forth by Marty Fraeman. Four of these benchmarks are available in Forth and C in <http://www.complang.tuwien.ac.at/forth/bench.zip>.

Pentomino and sha512 were included because they exhibit unusual performance characteristics (for Forth programs): They both spend much of their time in long definitions, with many branches for pentomino, and straight-line code for sha512.

Idiomatic Forth code calls many short routines, as exhibited in the appbench programs and in fft-bench. So the results for these programs may also be representative for other programming languages where call-heavy programs are idiomatic and implementations that neither inline nor tail-call-optimize. On the other hand, the results for the programs dominated by counted loops may be more representative for programs in Algol-family languages and for systems that tail-call optimize or inline.

5.3 Hardware

We have measured a variety of different microarchitectures and show results for them. Figure 7 gives information about what the code names we use for the microarchitectures mean.

5.4 Measurements

Each benchmark was run on each system and each microarchitecture 30 times, and measured with `perf stat`, measuring the events `instructions:u`, `cycles:u`, `branch-misses:u`, `L1-dcache-load-misses:u`, and `L1-icache-load-misses:u`, where available (but we only show results based on `cycles` and `instructions` here). The median of these runs is shown.

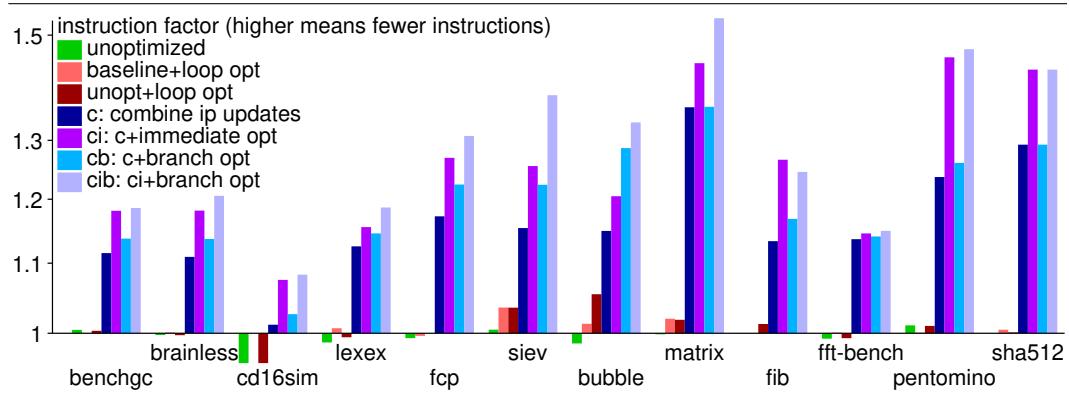

Figure 8 Reduction factor in the number of dynamically executed AMD64 instructions of various optimizations over *baseline*.

6 Results and discussion

6.1 Executed instructions

Figure 8 shows the effect of the IP update optimizations on the number of executed instructions on AMD64. For ARM A64 and RISC-V the results look similar.

For *unoptimized* and both loop optimization variants, the differences in executed instructions from the baseline are small, as expected (so small that sometimes you don't see the bar).

For most benchmarks *c* (combining IP updates) reduces the executed instructions, and *ci* (also optimize VM instructions with immediate operands) further reduces them (because more IP updates can be eliminated); adding *b* often has little effect on the number of executed instructions: in the usual case a load is replaced by an add.

On AMD64 and RISC-V where the IP updates have separate instructions, we can use the reduction in instructions to get an idea of the number of payload instructions in these benchmarks: If the unoptimized case has 1 IP update for n payload instructions, and the optimizations eliminate the proportion α of the IP updates on average, and the instruction reduction factor is f , we can compute $n = (1 - (1 - \alpha)f)/(f - 1)$. This leaves us with the problem of knowing α . However, if we assume that $\alpha = 1$, we get an upper bound for n ; e.g., for $f = 1.53$ (matrix), $n \leq 1.87$, while for $f = 1.2$ (brainless), $n \leq 5$. For matrix and siev *cib* eliminates all IP updates in the inner loop, and nearly all of the executed VM instructions of these benchmarks are in the inner loops, so α is close to 1, and n is close to 1.87 for matrix and close to 2.62 for siev.

6.2 Speedups from IP-update optimization variants

Figure 9 shows the speedups of the optimizations on Tiger Lake. As we will see, this is the microarchitecture where we typically see the best results, but Zen3 and Gracemont are not far off (Fig. 11).

On Tiger Lake, moving the IP updates to the start of each VM instruction (*unoptimized*) hurts a little on most benchmarks, but occasionally also helps.

Applying the loop optimization provides a speedup by a factor of about 2 on the three benchmarks (siev, bubble, matrix) that spend most of their time in short-to-medium length counted loops. However, for the huge loop body of sha512, the IP updates result in a

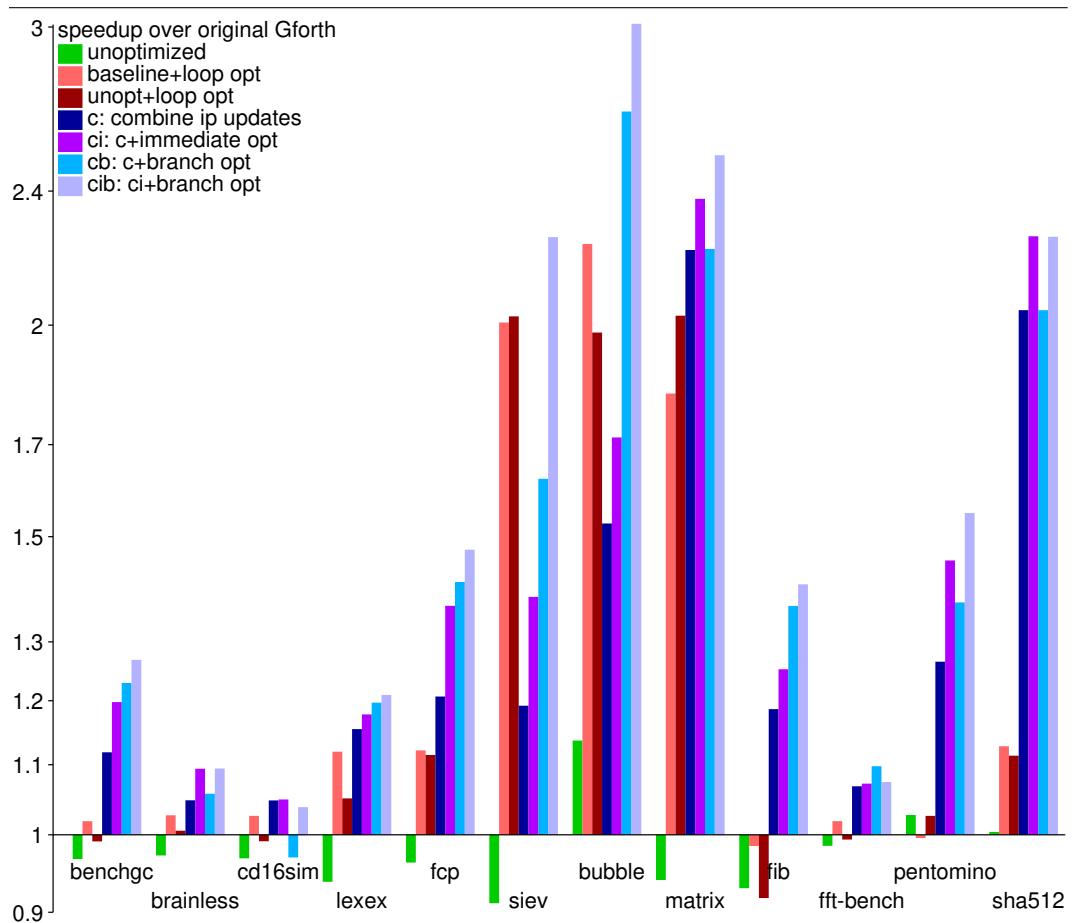

Figure 9 Speedup (reduction factor of execution cycles) on Tiger Lake of several optimizations over *baseline* (higher is better).

dependence chain that fills the processor buffers long before the loop-back branch breaks it, and the speedups of the loop optimization tend to be small. For fft-bench the inner loop is also a counted loop, but the loop body contains calls where the return breaks the IP dependence chain, so fft-bench does not benefit from the loop optimization. Pentomino hardly uses counted loops, so it cannot benefit from the loop optimization (as we implemented it). Most application benchmarks don't benefit, either.

Among the other variants, let us first look at *cib*: It dominates the loop optimization (whereas *c*, *ci* and *cb* don't, as demonstrated by *siev*). The speedups of *cib* depend on the benchmark, with *siev*, *bubble*, *matrix*, and *sha512* showing a speedup of > 2 on Tiger Lake, while the speedups on *fft-bench* and the application benchmarks are much more modest; in code where returns break the dependence chains, the main benefit of *cib* is the reduction in the number of executed instructions.

The results of *c*, *ci*, and *cb* are helpful in understanding the *cib* results: In short loops (*siev*, *bubble*) or code with many taken branches (*bubble*, *fib*) *cb* helps more than *ci*, because the loads of the branches are a large part of the latency chain in case of *ci*. By contrast, for programs with long loop bodies like *sha512*, the branch optimization does not work (it

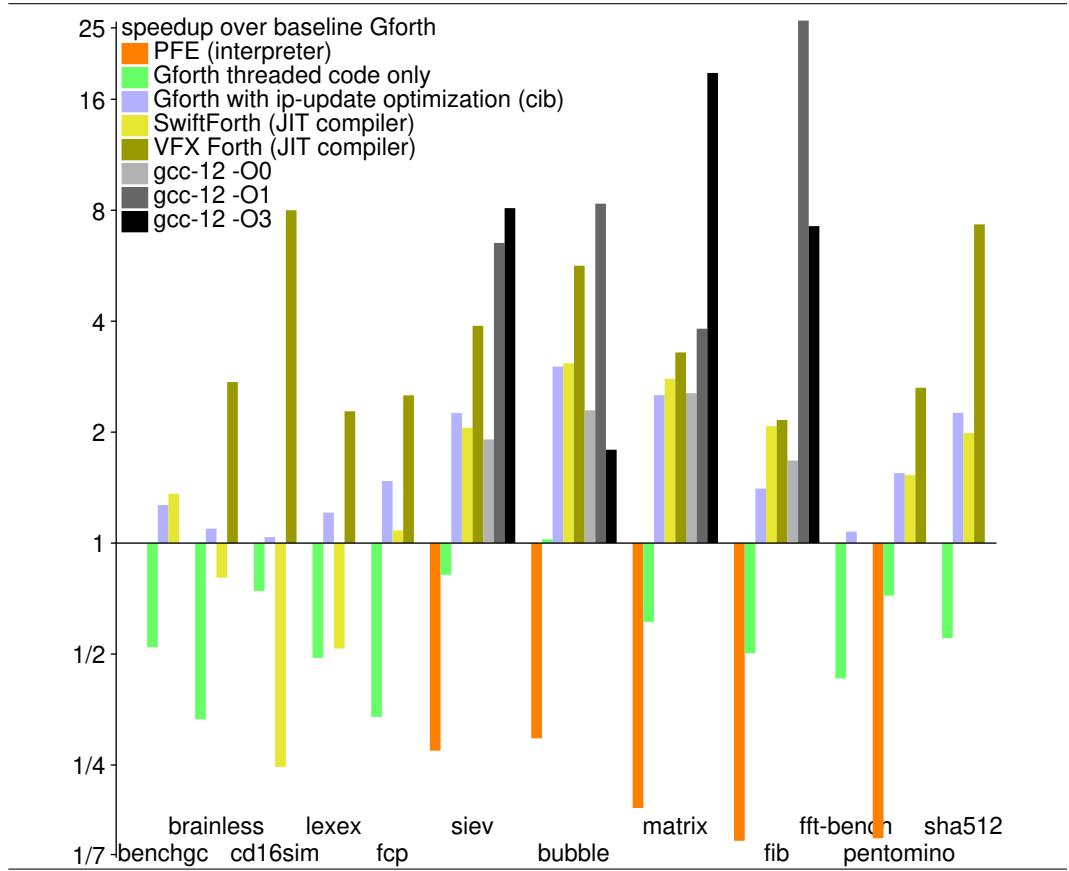

Figure 10 Speedup of several Forth systems and gcc over the Gforth baseline (higher is better), on Tiger Lake. If a benchmark does not work on a system, no bar is shown for the combination.

only covers short-distance branches) and we therefore see no difference between *ci* and *cib*. Pentomino has many branches, but many of them are long-distance branches as far as the branch optimization is concerned, so the benefit of the branch optimization is relatively small for this benchmark, and the benefit of the immediate optimization is more pronounced. Overall, for some benchmarks *ci* is better than *cb*, for others *cb* is better than *ci*; with the exception of cd16sim, both dominate *c*, and are dominated by *cib*. The difference is pretty big in some cases, so *cib* can be worth the additional implementation effort.

6.3 Comparison with other systems

Figure 10 compares a selection of the Gforth variants to several other Forth systems and to gcc. As in the other graphs, the baseline is Gforth version we started from.

Gforth with *cib* tends to be competitive with SwiftForth and with gcc -O0. SwiftForth shows some slowdowns for the application benchmarks despite executing significantly fewer instructions than Gforth; for cd16sim we identified the architectural pitfalls that it runs into⁷

⁷ I-cache/D-cache ping-pong from having instructions close to data, and `ret` mispredictions from using the return address of `call` as data instead of returning to it.

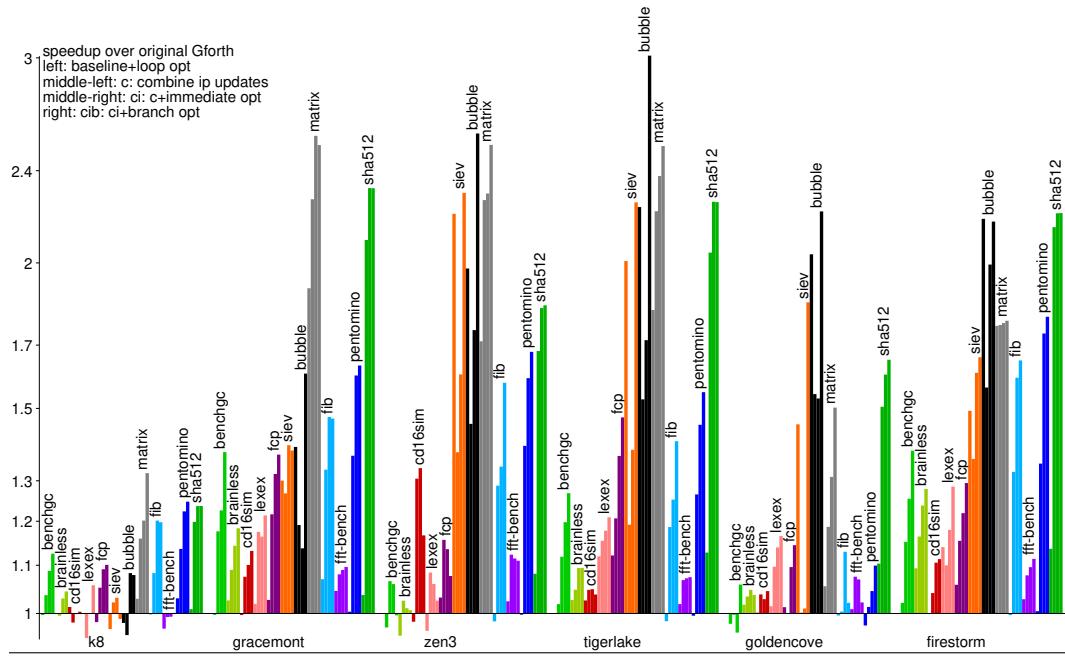

Figure 11 Speedup (reduction factor of execution cycles) of several optimizations over *baseline*; for each benchmark (colour), four bars show, from left to right: *l*, *c*, *ci*, *cib*.

and what implementation technique causes that, and reported it to the vendor. We did not investigate the SwiftForth performance on other benchmarks. The more sophisticated VFX Forth outperforms Gforth with *cib* usually by a factor of 2. Inlining of Forth definitions (performed by VFX, but not by Gforth) is particularly effective for *cd16sim*, leading to a speedup of VFX over *cib* by a factor of 8. Gforth with *cib* is a factor > 8 faster than PFE on the benchmarks where PFE works.

Gcc -O1 shows a factor 3–20 speedup over Gforth with *cib*, while for gcc -O3 the speedups over *cib* range from 0.6–8. For *bubble* the bad performance of gcc -O3 is caused by auto-vectorization, which exercises a slow hardware path for store-to-load-forwarding (due to partially overlapping accesses). We also looked at the gcc -O3 code for *fib*, but did not find an explanation for the slowdown compared to gcc -O1.

6.4 Speedups on different microarchitectures

Figure 11 shows a selection of the Gforth variants on several different microarchitectures. Most of them show similar speedups to Tiger Lake, which we discussed earlier.

One exception is Golden Cove (the P-Core of recent Intel CPUs); Golden Cove implements a hardware optimization that reduces the latency of adding a constant to zero cycles.⁸ This hardware optimization subsumes the *c* and *i* optimizations to some extent, and consequently,

⁸ <https://www.complang.tuwien.ac.at/anton/additions/>
<https://chipsandcheese.com/2021/12/21/gracemont-revenge-of-the-atom-cores/>

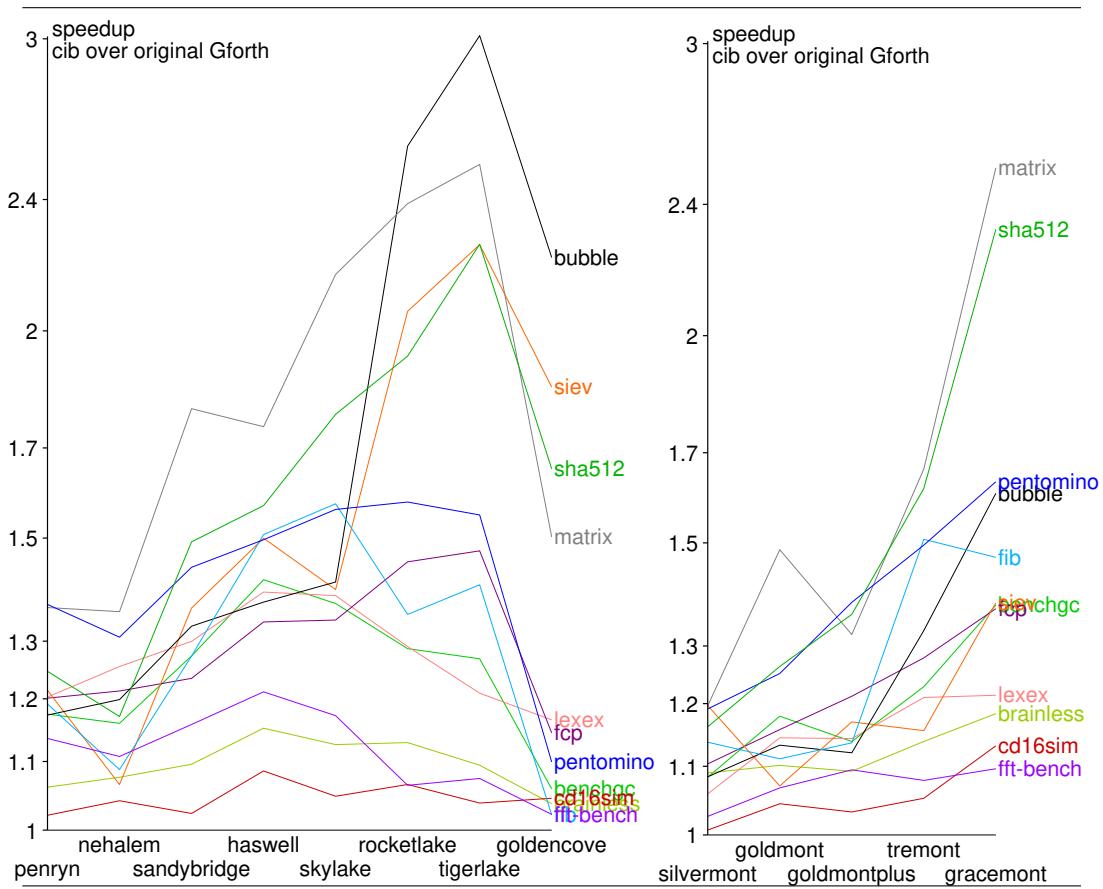

Figure 12 Speedups of *cib* over the baseline for different benchmarks on successive generations of Intel’s P-cores (left) and Intel’s E-cores (right).

we see lower speedups on Golden Cove than on Tiger Lake from these optimizations on a number of benchmarks. The benefit of the loop and branch optimization is still present, and shows up especially in code with short loops, such as *siev* and *bubble*, but the overall tendency is lower speedups from IP-update optimizations on Golden Cove. However, it still can pay off to apply IP-update optimizations, because CPUs with Golden Cove cores usually also have Gracemont E-cores, which benefit more from IP-update optimizations.

The other exception is the K8 microarchitecture (first released 2003). On the K8 the loop optimization tends to provide no benefit, and the other optimizations tend to provide benefits smaller than the reduction in instructions. This indicates that on the K8 the IP updates are not the critical path in instruction execution on any of these benchmarks.

We also looked at a variety of other CPUs (Fig. 12), and the tendency is that within a family of microarchitectures (e.g., Intel’s P-cores, with the exception of Golden Cove, as discussed above), the speedups from *cib* tend to be higher for more recent microarchitectures and lower for older microarchitectures. Along with the K8 results this explains why investigations on IP update optimizations have not been published earlier.

7 Applicability to other languages

In principle the IP-update optimizations can be applied to any VM implementation. In practice the benefit depends on how light-weight or heavy-weight the payload of your VM instructions is, on the characteristics of the executed programs.

Concerning program characteristics, loop-dominated programs benefit much more from the IP-update optimizations than call-dominated programs (see Section 6.2); but note that if you implement inlining or tail-call optimization, this can change call-dominated programs into loop-dominated programs.

Concerning the weight of VM instructions, IP update optimizations benefit VMs with lightweight instructions, such as Gforth, the OCaml interpreter, the JVM or WebAssembly. The lighter the payload is, the more these optimizations pay off.

By contrast, for a language implementation like Tcl with its heavy VM instructions, already dynamic superinstructions did not pay off; the speedup from the reduced dispatch overhead was small, and was compensated by increased I-cache misses [22].

Even if the VM instructions are middle-weight, we expect the benefit of the IP-update optimization to be small. E.g., if a VM instruction has an average payload of 10 instructions per VM instruction, the bottleneck will be in the payload (in the resource requirements, or in the latency), and the only benefit of the IP-update optimization will be to reduce the resource load, and that contribution will be relatively small (10%).

If you design a virtual machine that is lightweight enough that IP updates could be a bottleneck one day, it's a good idea to make it flexible enough make the loop optimization (Section 4.1) possible, which can be applied with relatively low effort.

8 Source code

The source code is in the git repository of Gforth:

```
git clone https://git.savannah.gnu.org/git/gforth.git
```

After that you can get the versions used for generating the data with:

```
cd gforth
# one of:
git checkout ecoop24-ip-updates-baseline #baseline
git checkout ecoop24-loopopt          #baseline+loop opt
git checkout ecoop24-ip-updates      #unopt, unopt+loop opt, c, ci, cb, cib
git checkout master #Gforth mainline
```

The main line of Gforth now uses *cib* by default.

You can find a package containing the checked out source code, binaries for AMD64, ARM A64, and RV64GC, benchmarks, and the resulting data on
<https://www.complang.tuwien.ac.at/anton/ip-updates.tar.xz>.

9 Related work

One difference between the approaches of Piumarta and Riccardi [17] and Ertl and Gregg [4] on selective inlining/dynamic superinstructions is that Piumarta and Riccardi eliminated the VM instruction slots of the VM instruction slots that are no longer needed for threaded-code dispatch. This eliminates as many IP updates as the *c* optimization, but Ertl and Gregg

expected that this “does not have much effect”. And indeed, the K8 results (similar to the hardware they used at the time) show a speedup ≤ 1.1 for c on most benchmarks (Section 6). However, on newer cores c provides speedups > 1.3 on some benchmarks, and we expect the same speedups from Piumarta and Riccardi’s instruction slot elimination. In any case, neither paper gives any performance evaluation of this issue, while the present work does and also explores additional optimizations: for loops, immediates, and branches.

kForth implements counted loops in the same way as the l optimization.⁹

There has been a significant body of work on combining VM instructions at VM-interpreter build time into (static) superinstructions [13, 18, 16, 11, 8, 3], which reduces instruction pointer updates, among other benefits. But again, none of these works have evaluated how much of the benefit is due to reducing IP updates.

More recent work on interpreter performance includes Rohou et al.’s reevaluation of the performance impact of indirect branches in the light of improvement in hardware indirect branch predictors [19], and Titzer’s work on an in-place interpreter for WebAssembly (which has been designed for translation) [21].

Larose et al. [14] argue that a sophisticated metacompiler (like RPython and Truffle) can optimize an AST interpreter written in a high-level language just as well as a VM interpreter. However, unless they completely eliminate all references to the AST or the VM code, they still have to maintain a pointer to the AST or VM code, and optimizing the IP updates is relevant.

In more ambitious earlier work [6], Ertl and Gregg eliminated the VM instruction pointer completely by eliminating all accesses to the threaded code: like the present work, it concatenates code snippets produced with gcc, but it patches constants and branch targets into the copied code snippets, making all access to the threaded code unnecessary. They found a median speedup by a factor 1.32 on a K7 (a 32-bit-only predecessor of the K8), quite an interesting contrast to the more modest speedups of the present IP-update optimization on the K8. However, this approach requires architecture-specific support for patching the constant and branch targets, whereas the present work is just as architecture-independent as dynamic superinstructions. This approach cannot fall back to threaded code, and therefore did not make it from proof-of-concept into a production feature of Gforth.

Xu and Kjolstad [24] have also used code snippets produced by a compiler and combined them, patching in constants and branch targets. The result also does not need a VM instruction pointer and its updates, and moreover, it uses the architecture’s call and return instructions (instead of jumps and indirect jumps). The price paid for this, like in Ertl and Gregg’s work [6], is architecture-specific code for patching the results.

The Maxine virtual machine [23] contains T1X, a compiler that uses snippets coming from a Java compiler, again without referencing the VM code, but also requiring architecture-specific code.

10 Conclusion

The IP-update optimization combination cib reduces the number of executed instructions by roughly a factor 1.2 on AMD64, ARM A64, and RISC-V. The effect on performance varies a lot across microarchitectures and benchmarks, between slowdowns by a factor 1.1 and speedups by a factor 3.01.

The reason for the more spectacular speedups is that, without cib , IP-update dependence chains become the critical path of execution on loop-dominated programs.

⁹ news:<us68iq\$3jsgk\$1@dont-email.me>

Another way to address this problem is the *loop optimization*: perform a loop-back branch to a location stored at loop entry, breaking the dependence chain. While the speedups from this optimization are not quite as spectacular as those from *cib*, and this optimization speeds up only some benchmarks, it is much easier to implement.

Abstract

Reverse-mode automatic differentiation (autodiff) has been popularized by deep learning, but its ability to compute gradients is also valuable for interactive use cases such as bidirectional computer-aided design, embedded physics simulations, visualizing causal inference, and more. Unfortunately, the web is ill-served by existing autodiff frameworks, which use autodiff strategies that perform poorly on dynamic scalar programs, and pull in heavy dependencies that would result in unacceptable webpage sizes. This work introduces Rose, a lightweight autodiff framework for the web using a new hybrid approach to reverse-mode autodiff, blending conventional tracing and transformation techniques in a way that uses the host language for metaprogramming while also allowing the programmer to explicitly define reusable functions that comprise a larger differentiable computation. We demonstrate the value of the Rose design by porting two differentiable physics simulations, and evaluate its performance on an optimization-based diagramming application, showing Rose outperforming the state-of-the-art in web-based autodiff by multiple orders of magnitude.

1 Introduction

The web provides a platform for interactive experiences with a uniquely low barrier to usage, because the browser obviates the need for software installation by automatically downloading JavaScript code and running it securely on the client. Industry tools like Google Slides [13] and Figma [11], as well as experimental tools like Sketch-n-Sketch [17]

 Leibniz International Proceedings in Informatics
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

and Penrose [54], leverage this platform to enable authoring of visual media. Interactive explainers like Red Blob Games [34], Bartosz Ciechanowski’s work [9], and Bret Victor’s “Explorable Explanations” [50] use the web to help people understand complicated ideas in depth, building up a causal mental model by using sliders to manipulate values and immediately see the effects.

Many of these interactions are fairly simple: often the user just drags a slider back and forth, manipulating a parameter in, for instance, a small physical simulation. But there is room for much richer interactions. An early exploration was g9.js [52], which lets the user directly drag around visual shapes, and automatically propagates those changes backward to modify the underlying parameters driving the visualization. This idea of *bidirectional editing* or *bidirectional transformations* [3] is quite powerful. Some more recent work [8] has explored bidirectional editing in computer-aided design (CAD) via *automatic differentiation (autodiff)*, a technique for efficiently computing derivatives of numerical functions. Autodiff has become popularized over the past few years by machine learning (ML) frameworks such as TensorFlow [2], PyTorch [32], and JAX [12].

Autodiff engines built for ML are focused on high throughput for functions composed of a relatively small number of operations on relatively large tensors. They use *reverse-mode* autodiff to compute the gradient of a *loss function* in an iterative loop, using a numerical optimization algorithm like stochastic gradient descent or Adam [25] to update the parameters of the ML model until the loss value is sufficiently reduced. The loss function is usually chosen to be parallelizable on a GPU. These characteristics do not generally apply to other domains, which often involve *scalar programs* [22] on which overhead between operations would dominate any tensor-level attempts at parallelism.

For scalar programs, program transformation tools are far more appropriate; examples include Tapenade [16] for Fortran and C, Zygote [21] for Julia [7], and Enzyme [29] for LLVM [26]. These tools consume and emit code that deals directly with scalars, reducing expressiveness limitations and operation-level overhead at the expense of the parallelism that ML frameworks gain by specializing to tensor operations. They typically leverage heavy modern compiler technology, using various optimization passes on the program after (and sometimes before) differentiation.

But in the interactive web setting, none of these existing points in the design space are appropriate. We are operating in an environment that is

- **dynamic:** the goal is to let the user author content or build up their mental causal model, by (either implicitly through direct manipulation or explicitly through writing code) specifying a differentiable function themselves. The autodiff engine must operate *online*, differentiating functions directly inside of the user’s browser.
- **bandwidth-constrained:** because of the no-install model described above, any JavaScript or WebAssembly code used for autodiff must be shipped over the network to the user’s browser. Heavyweight components are unacceptable because their bandwidth requirements would exacerbate page load times beyond the user’s patience.
- **latency-constrained:** the system must respond to the user’s manipulation of the differentiable function definition, at interactive speed. What we care about is not just the performance of the synthesized gradient, but the sum of that latency with the latency to synthesize the gradient in the first place; *quantitative* differences like a slow “compilation” step result in *qualitative* differences in the kinds of interaction possible.

All existing autodiff tools, including web-focused tools like TensorFlow.js [46], fall short on at least one of these constraints: they impose large constant factors for scalar programs, or depend on giant codebases that are difficult to package for the web and result in large bundles, or are too slow to use in an interactive setting, or some combination of these.

To address this gap, we present **Rose**,¹ a scalar-focused autodiff engine for the web that achieves fast compilation time and high generated code performance in a small bundle. As we will describe in Section 4, Rose is a hybrid autodiff system [22] which blends together techniques from tracing and program transformation before emitting WebAssembly [15]. Unlike prior program transformation approaches that take advantage of heavyweight compiler optimization toolchains, we produce efficient Rose IR before differentiating by using JavaScript as a *metaprogramming environment*, somewhat similar to tracing in popular ML frameworks. But unlike prior tracing approaches that expand all operations into one large graph, we reduce generated code size and thus compilation time by allowing the user to explicitly define *composable functions* that can be nested and reused. Our primary contributions are as follows:

- We establish the importance of, and constraints imposed by, the interactive web setting, and articulate how those constraints translate to system requirements for autodiff in such a setting.
- We describe a novel system design that satisfies these requirements using a careful blend of tracing with program transformation.
- We present experiments demonstrating how each component of our design is key to achieving the requirements we have laid out.
- We publish Rose, an open-source software package implementing this design for others to consume and build upon.

The rest of this paper is structured as follows. In Section 2 we give relevant general mathematical background information about autodiff; we introduce a running example that we then implement in Section 3, which discusses Rose from a user perspective. Then Section 4 discusses the novel design of Rose, focusing on the high level because that is our more interesting contribution, but also describing some low-level details of autodiff for the curious reader. Section 5 describes the experiments we conducted with results showing why this design is key to achieving our design goals. Finally we discuss related work in Section 6, and conclude with future work in Section 7.

2 Background

To illustrate the basic ideas of reverse-mode autodiff, we'll walk through the classic example of using gradients to perform linear regression via least-squares optimization. Nothing in this section is new. Almost all the content here can be found in standard textbooks for calculus, linear algebra, and convex optimization; all the rest can be found in the research literature on autodiff [39].

Suppose we have n measurements $\mathbf{y} \in \mathbb{R}^n$ of a dependent variable, each corresponding to one of n data points $\mathbf{x}_1, \dots, \mathbf{x}_n \in \mathbb{R}^m$. These data can be assembled into a matrix $\mathbf{X} \in \mathbb{R}^{n \times (m+1)}$ defined by

$$\mathbf{X} = \begin{bmatrix} 1 & \mathbf{x}_1^\top \\ \vdots & \vdots \\ 1 & \mathbf{x}_n^\top \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & \cdots & x_{1m} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n1} & \cdots & x_{nm} \end{bmatrix}.$$

We would like to predict the dependent variable as a linear function $\hat{\mathbf{y}} = \mathbf{X}\beta$ where the parameters $\beta \in \mathbb{R}^{m+1}$ are chosen to minimize the sum of squares of the errors $\varepsilon = \mathbf{y} - \hat{\mathbf{y}}$.

¹ Not to be confused with the ROSE (all caps) compiler infrastructure. [38]

That is, one would like to find an optimal solution to the optimization problem

$$\min_{\beta \in \mathbb{R}^{m+1}} f(\beta) \quad \text{where} \quad f(\beta) = \|\varepsilon\|^2 = \|\mathbf{y} - \hat{\mathbf{y}}\|^2 = \|\mathbf{y} - \mathbf{X}\beta\|^2.$$

Applying convex optimization theory here is standard so we won't belabor it, but because this particular f is differentiable, convex, and smooth, there exists a step size $\eta > 0$ such that if we start with any $\beta_0 \in \mathbb{R}^{m+1}$ and iteratively compute $\beta_{i+1} = \beta_i - \eta \nabla f(\beta_i)$, then

$$f(\beta_{i+1}) \leq f(\beta_i) \quad \forall i \in \mathbb{N}, \quad \text{and} \quad \lim_{i \rightarrow \infty} f(\beta_i) \leq f(\beta) \quad \forall \beta \in \mathbb{R}^{m+1}.$$

This is gradient descent. Crucially, it depends on being able to compute the gradient ∇f .

2.1 The vector-Jacobian product

As briefly mentioned in Section 1, reverse-mode autodiff is a general method for computing gradients, which takes in an algorithm to compute a function, and returns an algorithm to compute its gradient. Unlike other approaches to compute derivatives, the power of autodiff lies in its *compositionality* and *efficiency*: we naturally express functions by composing together smaller functions. If we possess an algorithm that computes a given function with a given time complexity, reverse-mode autodiff gives us an algorithm to compute its derivative with the same time complexity, in a way that can be directly composed with derivatives for other functions. For example, in least-squares we compose together three functions

$$\begin{array}{lll} \xi : \mathbb{R}^{m+1} \rightarrow \mathbb{R}^n & \varphi : \mathbb{R}^n \rightarrow \mathbb{R}^n & \psi : \mathbb{R}^n \rightarrow \mathbb{R} \\ \xi(\beta) = \mathbf{X}\beta & \varphi(\hat{\mathbf{y}}) = \mathbf{y} - \hat{\mathbf{y}} & \psi(\varepsilon) = \|\varepsilon\|^2 \end{array}$$

to form $f = \psi \circ \varphi \circ \xi$. Clearly, the gradient itself is insufficient to express ∇f compositionally, because ξ and φ are not scalar-valued and thus do not have gradients. So we must first have a compositional definition for the derivative.

The *Jacobian* of a function $\mathbf{f} : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is the matrix-valued function $\mathbf{J}_\mathbf{f} : \mathbb{R}^n \rightarrow \mathbb{R}^{m \times n}$ defined by

$$\mathbf{J}_\mathbf{f}(\mathbf{x}) = \begin{bmatrix} \frac{\partial \mathbf{f}}{\partial x_1} & \dots & \frac{\partial \mathbf{f}}{\partial x_n} \end{bmatrix} = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \dots & \frac{\partial f_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_m}{\partial x_1} & \dots & \frac{\partial f_m}{\partial x_n} \end{bmatrix}.$$

From this, if we fix $\mathbf{x} \in \mathbb{R}^n$ then we can define a function $\text{vjp}_\mathbf{f}^\mathbf{x} : \mathbb{R}^{1 \times m} \rightarrow \mathbb{R}^{1 \times n}$, called the *vector-Jacobian product (VJP)*, operating on row vectors called *adjoints* by $\text{vjp}_\mathbf{f}^\mathbf{x}(\hat{\mathbf{y}}) = \hat{\mathbf{y}} \mathbf{J}_\mathbf{f}(\mathbf{x})$. In the special case of $m = 1$ we can recover the gradient by $\nabla \mathbf{f}(\mathbf{x}) = \text{vjp}_\mathbf{f}^\mathbf{x}(1)^\top$, but unlike the gradient, this notion of a derivative actually composes. For instance, if we also have $\mathbf{g} : \mathbb{R}^m \rightarrow \mathbb{R}^p$, then

$$\text{vjp}_{\mathbf{g} \circ \mathbf{f}}^\mathbf{x} = \text{vjp}_\mathbf{f}^\mathbf{x} \circ \text{vjp}_\mathbf{g}^\mathbf{y} \quad \text{where} \quad \mathbf{y} = \mathbf{f}(\mathbf{x}).$$

This is the chain rule for reverse-mode autodiff, so-called because it composes $\text{vjp}_\mathbf{f}$ and $\text{vjp}_\mathbf{g}$ in the reverse order of how \mathbf{f} and \mathbf{g} themselves were originally composed. As shown here, computing the derivative $\text{vjp}_{\mathbf{g} \circ \mathbf{f}}$ depends on computing the original function \mathbf{f} itself, so in practice the term "VJP" is sometimes actually used to refer to the mapping

$$\begin{aligned} \mathbb{R}^n &\rightarrow \mathbb{R}^m \times (\mathbb{R}^{1 \times m} \rightarrow \mathbb{R}^{1 \times n}) \\ \mathbf{x} &\mapsto (\mathbf{f}(\mathbf{x}), \text{vjp}_\mathbf{f}^\mathbf{x}) \end{aligned}$$

that returns both the output of the original function – which we call a *primal* value to contrast it with the VJP's adjoints – and the VJP function.

We'll provide a more general set of composable VJPs in Sections 4.1 and 4.3, but for this example, we can derive the VJPs

$$\begin{array}{lll} \text{vjp}_\xi^\beta : \mathbb{R}^{1 \times n} \rightarrow \mathbb{R}^{1 \times (m+1)} & \text{vjp}_\varphi^{\hat{y}} : \mathbb{R}^{1 \times n} \rightarrow \mathbb{R}^{1 \times n} & \text{vjp}_\psi^\epsilon : \mathbb{R} \rightarrow \mathbb{R}^{1 \times n} \\ \text{vjp}_\xi^\beta(\ddot{\mathbf{y}}) = \ddot{\mathbf{y}} \mathbf{X} & \text{vjp}_\varphi^{\hat{y}}(\ddot{\epsilon}) = -\ddot{\epsilon} & \text{vjp}_\psi^\epsilon(\ddot{\sigma}) = 2\ddot{\sigma}\epsilon^\top \end{array}$$

of the functions we decomposed earlier. One key property to notice here is that, given algorithms to compute ξ , φ , and ψ , we immediately have algorithms to compute vjp_ξ , vjp_φ , and vjp_ψ , respectively, with the same time complexities. For instance, ξ is $O(mn)$ with naïve matrix multiplication, as is vjp_ξ . This is not too surprising, since that is also the same time complexity as directly computing and multiplying by \mathbf{J}_ξ . But the time complexity for both φ and ψ is $O(n)$, as are the formulas given above for vjp_φ and vjp_ψ , in contrast to the $O(n^2)$ cost of naïvely computing \mathbf{J}_φ or \mathbf{J}_ψ . This is because those Jacobians are *sparse*; the ability of reverse-mode autodiff to preserve time complexity in the presence of sparse Jacobians is called the *cheap gradient principle*.

In any case, from these simpler VJPs we can easily compose the gradient of f as

$$\begin{aligned} \nabla f(\beta) &= \text{vjp}_f^\beta(1)^\top = \text{vjp}_\xi^\beta(\text{vjp}_\varphi^{\hat{y}}(\text{vjp}_\psi^\epsilon(1)))^\top = (-2\epsilon^\top \mathbf{X})^\top = 2\mathbf{X}^\top(\mathbf{X}\beta - \mathbf{y}) \\ \text{where } \hat{\mathbf{y}} &= \epsilon(\beta) = \mathbf{X}\beta \quad \text{and} \quad \epsilon = \varphi(\hat{\mathbf{y}}) = \mathbf{y} - \hat{\mathbf{y}}. \end{aligned}$$

2.2 The Jacobian-vector product

We've talked about the VJP used for reverse-mode autodiff, which is the more useful for optimization, but also the more challenging to implement and specify. Rose allows users to specify custom derivatives for reasons described in Section 3.2, so to reduce user burden, we allow those custom derivatives to be defined using the simpler *Jacobian-vector product (JVP)* instead of the VJP. In Section 4.1 we'll discuss the actual program transformation used to derive the VJP from the JVP [39], but here we first lay out the mathematical groundwork.

For $\mathbf{f} : \mathbb{R}^n \rightarrow \mathbb{R}^m$, the JVP of \mathbf{f} at $\mathbf{x} \in \mathbb{R}^n$ is a function $\text{jvp}_{\mathbf{f}}^x : \mathbb{R}^n \rightarrow \mathbb{R}^m$ that operates on column vectors called *tangents* by $\text{jvp}_{\mathbf{f}}^x(\dot{\mathbf{x}}) = \mathbf{J}_{\mathbf{f}}(\mathbf{x})\dot{\mathbf{x}}$. In the special case of $n = 1$ we can recover the ordinary derivative by $\mathbf{f}'(\mathbf{x}) = \text{jvp}_{\mathbf{f}}^x(1)$. But more generally, given $\mathbf{g} : \mathbb{R}^m \rightarrow \mathbb{R}^p$ we also have a chain rule

$$\text{jvp}_{\mathbf{g} \circ \mathbf{f}}^x = \text{jvp}_{\mathbf{g}}^y \circ \text{jvp}_{\mathbf{f}}^x \quad \text{where } \mathbf{y} = \mathbf{f}(\mathbf{x})$$

that composes $\text{jvp}_{\mathbf{f}}$ and $\text{jvp}_{\mathbf{g}}$ in the same order as \mathbf{f} and \mathbf{g} , hence the name “forward-mode.” This is much simpler computationally, because while reverse-mode needed to compose together the VJPs themselves until the end when it could call them with the final adjoint value, forward-mode can simply use the mapping

$$\begin{aligned} \mathbb{R}^n \times \mathbb{R}^n &\rightarrow \mathbb{R}^m \times \mathbb{R}^m \\ (\mathbf{x}, \dot{\mathbf{x}}) &\mapsto (\mathbf{f}(\mathbf{x}), \text{jvp}_{\mathbf{f}}^x(\dot{\mathbf{x}})) \end{aligned}$$

to package together the primal and tangent values.

The judgment is somewhat subjective, but we invite the reader to decide for themselves whether the VJPs derived earlier or these JVPs

$$\begin{array}{lll} \text{jvp}_\xi^\beta : \mathbb{R}^{m+1} \rightarrow \mathbb{R}^n & \text{jvp}_\varphi^{\hat{y}} : \mathbb{R}^n \rightarrow \mathbb{R}^n & \text{jvp}_\psi^\epsilon : \mathbb{R}^n \rightarrow \mathbb{R} \\ \text{jvp}_\xi^\beta(\dot{\beta}) = \mathbf{X}\dot{\beta} & \text{jvp}_\varphi^{\hat{y}}(\dot{\hat{y}}) = -\dot{\hat{y}} & \text{jvp}_\psi^\epsilon(\dot{\epsilon}) = 2\epsilon^\top \dot{\epsilon} \end{array}$$

are closer to the original definitions of ξ , φ , and ψ .

When packaging together \mathbf{f} with $\text{jvp}_{\mathbf{f}}$, it is convenient to represent the pair $(\mathbf{x}, \dot{\mathbf{x}}) \in \mathbb{R}^n \times \mathbb{R}^n$ as the single vector $\bar{\mathbf{x}} = \mathbf{x} + \dot{\mathbf{x}}\varepsilon \in \mathbb{D}^n$, making use of the infinitesimal element ε in the *dual numbers* defined by the commutative algebra $\mathbb{D} = \{a + b\varepsilon \mid a, b \in \mathbb{R}\}$ where $\varepsilon^2 = 0$. For dual numbers $\bar{x} = x + \dot{x}\varepsilon \in \mathbb{D}$ and $\bar{y} = y + \dot{y}\varepsilon \in \mathbb{D}$, the arithmetic operations

$$\begin{aligned}\bar{x} + \bar{y} &= x + y + (\dot{x} + \dot{y})\varepsilon \\ \bar{x} - \bar{y} &= x - y + (\dot{x} - \dot{y})\varepsilon \\ \bar{x}\bar{y} &= xy + (\dot{x}y + x\dot{y})\varepsilon \\ \frac{\bar{x}}{\bar{y}} &= \frac{x}{y} + \frac{\dot{x}y - x\dot{y}}{y^2}\varepsilon \quad \text{where } y \neq 0\end{aligned}$$

correspond directly to the JVPs of the corresponding arithmetic operations on real numbers. This allows us to define what we'll call the *dual JVP*

$$\begin{aligned}\overline{\text{jvp}}_{\mathbf{f}} : \mathbb{D}^n &\rightarrow \mathbb{D}^m \\ \overline{\text{jvp}}_{\mathbf{f}}(\mathbf{x} + \dot{\mathbf{x}}\varepsilon) &= \mathbf{f}(\mathbf{x}) + \text{jvp}_{\mathbf{f}}^{\mathbf{x}}(\dot{\mathbf{x}})\varepsilon\end{aligned}$$

which operates on column vectors of dual numbers. In this framing, specifying the JVPs of our three functions

$$\begin{array}{lll}\overline{\text{jvp}}_{\xi} : \mathbb{D}^{m+1} &\rightarrow \mathbb{D}^n & \overline{\text{jvp}}_{\varphi} : \mathbb{D}^n &\rightarrow \mathbb{D}^n & \overline{\text{jvp}}_{\psi} : \mathbb{D}^n &\rightarrow \mathbb{D} \\ \overline{\text{jvp}}_{\xi}(\bar{\beta}) &= \mathbf{X}\bar{\beta} & \overline{\text{jvp}}_{\varphi}(\bar{\mathbf{y}}) &= \mathbf{y} - \bar{\mathbf{y}} & \overline{\text{jvp}}_{\psi}(\bar{\varepsilon}) &= \bar{\varepsilon}^\top \bar{\varepsilon}\end{array}$$

becomes almost trivial. So when we refer to the JVP in Rose, we're always talking about this dual JVP, not the raw JVP which would operate on real numbers.

2.3 The Hessian

While gradient descent is a first-order method that only makes use of the gradient, other optimization techniques such as Newton's method also need the *Hessian*, which turns $f : \mathbb{R}^n \rightarrow \mathbb{R}$ into a matrix-valued function $\mathbf{H}_f : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$ yielding all the second-order partial derivatives of f at a given point. The JVP and VJP can be used together to define the Hessian, which is actually just the Jacobian of the gradient; that is, $\mathbf{H}_f = \mathbf{J}_{\nabla f}$. We already know how to use the VJP of a function to compute its gradient. To compute the Jacobian, we just need to observe that the i^{th} row of the Jacobian is equal to the JVP applied to the i^{th} basis element \mathbf{e}_i of \mathbb{R}^n :

$$\mathbf{H}_f(\mathbf{x}) = [\text{jvp}_{\nabla f}^{\mathbf{x}}(\mathbf{e}_1) \quad \cdots \quad \text{jvp}_{\nabla f}^{\mathbf{x}}(\mathbf{e}_n)] \quad \text{where } \nabla f(\mathbf{x}) = \text{vjp}_{\mathbf{f}}^{\mathbf{x}}(1)^\top$$

3 Using Rose

Now that we've discussed the mathematical ideas behind Rose, in this section we'll describe how programmers use Rose to understand how it fits into the context described in Section 1. Then in Section 4 we'll describe our design that blends together tracing with program transformation to fit into this context.

Listing 1 shows a comprehensive end-to-end example using Rose to perform gradient descent to solve the linear regression problem laid out in Section 2. This entire example is JavaScript code, which makes use of Rose as a library; lines 1–2 use standard JavaScript `import` statements to pull in definitions from the Rose library. Lines 3–10 use arithmetic primitives from Rose to implement the loss function from Section 2:

$$f(\beta) = \|\mathbf{y} - \mathbf{X}\beta\|^2 = \sum_{i=1}^n \left(y_i - \beta_0 - \sum_{j=1}^m x_{ij}\beta_j \right)^2$$

```

1 import { Real, Vec, compile, fn, struct, vjp } from "rose";
2 import { add, mul, sub, sum } from "rose";
3 const sqr = (x) => mul(x, x);
4 const leastSquares = ({ m, n }) => fn([
5   x: Vec(n, Vec(m, Real)), y: Vec(n, Real),
6   b0: Real, b: Vec(m, Real),
7 ], Real, ({ x, y, b0, b }) => sum(n, (i) => {
8   const yHat = add(b0, sum(m, (j) => mul(x[i][j], b[j])));
9   return sqr(sub(y[i], yHat));
10 }));
11 const linearRegression = async ({ x, y, eta }) => {
12   const [n, m] = [y.length, x[0].length];
13   const Beta = struct({ b0: Real, b: Vec(m, Real) });
14   const f = leastSquares({ m, n });
15   const g = fn([Beta], Real, ({ b0, b }) => f({ x, y, b0, b }));
16   const h = fn([Beta], Beta, (beta) => vjp(g)(beta).grad(1));
17   const grad = await compile(h);
18   let b0 = 0; let b = Array(m).fill(0);
19   for (;;) {
20     const beta = grad({ b0, b });
21     const bb0 = b0 - eta * beta.b0;
22     const bb = b.map((bi, i) => bi - eta * beta.b[i]);
23     if (bb0 === b0 && bb.every((bi, i) => bi === b[i])) break;
24     b0 = bb0; b = bb;
25   }
26   return { b0, b };
27 };
28 console.log(await linearRegression({ eta: 1e-4,
29   x: [[10], [8], [13], [9], [11], [14], [6], [4], [12], [7], [5]],
30   y: [8.04, 6.95, 7.58, 8.81, 8.33, 9.96, 7.24, 4.26, 10.84, 4.82, 5.68],
31 }));

```

■ Listing 1 Using Rose to do linear regression on the first dataset in Anscombe’s quartet [4].

Lines 4–7 define the type of the `leastSquares` function, which takes as input $\mathbf{x}_1, \dots, \mathbf{x}_n \in \mathbb{R}^m$, as well as $\mathbf{y} \in \mathbb{R}^n$ and $\beta \in \mathbb{R}^{m+1}$, and returns a scalar. Lines 11–27 wrap around that low-level function to provide a high-level method to perform linear regression, which is then used by lines 28–31. More specifically, line 13 uses Rose to define the type of $\beta \in \mathbb{R}^{m+1}$, a vector with m elements plus an additional scalar bias. Line 14 uses the earlier `leastSquares` definition to get a Rose function for the specific $m, n \in \mathbb{N}$ needed, and line 15 partially applies that function using the provided `x` and `y` values as constants. Line 16 uses Rose’s builtin `vjp` function to take the gradient of that partially applied loss function. While mathematically it can be useful to distinguish column and row vectors, the Rose library does not, so the VJP directly produces the gradient. Line 17 compiles that gradient function to WebAssembly, producing a function that can be called with concrete standard JavaScript values instead of abstract Rose values. Finally, lines 18–26 perform gradient descent by calling the compiled `grad` function.

As demonstrated by the above examples, Rose works by letting the user define *differentiable functions* of the form `fn(paramTypes, returnType, body)`. We'll discuss this more in Section 4, but the high-level idea from a user perspective is that normal JavaScript functions like the one defined on line 3 of Listing 1 roughly correspond to what one might think of as *macros* that get expanded on demand to produce code, while Rose functions defined using `fn` correspond to traditional functions, and must be well-typed. One could define that `sqr` "macro" as a function instead as

```
const sqr = fn([Real], Real, (x) => mul(x, x));
```

where the difference is that the body of this function would then be traced only *once* immediately when it is defined, as opposed to the `sqr` "macro" defined in Listing 1 which gets expanded/traced every time it is called (which in this case happens to only be on line 9). This ability for users to choose between these two ways to define functions is a key feature in the novel design of Rose, and we will see in Section 5 that it is crucial to achieving the design goals for interactive differentiable web applications that we laid out in Section 1.

3.1 Opaque functions

The above example works well using only builtin arithmetic functions, but it's not interactive; let's look at an interactive example that takes advantage of Rose's ability to call predefined JavaScript functions and define custom derivatives for them. The Rose project website² has an interactive widget displaying the local quadratic approximation to the function $(x, y) \mapsto x^y$, allowing a user to drag the point around to see how the shape of the local quadratic approximation shifts; see the full version of this paper [10] for a screenshot. The page also allows the user to modify the mathematical expression defining the function, causing Rose to immediately re-derive the gradient and Hessian, and compile the new function to WebAssembly. For brevity we omit the code to generate the user interface, and instead focus on how one would use Rose to calculate the first and second derivatives used to visualize the quadratic approximation.

Listing 2 shows a Rose program calculating the value, gradient, and Hessian of the power function at $x = 2$ and $y = 3$. Line 2 imports a power function with a custom derivative, as we'll describe shortly. Lines 3–4 define type aliases for \mathbb{R}^2 and $\mathbb{R}^{2 \times 2}$, respectively. Rose types are simply JavaScript values, so type aliases are defined using `const` in the same way as any other JavaScript value.

Recall that the vector-Jacobian product (VJP) introduced in Section 2.1 swaps the domain and codomain from the original function. In addition, JavaScript only allows functions to return one argument. Therefore to take the VJP of a Rose function, that function must have only have one parameter. So, line 5 wraps the `pow` function to take a single vector argument rather than two scalar arguments, allowing it to be passed to Rose's `vjp` function. Just as we discussed in Section 2.1, we compute the gradient by passing in a value of 1.

Lines 7–10 then use the gradient `g` of `f` to compute its Hessian by differentiating once more. Line 8 runs the forward pass for the Hessian just once and saves all necessary intermediate values, after which line 9 runs the backward pass twice with the two basis vectors to compute the full Hessian matrix. Lines 11–14 wrap these three functions into a single function that calls all three and returns the results in a structured form. Finally, line 15 compiles that function to WebAssembly, and line 16 calls it at the point $(2, 3)$.

² <https://rosejs.dev/>

```

1 import { Real, Vec, compile, fn, vjp } from "rose";
2 import { pow } from "./pow.js";
3 const R2 = Vec(2, Real);
4 const R22 = Vec(2, R2);
5 const f = fn([R2], Real, ([x, y]) => pow(x, y));
6 const g = fn([R2], R2, (v) => vjp(f)(v).grad(1));
7 const h = fn([R2], R22, (v) => {
8   const { grad } = vjp(g)(v);
9   return [grad([1, 0]), grad([0, 1])];
10 });
11 const all = fn([Real, Real], { z: Real, g: R2, h: R22 }, (x, y) => {
12   const v = [x, y];
13   return { z: f(v), g: g(v), h: h(v) };
14 });
15 const compiled = await compile(all);
16 console.log(compiled(2, 3));

```

■ Listing 2 An example Rose program.

```

1 import { Dual, Real, add, div, mul, fn, opaque } from "rose";
2 const log = opaque([Real], Real, Math.log);
3 log.jvp = fn([Dual], Dual, ({re:x,du:dx}) => {
4   return { re: log(x), du: div(dx, x) };
5 });
6 export const pow = opaque([Real, Real], Real, Math.pow);
7 pow.jvp = fn([Dual, Dual], Dual, ({re:x,du:dx}, {re:y,du:dy}) => {
8   const z = pow(x, y);
9   const dw = add(mul(dx, div(y, x)), mul(dy, log(x)));
10  return { re: z, du: mul(dw, z) };
11 });

```

■ Listing 3 The contents of `pow.js` defining a differentiable power function.

Listing 3 shows how the `pow` function can be defined to call JavaScript's existing `Math.pow` function. Because Rose cannot see the definition of this `opaque` function, it must be given a definition for its derivative. Lines 3–5 use Rose define the logarithm's dual JVP, which is automatically transposed to produce a VJP as we'll describe in Section 4. Specifically, the signature of this function takes the original `log` function and maps every instance of the `Real` numbers to become the `Dual` numbers we introduced in Section 2.2. In this case, the returned tangent is given by the familiar rule $\frac{d}{dx} \ln x = \frac{1}{x}$ from calculus.

Similarly, lines 6–11 define the power function along with its derivative. Note that, while these two functions use `opaque` to define their bodies, they define their derivatives via `fn`, the same as the Rose functions we discussed in earlier sections. This means that only the first forward derivative needs to be provided. Since the body of this first derivative is transparent to Rose, the reverse derivative and any higher derivatives can be computed automatically.

15:10 Rose: Composable Autodiff for the Interactive Web

```
import { Dual, Real, fn, mul, neg, opaque } from "rose";
const sin = opaque([Real], Real, Math.sin);
const cos = opaque([Real], Real, Math.cos);
sin.jvp = fn([Dual], Dual, ({ re: x, du: dx }) => {
    return { re: sin(x), du: mul(dx, cos(x)) };
});
cos.jvp = fn([Dual], Dual, ({ re: x, du: dx }) => {
    return { re: cos(x), du: mul(dx, neg(sin(x))) };
});
```

■ Listing 4 Definitions of sine and cosine functions with custom derivatives.

```
import { Dual, Real, fn, opaque } from "rose";
const print = opaque([Real], Real, (x) => {
    console.log(x);
    return x;
});
print.jvp = fn([Dual], Dual, (z) => {
    print(z.re);
    return z;
});
```

■ Listing 5 A custom Rose function for print debugging.

3.2 Custom derivatives

Rose lets users define custom derivatives for functions that depend on each other, as in Listing 4. The user can also define their own functions to use with `opaque`. For instance, one might want to define a `print` function for debugging purposes as in Listing 5, but Rose cannot look inside the definition of `print`; by setting `print.jvp`, the programmer can tell Rose that the derivative of this function should similarly perform its side effect and otherwise act like the identity function.

The other situation is when Rose has automatically constructed a derivative for a function, but that derivative is unstable or otherwise exhibits some undesirable property. Rose allows the user to set a custom derivative for any function, not just `opaque` ones. For instance, by default the derivative of the square root function tends to infinity as the argument approaches zero, which causes problems if it is ever called with a zero argument. To prevent this exploding-gradient problem, we sometimes use a square root with a clamped derivative, as in Listing 6.

In all of these examples, notice that the user only needs to specify the JVP, and not the VJP; this is true even if they later decide to use any of these functions in a VJP context, because Rose uses transposition (described in Section 4.3) to automatically construct a VJP from the JVP. A large part of the value of autodiff is that it ensures that the derivative remains in sync with the primal function by construction. Similarly, if we can also assist in keeping the forward-mode and reverse-mode derivatives in sync when one of them must be manually specified, this is a significant benefit for user ergonomics and maintainability.

```

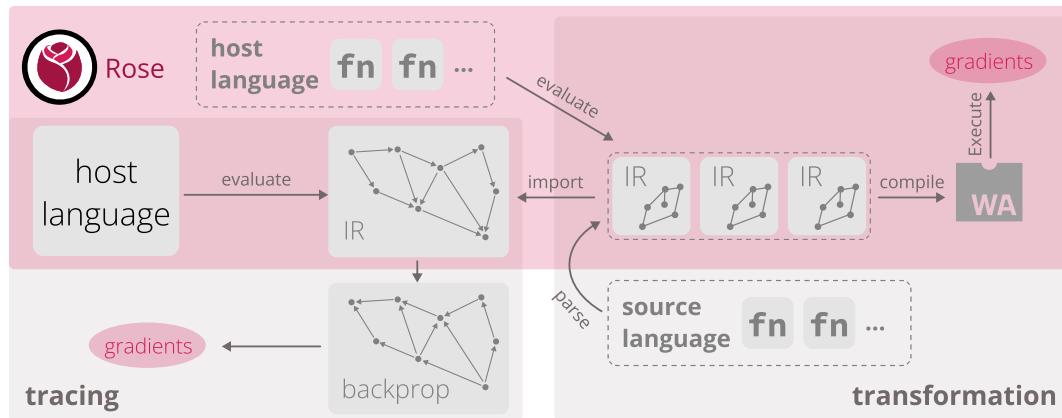

import * as rose from "rose";
import { Dual, Real, div, fn, gt, mul, select } from "rose";

const max = (x: Real, y: Real) =>
  select(gt(x, y), Real, x, y);

const sqrt = fn([Real], Real, (x) => rose.sqrt(x));
sqrt.jvp = fn([Dual], Dual, ({ re: x, du: dx }) => {
  const y = sqrt(x);
  const dy = mul(dx, div(1 / 2, max(1e-5, y)));
  return { re: y, du: dy };
});

```

■ Listing 6 A custom derivative of the square root function to avoid exploding gradients.

■ Figure 1 With **Rose**, the programmer uses the host language for *metaprogramming* like in tracing autodiff, and defines composable *functions* like in **transformation** autodiff.

4 Design

The previous section described a user experience that hints at the design of Rose; this section makes that design explicit. Autodiff frameworks typically fall into the two categories of *tracing* and *transformation*, with some *hybrid* frameworks combining aspects from the two extremes [22]. Rose chooses a specific point in the space of possible hybrid approaches, as diagrammed in Figure 1. To highlight the novel aspects of this design, we will first briefly describe tracing and transformation autodiff; then we will explain how Rose uses parts of both approaches to provide an autodiff engine for the setting described in Section 1.

In tracing autodiff, the programmer writes code in what we call the *host language* (e.g. Python [2, 32]). They use an autodiff library to construct differentiable scalars, vectors, matrices, and other tensors. Each such tensor can be thought of as a single node in a large *computation graph*. Then the programmer calls functions from that autodiff library which take in differentiable tensors and produce more differentiable tensors. Each such function call creates edges in the computation graph from the arguments to the return value. Eventually, a final differentiable scalar value is produced. The programmer calls a special procedure from the autodiff framework, passing in this final scalar value. The autodiff framework traces

backward through the computation graph in reverse topological order, attaching gradient values to every node as it goes. The programmer can then use the autodiff framework to access the gradient value attached to any node as they please.

In transformation autodiff, the programmer writes code in what we will call the *source language* (e.g. Fortran [16] or Julia [20]). The compiler frontend parses and typechecks this source language to convert it to an *intermediate representation (IR)*. This first step typically preserves most of the structure of what the programmer wrote, modulo source formatting. In particular, function definitions and calls in the source text are typically represented as a call graph in an imperative IR, or as lambda terms in a functional IR. Then, the autodiff framework takes in this IR to compute the function the programmer wrote, and emits transformed IR to compute that function along with its gradient. Crucially, this autodiff transformation preserves the asymptotic size of the original program: if the IR representation of the original program has size n , then the size of the transformed program to compute gradients is $O(n)$. Then, the compiler backend converts the IR to an executable binary like normal, which can be run to compute the desired gradients.

Figure 1 shows how Rose combines these two approaches. Like tracing, Rose lets the programmer write in a host language they are familiar with: JavaScript, in this case. And like tracing, the programmer is free to use all the features of the host language to describe the shape of their computation. But unlike tracing, and more like transformation, Rose also allows the programmer to explicitly define multiple functions that can be composed together to form a larger computation. Unlike transformation, the programmer’s code does not get directly parsed and typechecked to produce the IR; the IR is instead produced by symbolic evaluation like in tracing. But like transformation, the IR can include control flow and function calls, which get explicitly transformed by autodiff rather than being effectively erased as in tracing. And like transformation, the resulting differentiated IR is compiled to WebAssembly [15] that can then be repeatedly executed to compute gradients for the same program.

By restricting our IR to not allow recursive functions, we are able to use a compilation strategy similar to destination-passing style [40] to avoid the cost of sophisticated memory management, increasing performance. This strategy not to deallocate memory while computing gradients is justified by the way that reverse-mode autodiff generally needs to retain intermediate values, as described in Section 4.3. Importantly, while Rose IR does not allow recursion, the programmer can freely express recursive computations by using the host language for metaprogramming, as we will later discuss in Sections 4.4 and 5.4.2.

In the following subsections, we will discuss the Rose IR at a theoretical level and explain the autodiff and transposition [39] program transformations which we use to compute gradients; then in Section 4.4 we will step back again to discuss how the programmer interacts with this IR indirectly through Rose as a library. All inference rules can be found in the full version of this paper [10].

4.1 Rose intermediate representation

Figure 2 shows the abstract syntax for the Rose IR. It is a first-order functional language with non-mutable array types, and a “reference” or “accumulator” type constructor [33], written $\&\tau$. The full version of this paper [10] gives the typing rules for the Rose IR. These are all fairly standard, except for the rules for type constraints κ . We will explain these less common features of the language in the context of a specific example. Section 4.3 will demonstrate the need for accumulators in more detail, but at a high level, they arise naturally because the backward pass of reverse-mode autodiff essentially runs the program backward in

```

 $m, n \in \mathbb{Z}_{\geq 0}$ 
 $c \in \mathbb{R}$ 
 $\kappa ::= \text{Type} \mid \text{Value} \mid \text{Index}$ 
 $\tau ::= t \mid () \mid \text{Bool} \mid \text{Real} \mid n \mid \&\tau \mid [\tau]\tau \mid (\tau, \tau) \mid \langle t: \kappa \rangle(\underline{\tau}) \rightarrow \tau$ 
 $\ominus ::= \neg \mid - \mid \text{abs} \mid \text{sgn} \mid \text{ceil} \mid \text{floor} \mid \text{trunc} \mid \text{sqrt}$

2   let z: Real = 0.0 in
3   let t: (Real, [n]()) =
4     accum a from z in
5       [for i: n,
6        let x: Real = v[i] in
7        let u: () = a += x in
8        u
9      ]
10     in
11   let y: Real = fst t in
12   y

```

Listing 7 A Rose IR function to compute the sum of a vector of real numbers.

time, so reads become accumulation, and writes become reads. Having a type which restricts mutation in this way makes it easier to ensure correctness without introducing additional data dependencies that hinder compiler optimization.

Rose users write JavaScript, so prior examples have been written in JavaScript. However, in this subsection, and Sections 4.2 and 4.3, we describe the IR and so the examples are written in Rose IR. To make this distinction clear, we will format IR examples differently by putting them inside grey boxes.

Listing 7 computes the sum of a vector of real numbers. Line 1 says that the function is generic over the size of the array, where the size is represented as a type n with the `Index` constraint. The three type constraints in Rose IR are ordered as a hierarchy `Index` $<$ `Value` $<$ `Type`. Semantically, `Type` refers to any type that can be stored in a variable; the only types that don't satisfy `Type` are function types, since Rose IR is first-order. `Value` is contrasted with reference types: that is, types $\tau : \text{Type}$ satisfy the `Value` constraint unless they are of the form $\tau = \&\tau'$. Only `Value` types can be used in other type constructors, so for example, a reference cannot be stored as an element of an array. Finally, the `Index` constraint marks types that can be used as the index type of an array; the only Rose IR types that satisfy this constraint are those of the form $n \in \mathbb{N}$, which correspond to the value set $\{0, \dots, n - 1\}$.

Line 2 defines a local called `z` of type `Real` with the value `0.0`. This is used by the `accum` block on lines 4 to 10. This block serves as the scope for the variable `a` of type `&Real`, because `z` is of type `Real`. The variable `a` is in scope for lines 5 to 9 and goes out of scope on line 10. As mentioned above, this is an *accumulator* type: it represents a container holding a value of type `Real`, but that value cannot be read, and can only be accumulated. In other words, there is no operation of type `&Real → Real`. But, given a value of type `Real`, one can use the `+=` operation to accumulate into the value contained in `a`.

With this accumulator in hand, lines 5 to 9 execute. These lines are an *array constructor* with index type `n`, as shown on line 5. The value type of this array constructor is the unit type `()` so its resulting array type `[n]()` holds no data; its sole importance comes from the side effect it performs on line 7. The result is that every element of `v` gets accumulated into the value of `a`, so after this `for` block executes, the inner value of `a` is equal to the sum of all the values from `v`. Again, though, `a` cannot actually be read.

Finally, after the body of the `accum` block executes, it returns the inner value from `a`, along with the value that was returned from the `accum` block body itself, which is of type `[n]()` as mentioned before. These two items are packaged together into a tuple `t` of type `(Real, [n]())`. Because no accumulator type can be part of a tuple, this prevents `a` itself from escaping from the `accum` body, so it is guaranteed to be inaccessible after the `accum` block executes. Thus, every accumulator of type `&τ` starts as accumulate-only, and then when it goes out of scope, its value is guaranteed to be inaccessible except as a “decayed” read-only value of type `τ`. These semantics may seem unintuitive, but they turn out to perfectly model the mapping from forward-mode to reverse-mode autodiff described in Section 4.3.

That function definition was quite verbose, as it strictly adhered to the syntax from Figure 2 for clarity. In the remainder of this section, we will allow ourselves syntactic sugar to write expressions in places where the strict syntax requires variable names, with the understanding that these could be desugared by introducing intermediate `let` bindings:

```
def sum<n: Index>(v: [n]Real): Real =
  fst (accum a from 0.0 in [for i: n, a += v[i]])
```

4.2 Forward-mode autodiff

As we showed in Section 2.2, the forward-mode JVP can often be easier to specify than the reverse-mode VJP, which is why we allow the user to specify custom derivatives using the JVP as described in Section 3.2. So, we decompose reverse-mode autodiff into two parts [39], first applying forward-mode autodiff as we will describe shortly, and then applying a second transformation which we will describe in Section 4.3. The full version of this paper [10] lists inference rules for forward-mode autodiff of Rose IR. Specifically, these rules can be used to transform a function f into a function f' that computes the *dual JVP* of f , where the dual numbers are represented in Rose IR by the tuple type `Dual = (Real, Real)`.

Consider this function, which assumes that `sin : <>(Real) → Real` already exists:

```
def f(u: Real): Real =
  let v: Real = sin(u) in
  let w: Real = -v in
  w
```

We assume that we are already given a dual JVP for `sin`. For instance, if the function `cos : <>(Real) → Real` also exists, then `JVPsin : <>(Dual) → Dual` might be:

```
def jvp_sin((x, dx): Dual): Dual = (sin(x), dx * cos(x))
```

Then, by applying the inference rules we have laid out, we get $\overline{\text{jvp}}_f : \langle\rangle(\text{Dual}) \rightarrow \text{Dual}$:

```
def jvp_f(u: Dual): Dual =
  let v: Dual = jvp_sin(u) in
  let (v_re, v_du) = v in
  let w: Dual = (-v_re, -v_du) in
  w
```

All the rules for forward-mode autodiff are straightforward and quite standard, so we will not dwell on them here. Now we move on to the more complicated transformation, which maps from forward-mode autodiff to reverse-mode autodiff.

4.3 Transposition

The name “transposition” comes from the fact that the JVP and VJP can be thought of as transposes of each other, in the sense of transposing a matrix. Recall that, for $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and $x \in \mathbb{R}^n$, we have

$$\begin{aligned} \text{jvp}_f^x : \mathbb{R}^n &\rightarrow \mathbb{R}^m & \text{vjp}_f^x : \mathbb{R}^{1 \times m} &\rightarrow \mathbb{R}^{1 \times n} \\ \text{jvp}_f^x(\dot{x}) &= \mathbf{J}_f(x)\dot{x} & \text{vjp}_f^x(\ddot{y}) &= \ddot{y}\mathbf{J}_f(x) \end{aligned}$$

which both make use of the Jacobian matrix $\mathbf{J}_f(x) : \mathbb{R}^{m \times n}$. So, $\mathbf{J}_f(x)$ is the matrix of the linear transformation jvp_f^x . But then, observe that $\mathbf{J}_f(x)^\top : \mathbb{R}^{n \times m}$ is the matrix of the linear transformation

$$\begin{aligned} \mathbb{R}^m &\rightarrow \mathbb{R}^n \\ \dot{y} &\mapsto \mathbf{J}_f(x)^\top \dot{y} = (\dot{y}^\top \mathbf{J}_f(x))^\top = \text{vjp}_f^x(\dot{y}^\top)^\top. \end{aligned}$$

If we had an explicit dense representation of \mathbf{J}_f then it would be trivial to transpose. But we don’t; instead, we have an implicit, potentially sparse, representation of \mathbf{J}_f in the form of the dual JVP function $\overline{\text{jvp}}_f$. The full version of this paper [10] lists inference rules to transpose the linear derivative represented by the dual JVP in Rose IR. This transformation is considerably more complicated than the initial transformation to do forward-mode autodiff. We will walk through this transformation using the example from Section 4.2, leaving a more systematic exposition to the prior literature [33, 39] on which our approach was based.

Now, back to the example. By strictly following the inference rules we have laid out, we end up with Listing 8. As is common with program transformations like this, the resulting code is highly redundant; via a straightforward optimization pass that we omit here for brevity, we obtain the following:

```
def fwd_f((u, _): Dual): (Dual, Tape_sin) =
  let ((v, _), t) = fwd_sin((u, 0)) in
  let w = -v in
  ((w, 0), t)
def bwd_f(ddu: &Dual, (_, dw): Dual, t: Tape_sin): () =
  let dv = -dw in
  bwd_sin(ddu, (0, dv), t)
```

This example hints at the fact that the infinitesimal part is always zero for dual numbers representing primal values, and the real part is always zero for dual numbers representing adjoint values. Thus, in our actual system, in the aforementioned optimization pass we also translate the `Dual` type back to `Real`, essentially reversing our replacement of `Real` with `Dual` from Section 4.2:

15:16 Rose: Composable Autodiff for the Interactive Web

```

type Tf = (Dual, (Dual, (Tape_sin, (Real, (Real, (Dual, ()))))))
def fwd_f(u: Dual): (Dual, Tf) =
  let (v, t0) = fwd_sin(u) in
  let (v_re, v_du) = v in
  let w_re = -v_re in
  let w_du = 0 in
  let w = (w_re, v_re) in
  (w, (v, (t0, (w_re, (w_du, (w, ()))))))
def bwd_f(ddu: &Dual, dw0: Dual, t: Tf): () =
  let (v, (t0, t1)) = t in
  let (dv, ()) = accum ddv from v in (
    let v_re = fst v in
    let ddv_re = &fst ddv in
    let v_du = snd v in
    let ddv_du = &snd ddv in
    let (w_re, t2) = t1 in
    let (dw_re, ()) = accum ddw_re from w_re in (
      let (w_du, t3) = t2 in
      let (dw_du, ()) = accum ddw_du from w_du in (
        let (w, t4) = t3 in
        let (dw1, ()) = accum ddw from w in (
          ddw += dw0
        ) in
        let (dw1_re, dw1_du) = dw1 in
        ddw_re += dw1_re ;
        ddw_du += dw1_du
      ) in
      ddv_du += -dw_du
    ) in
    ()
  ) in
  bwd_sin(ddu, dv, t0)

```

■ Listing 8 Strict transposition of the function f from Section 4.2.

```

def fwd_f(u: Real): (Real, Tape_sin) =
  let (v, t) = fwd_sin(u) in
  let w = -v in
  (w, t)
def bwd_f(ddu: &Real, dw: Real, t: Tape_sin): () =
  let dv = -dw in
  bwd_sin(ddu, dv, t)

```

Thus concludes the transposition of f. Similarly we can also transpose jvp_sin:

```

def fwd_sin(x: Real): (Real, Real) =
  (sin(x), cos(x))
def bwd_sin(ddx: &Real, dy: Real, z: Tape_sin): () =
  ddx += dy * z

```

```

import { Real, add, div, fn } from "rose";
const f = (x) =>
  fn([Real], Real, (y) => div(x, y));
const g = (y) =>
  fn([Real], Real, (x) => div(x, y));
let [f0, f1, f2] = [f(5), f(7), f(5)];
fn([Real], Real, (z) => add(f1(z), f1(z)));

```

```

def f0(y: Real): Real =
  5 / y
def f1(x: Real): Real =
  7 / y
def f2(x: Real): Real =
  5 / y
def h(z: Real): Real =
  f1(z) + f1(z)

```

Figure 3 JavaScript code (left) that produces Rose IR (right) when evaluated.

4.4 Metaprogramming

We have described the right-hand side of Figure 1; now all that remains in this section is to describe the “evaluate” step on the left-hand side. Figure 3 shows a simple example of how evaluating JavaScript code produces Rose IR. In this example, we have two JavaScript functions `f` and `g`, each of which uses `fn` to construct and return a Rose function when called. We call `f` three times and never call `g`, so three Rose IR functions resulted from the single instance of `fn` in the source of `f`, and zero Rose IR functions resulted from the instance of `fn` in the source of `g`. Then, we call `fn` one more time, and in the body of that `fn`, we call `f1` twice. Note that those calls to `f1` remain in the resulting IR; Rose does not inline calls, in contrast to standard tracing autodiff frameworks.

5 Evaluation

As discussed in Section 4, Rose is characterized by three primary design choices:

- D1 Allow users to define and compose custom functions using `fn`.
- D2 Use program transformation to compile to WebAssembly.
- D3 Use tracing to allow metaprogramming in JavaScript.

These design choices are motivated by Rose’s role as a toolkit for building interactive, differentiable web applications. The dynamic bandwidth- and latency-constrained environment of web browsers poses significant constraints on the size and speed of Rose. In addition to good performance, Rose also needs to be expressive and flexible enough for the end user to build web applications in a myriad of domains.

In this section, we evaluate Rose both quantitatively and qualitatively by integrating Rose into three web-based applications for diagramming, physical simulation, and reinforcement learning (Section 5.1). In subsequent subsections, we report on Rose’s performance (Sections 5.2 and 5.3) and discuss qualitative observations of how Rose’s design choices impact its expressiveness and flexibility (Section 5.4).

5.1 Benchmark and applications

To the best of our knowledge, there are no benchmark suites for evaluating autodiff performance generally [41], let alone web-based autodiff of scalar programs. Further, measuring performance on just a benchmark would limit our ability to qualitatively evaluate the expressiveness of Rose in real-world applications. Therefore, we opted to find applications in which autodiff plays a central role, and re-implement the autodiff module or the entire application using Rose. We believe this approach gives us better ecological validity (i.e. the realism of our evaluation setup) and potentially leads to a rich source of examples. Our

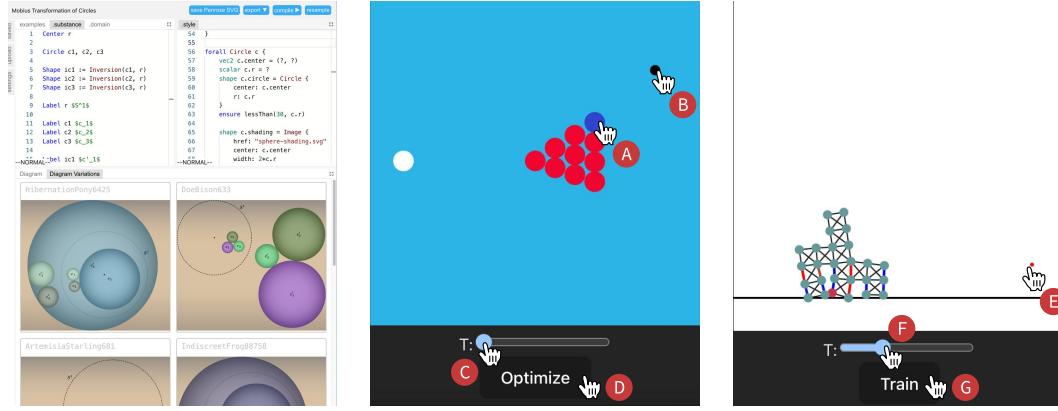

Figure 4 Three web-based applications re-implemented with Rose. **Left:** the Penrose IDE. **Middle:** billiards simulator that optimizes **D** for cue ball angle and speed such that the object ball **A** reaches the target **B**. **Right:** mass-spring robot controlled by a neural net trained **G** with a designated goal **D**. Both simulations can be replayed by dragging the sliders at any point **D** and **G**.

search resulted in two frameworks that are rich sources of applications and benchmarks: **Penrose** [54], a web-based diagramming framework; and **Taichi** [19], a Python library for high-performance parallel programming. The two frameworks also have sufficiently different settings that together they illustrate the flexibility of Rose.

Penrose allows the user to specify a diagram by constructing a custom numerical optimization problem in a DSL called Style, then runs a numerical solver to rearrange the shapes in the diagram until it finds a local minimum. Optimizing the layout of these diagrams involves defining and differentiating a wide range of mathematical operations on scalars, from simple operations like finding the distance between points to more sophisticated calculations like Minkowski addition, KL divergence, and silhouette points. The main application of Penrose is a web-based IDE (Figure 4, left), where users live-edit programs to produce layout-optimized diagrams. Importantly, the framework uses TensorFlow.js for autodiff and ships with 173 “registry” diagrams for performance testing, each of which was compiled to a unique differentiable computation. Therefore, we deemed it as a suitable target for performance comparison with TensorFlow.js, the closest baseline to which we can compare Rose’s performance. This set of registry diagrams is quite diverse, comprising a total of 97 unique Style programs which are preprocessed by the Penrose compiler frontend before being passed to Rose.

Many applications of Taichi involve differentiable programming and DiffTaichi [18] presents a few example Python applications that combines physical simulation and neural networks. We used Rose to implement and augment two such differentiable simulations from Taichi: **billiards** and **robot** (Figure 4, middle and right). The **billiards** example is a differentiable simulation of pool combination shots. The program simulates rigid body collisions between a cue ball and object balls. Leveraging the differentiability of the simulation, a gradient descent optimizer solves for the initial position and velocity of the cue ball to send a designated object ball to a target position. The **robot** example simulates a robot made of a mass-spring system, where springs are actuated to move the robot towards a goal position. A neural network controller is trained on simulator gradients to update the spring actuation magnitude over time. In both cases, the simulation is run to completion, remembering intermediate computations along the way, and then autodiff is used to run back through the simulation in reverse to compute gradients for the initial state.

All three applications were implemented using Rose’s JavaScript binding. They all run in major browsers such as Safari and Chrome. To showcase the benefits of running in the web browser, we added interactive features to the Taichi applications (Figure 4). For instance, the Taichi version of `billiards` is a command-line application that outputs a series of static images based on hard-coded parameters for the choice of the object ball and goal position. The Rose version allows the user to interactively explore the simulator by selecting the object ball (Figure 4(A)), moving the goal position (Figure 4(B)), optimizing the cue ball position (Figure 4(D)), and re-playing the simulation (Figure 4(C)).

5.2 Size

Similar to TensorFlow.js, Rose is a client-side JavaScript package that is typically bundled with the rest of a web application and delivered over the internet. To run in web browsers, Rose needs to be comparable or smaller than similar packages such as TensorFlow.js. As a baseline, a common TensorFlow.js distribution, `@tensorflow/tfjs-core` version 4.18.0 (latest at time of writing), is 479.98 kB after minification (85.88 kB after gzip). We publish Rose via the npm package `rose`,³ which is at version 0.4.10 at time of writing. The Rose WebAssembly binary size [5] is 168.51 kB (63.97 kB after gzip), and the JavaScript wrapper layer is 31.77 kB after minification (8.74 kB after gzip). For a more extreme comparison, there are projects that package heavy compiler infrastructure like LLVM to WebAssembly [47], but those produce binaries on the order of a hundred megabytes, causing unacceptable load times for end users. Another reference point is the Taichi package on PyPI, which is about 50–80 megabytes depending on the platform. It is unclear how difficult it would be to package Taichi to run in the browser using Pyodide [37], which is 6.4 megabytes and whose authors claim to be 3×–5× slower than native Python.

5.3 Performance

To compare with the TensorFlow.js baseline for execution performance, we replaced the Penrose TensorFlow.js-based autodiff engine with one written in Rose and ran both versions on the benchmark of 173 diagrams (Section 5.1). We measured the amount of time it took for each autodiff engine to perform any necessary compilation, plus the time taken by the Penrose L-BFGS [27] optimization engine to converge on each diagram. We specifically include the time it takes for Rose to do autodiff, transposition, and WebAssembly compilation, despite the fact that TensorFlow.js does not have an analogous compilation step. On the surface this puts Rose at a disadvantage, but fast compilation time is essential when constructing Rose functions dynamically in a user-facing web application, as Penrose does.

Figure 5 shows the results.⁴ The quartiles for the ratio of TensorFlow.js optimization time to Rose optimization time were 37×, 173×, and 598×. These results show that Rose provides an enormous advantage over TensorFlow.js (the state-of-the-art for autodiff on the web) for scalar programs like those found in Penrose diagrams. Because these numbers include both compile time and optimization time, the results demonstrate the end-to-end performance of Rose.

³ <https://www.npmjs.com/package/rose>

⁴ All numbers we report in this section were measured in the V8 JavaScript engine (used in both Chrome and Node.js) on a 2020 MacBook Pro with M1 chip.

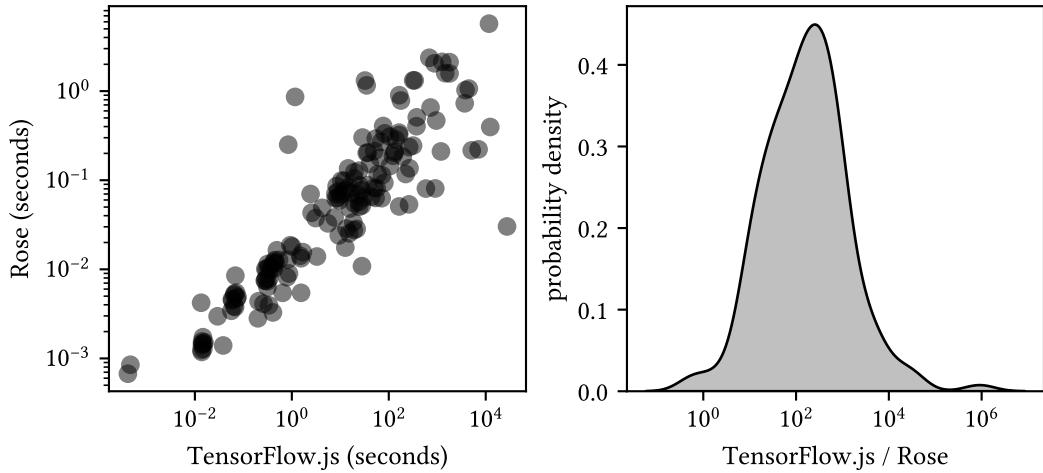

Figure 5 Left: Log-log scatterplot of Penrose diagram optimization time with TensorFlow.js versus Rose. **Right:** Log-scale kernel density estimate (KDE) plot of the optimization time of TensorFlow.js to Rose.

We omitted 10 of the 173 diagrams from our data analysis:

- **9 NaN failures:** Penrose aborts if it detects a “not-a-number” (NaN) value in the gradient as it is optimizing. This occurred in the TensorFlow.js version of Penrose for nine diagrams. *The Rose version of Penrose did not encounter NaNs for these programs.*
- **1 timeout:** For one diagram, we stopped the TensorFlow.js version of Penrose after it had run for over 24 hours. *The Rose version of Penrose took 42 milliseconds to compile and optimize this diagram.*

Tensorflow.js runs on both CPU and GPU. We used the “cpu” backend in our comparison because we found that, for scalar programs, it was faster than their GPU backend. To double-check this, we took the 88 diagrams (over half) that were quickest to run with TensorFlow.js, and also ran them with `@tensorflow/tfjs-node` and `@tensorflow/tfjs-node-gpu`, which they claim are faster than the “cpu” backend. We found that the Node backend is *79% slower* (median ratio) than the “cpu” backend, and the Node GPU backend is *75% slower* (median ratio) than the “cpu” backend. Also, those backends are unable to run in a browser, unlike the “cpu” backend, so they would be inappropriate for a direct comparison to Rose.

As we will discuss in Section 5.4.1, Rose’s ability to define separate functions in a graph (rather than just a single graph of scalar or tensor values) is crucial to producing small enough WebAssembly binaries to feed to the browser. To investigate whether WebAssembly brought significant performance gains in the first place to be worth facing that challenge, we compared against a modified version of Rose which emits JavaScript code instead of WebAssembly. This experiment gave quartile slowdowns of 10%, 49%, and 100% for optimization of Penrose diagrams, showing that WebAssembly provides a significant advantage over JavaScript as a compilation target for Rose.

For the two Taichi applications (Figure 4, middle and right), we compare the running time of training/optimizing with the Python command-line counterparts. On average (of 10 runs), Rose is on par with the native performance of the Python versions: for the default initial condition in `billiards`, Rose completed the optimization in $22.7s \pm 0.2s$ while Taichi completed it in $20.6s \pm 0.8s$; for the default condition in `robot`, Rose finished 100 iterations of learning in $32.1s \pm 0.2s$ while Taichi took $31.3s \pm 1.1s$.

In the Penrose IDE (Figure 4, left), the main interaction that will trigger differentiation is compiling the DSL to diagrams. As reported in the previous section, Rose-based Penrose is significantly faster than the TensorFlow.js version, often leading to visible reduction in diagram layout optimization time in the user interface.

5.4 Qualitative observations

Our implementation effort to port both Penrose and Taichi applications to Rose spanned thousands of lines of code, including replacing the Penrose autodiff engine and function library and rewriting both `billiards` and `robot` for scratch. In this process, we have written a wide variety of differentiable programs using Rose, and had a chance to observe how Rose’s main design choices (D1, D2, D3) impact the way programs are written. In this section, we report on our qualitative observations using Rose in these real-world settings, highlighting how these design choices interact with each other to form a coherent system.

5.4.1 Writing scalar programs as composable functions

The original versions of Penrose, `billiards`, and `robot` are naturally written as scalar programs. In Penrose, `bboxCircle` (line 10 of Listing 9) computes the bounding box by performing arithmetic on scalar values for the center and radius of a circle. In Taichi, both `billiards` and `robot` involve hand-crafted scalar programs for differentiable simulations. For instance, `apply_spring_force` (Figure 6) loops through individual springs in the robot, computing the force on the spring based on scalar-valued parameters, and scatter forces to end points of springs.

Because Rose is designed for writing scalar programs, translating both Penrose and Taichi source programs to Rose is straightforward and largely preserves the structures of the programs. For instance, when translating the Python programs from Taichi into TypeScript and Rose, as shown in Figure 6, Taichi kernels can be translated one-to-one to Rose functions.

Reflecting on the design choices, the combination of transformation to WebAssembly (D2) and the basic building block of composable functions (D1) gives the user both performance gains and an ergonomic programming interface. In the case of Taichi, the Rose abstraction of `fn` is not only useful for one-to-one translation from Taichi, but also necessary for running the simulator in browsers. Major WebAssembly engines have limits on WebAssembly binary size and on the number of local variables in each function. While it is possible to encapsulate much of the simulation code of `billiards` and `robot` in bigger JavaScript functions, the compiled size and local counts of these functions would quickly exceed these limits and would not run in the browser. Therefore, segmenting the source into functional units of `fns` effectively reduces the size of emitted WebAssembly functions and modules, avoiding these errors and reducing compile times.

5.4.2 Metaprogramming and function dynamism

The Rose IR is designed to be performant and easy to compile to WebAssembly (D2) and therefore has limited expressiveness (Section 4). Metaprogramming using JavaScript enables the user to dynamically generate complex computation graphs that are impossible to specify with the Rose IR alone (D3). For instance, the `bboxGroup` function in Listing 9 computes the bounding box of a `Group` in Penrose, a recursive collection of shapes. For non-collection shape types such as `Circle`, we ported the TensorFlow.js implementation to Rose easily, e.g. `bboxCircle`. However, `bboxGroup` needs to recurse over the `Group` data structure to find out

```

@ti.kernel
def apply_spring_force(t: ti.i32):
    for i in range(n_springs):
        a = spring_anchor_a[i]
        b = spring_anchor_b[i]
        pos_a = x[t, a]
        pos_b = x[t, b]
        dist = pos_a - pos_b
        length = dist.norm() + 1e-4
        target_length = spring_length[i] *
            (1.0 + spring_actuation[i] * act[t, i])
        impulse = dt * (length - target_length) *
            spring_stiffness[i] / length * dist
        ti.atomic_add(v_inc[t + 1, a], -impulse)
        ti.atomic_add(v_inc[t + 1, b], impulse)

    const apply_spring_force = fn(
        [Objects, Act], Objects, (x, act) => {
            const v_inc = [];
            for (let i = 0; i < n_objects; i++)
                v_inc.push([0, 0]);
            for (let i = 0; i < n_springs; i++) {
                const spring = robot.springs[i];
                const a = spring.object1;
                const b = spring.object2;
                const pos_a = x[a];
                const pos_b = x[b];
                const dist = vsub2(pos_a, pos_b);
                const length = add(norm(dist), 1e-4);
                const target_length = mul(spring.length,
                    add(1, mul(act[i], spring.actuation)));
                const impulse =
                    vmul(div(mul(dt * spring.stiffness,
                        sub(length, target_length)),
                        length),
                        dist);
                v_inc[a] = vsub2(v_inc[a], impulse);
                v_inc[b] = vadd2(v_inc[b], impulse);
            }
            return v_inc;
        });

```

Figure 6 A function that applies spring actuation on the mass-spring robot model in the `robot` example, written in Taichi (**Left**) and Rose (**Right**). The translation from Taichi to Rose is straightforward.

the bounding boxes of individual shapes before aggregating them into the final bounding box. This requires conditional dispatch of (1) Rose functions based on a discrete tag (`shape.kind`) and (2) recursive calls to `bboxGroup` to handle nested groups.

Figure 7 shows an example of calling `bboxGroup` on nested groups of shapes. The diagram in Figure 7 (left) has 1 group containing the whole diagram, and 3 subgroups of molecules that contain shapes such as `Text` and `Circle`. Figure 7 shows how `bboxGroup` uses JavaScript language features to compose Rose functions into a computation graph, denoting JavaScript constructs in gray and Rose functions in red. First, for each member shape, we `switch` on `shape.kind` to determine whether to (a) call individual Rose bounding box functions like `bboxCircle` or (b) recurse to call `bboxGroup`. Then, after all the child bounding boxes are computed, we use JavaScript `map` and `reduce` to aggregate via Rose `min` and `max` functions.

In the case of Penrose, metaprogramming actually helped us reduce the lines of code to refactor, because many plain JavaScript functions can stay the same and we only had to refactor functions that involve actual computation. We also speculate that by reducing the size of Rose-specific constructs, new users can learn a smaller API easier and experience a smoother learning curve.

6 Related work

Autodiff first started being seriously studied a few decades ago [48], with Griewank and Walther’s book [14] consolidating research on the topic up until its publication. Some tools were developed, such as Tapenade [16] which operates over C and Fortran. The machine learning community developed an interest in autodiff over the past decade, resulting in popular tools including TensorFlow [2], PyTorch [32], and JAX [12] as mentioned in Section 1. JAX is particularly interesting because in a way it blends together tracing and transformation like we do here, but unlike Rose, JAX is not scalar-friendly and does not allow the programmer to explicitly define functions to serve as boundaries for tracing. Other autodiff systems include Zygote [21] for Julia, and Enzyme [29, 30, 31] for LLVM IR [26]. For graphics programming, $\text{A}\delta$ [53] and Dr.Jit [22] can be used to differentiate shaders.

```

1  const bboxGroup = (shapes) => {
2    const bboxes = shapes.map(bbox);
3    const left = bboxes.map((b) => b.left).reduce(min);
4    const right = bboxes.map((b) => b.right).reduce(max);
5    const bottom = bboxes.map((b) => b.bottom).reduce(min);
6    const top = bboxes.map((b) => b.top).reduce(max);
7    return { left, right, bottom, top };
8  };
9
10 const bboxCircle = fn([Circle], Rectangle,
11   ({ center: [x, y], radius: r }) => {
12     const left = sub(x, r);
13     const right = add(x, r);
14     const bottom = sub(y, r);
15     const top = add(y, r);
16     return { left, right, bottom, top };
17   },
18 );
19
20 const bbox = (shape) => {
21   switch (shape.kind) {
22     case "Rectangle": return shape.value;
23     case "Circle": return bboxCircle(shape.value);
24     case "Group": return bboxGroup(shape.value);
25   }
26 };

```

Listing 9 Examples of JavaScript metaprogramming to construct Rose functions for recursive data structures.

The programming languages community has also taken an interest in autodiff [36], producing proofs of correctness [1], program transformations for SSA [20] and CPS [51], and more recently, reformulations of reverse-mode autodiff in terms of dual numbers [44], as well as a new autodiff formulation called CHAD [49, 45]. Some work also attempts to bridge the gap between programming language theory and the machine learning domain by facilitating automatic parallelization [6, 33]. The latter work also resulted in a formalization of function transposition [39] which directly inspired the low-level design of autodiff in Rose.

Rose supports higher-order derivatives because its core IR is closed under differentiation and transposition. A more sophisticated approach we don't explore here would be derivative towers [23, 35], sometimes called “Taylor towers” because they use Taylor expansions instead of the chain rule. We would be interested to see how derivative towers can be combined with our approach in future work, while avoiding the pitfalls of perturbation confusion [42, 28]. Another optimization that becomes crucial when scaling up autodiff is checkpointing, which cuts down drastically on memory requirements; for instance, while the semantics of Rose can in general result in keeping around arbitrarily many intermediate results, a recursive “divide-and-conquer” checkpointing scheme [43] reduces the memory impact of reverse-mode autodiff to a logarithmic factor; the cost, though, is that the asymptotic running time would also suffer a logarithmic factor.

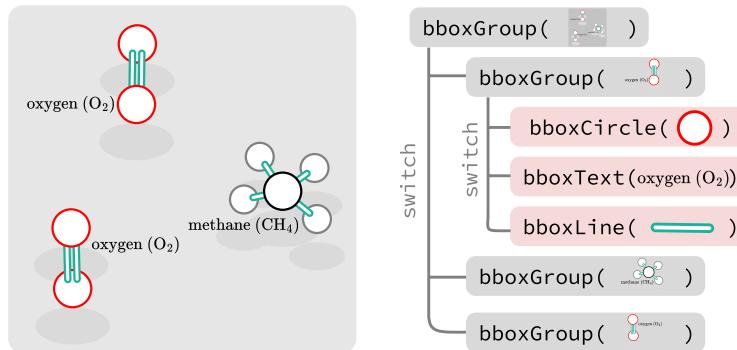

Figure 7 In Penrose, we used JavaScript to programmatically generate Rose functions. **Left:** a figure comprised of a top-level group containing all molecules and sub-groups for each molecule. **Right:** the `bboxGroup` function conditionally generates Rose functions or recursively calls itself based on the shape type.

7 Conclusion and future work

This paper introduced Rose, an embedded domain-specific language for automatic differentiation of interactive programs on the web, which blends together the two primary autodiff techniques of tracing and transformation. Currently Rose targets WebAssembly, which runs on the CPU; as we showed in Section 5.3, this already provides an enormous performance advantage for scalar programs when compared to the state-of-the-art for autodiff on the web. In future work, we would also like to pursue further performance gains by implementing a backend that targets WebGPU [24]. We have already laid the groundwork for this by drawing inspiration for the Rose IR from Dex [33] to be friendly to automatic parallelization, such as the `for` construct and accumulate-only reference types. In general, we plan to continue this line of work to open up new modes of differentiable interactivity.

Mover Logic: A Concurrent Program Logic for Reduction and Rely-Guarantee Reasoning

Cormac Flanagan 

University of California, Santa Cruz, CA, USA

Stephen N. Freund  

Williams College, Williamstown, MA, USA

Abstract

Rely-guarantee (RG) logic uses thread interference specifications (relies and guarantees) to reason about the correctness of multithreaded software. Unfortunately, RG logic requires each function postcondition to be “stabilized” or specialized to the behavior of other threads, making it difficult to write function specifications that are reusable at multiple call sites.

This paper presents mover logic, which extends RG logic to address this problem via the notion of atomic functions. Atomic functions behave as if they execute serially without interference from concurrent threads, and so they can be assigned more general and reusable specifications that avoid the stabilization requirement of RG logic. Several practical verifiers (Calvin-R, QED, CIVL, Armada, Anchor, etc.) have demonstrated the modularity benefits of atomic function specifications. However, the complexity of these systems and their correctness proofs makes it challenging to understand and extend these systems. Mover logic formalizes the central ideas of reduction in a declarative program logic that provides a foundation for future work in this area.

2012 ACM Subject Classification Theory of computation → Program verification; Theory of computation → Program specifications; Software and its engineering → Concurrent programming languages; Software and its engineering → Formal software verification

1 Introduction

Verifying that a multithreaded software system behaves correctly for all possible inputs and thread interleavings is a critically important problem in computer science. To verify large systems, verification techniques must employ *modular reasoning* in which each function’s implementation is verified with respect to its specification. In a multithreaded system, writing precise and reusable function specifications is a rather difficult challenge, since concurrent threads can observe and change the state of a function call not just in its initial and final states, but also at any intermediate states during the function’s execution. Thus, function specifications must describe not just the function’s precondition and postcondition, but also how the function may influence and be influenced by other concurrent threads. To address this problem, Rely-Guarantee (RG) logic [33] uses function specifications that include:

- a *guarantee* G describing how each step of the function may update shared state, and
- a *rely assumption* R describing the behavior of interleaved steps of other threads. The rely assumption might, for example, specify that interleaved steps preserve a data invariant.

Under RG logic, however, a function’s postcondition must summarize not only the behavior the function itself but also the behavior of interleaved steps of other threads [56]. Consequently, RG function specifications are often specialized to the rely assumption and data invariants of a particular client, limiting reuse of those function specifications in other clients, as we illustrate in Section 2.

Lipton’s theory of reduction [41] provides a promising approach to address this problem. It uses a commuting argument to show that certain functions are *atomic* and behave as if they execute serially (without interleaved steps of other threads). Consequently, atomic functions do not require interleaved rely assumptions, and they can be precisely specified using preconditions and postconditions that are independent of any specific client.

Reduction has been widely adopted in a variety of software validation tools, including dynamic analyses [17, 54, 55, 9], type systems [50, 24, 23, 22], and other tools [6, 61, 62, 60]. Over the past two decades, software verifiers based on reduction (*e.g.*, Calvin-R [25], QED [15], CIVL [30, 38], Armada [42], and Anchor [19]) have demonstrated the utility of atomic function specifications in verifying sophisticated concurrent code. To date, however, reduction-based verifiers have not been based on an underlying program logic, such as RG logic. Instead, their soundness arguments are typically based on monolithic proofs whose complexity inhibits further research. To address this complexity barrier, we present mover logic, which extends RG logic to support atomic function specifications via reduction-based reasoning.

In mover logic, thread interference points are documented with `yield` annotations that have no run-time effect. Mover logic verifies that every sequence of operations between two yield points is reducible and hence amenable to sequential reasoning. In order to verify reducibility, mover logic uses synchronization specifications describing both when each thread can access each shared location and how those accesses commute with concurrent accesses of other threads. In contrast to RG logics that must stabilize all state predicates under the rely assumption, mover logic only needs to stabilize predicates at `yield` points. Atomic functions have no yield points and can thus be specified with traditional pre- and postconditions. Moreover, atomic function specifications need not include a client-specific rely assumption that would limit reuse in other clients that have different rely assumptions or data invariants.

Mover logic is a declarative program logic (similar in style to Hoare Logic and RG Logic) that helps explain and justify many subtle aspects of reduction-based verification, including:

- what code blocks are reducible;
- where `yield` annotations are required;
- which functions are atomic;
- what atomic and non-atomic function specifications mean;
- what reasoning is performed by the verifier;
- why this reasoning is sound; and
- which programs are verifiable or not verifiable, and why.

Mover logic simplifies the soundness proof for any specific verifier, because the proof now must only show that the verifier follows the rules of mover logic.

The presentation of our results proceeds as follows.

- Section 2 illustrates the specification entanglement problem of RG logic and shows how mover logic avoids this problem.
- Section 3 reviews Lipton’s theory of reduction.
- Sections 4 and 5 present an overview of mover logic and additional examples.
- Section 6 formalizes a core multithreaded language.
- Section 7 and 8 present mover logic for this language.
- Sections 9 and 10 discuss related work and summarize our contributions.

For clarity of exposition, our presentation of mover logic targets an idealized multithreaded language that captures the essential complexities of multithreaded function specifications. Extending the logic to more complex languages remains an important topic for future work.

2 Limitations of Rely-Guarantee Logic

We motivate the need for mover logic via the example code in Figure 1 (left). That code consists of:

1. A **counter library** that contains the function `add(n)` that adds `n` to the variable `x` and returns the new value of `x`. The initial value of variable `x` is 0, and it is protected by lock `m`, whose value is either the thread identifier `tid` of the thread holding the lock or 0 if unheld. The lock is initially unheld.
2. A **first client** that creates two threads, and each thread calls `add(2)` multiple times before asserting that `x` is even.

This program verifies under RG logic based on the invariant that `x` is always even. This `even(x)` invariant is a precondition and postcondition for both `add()` and `client()`¹:

```
requires even(x)
ensures even(x)
```

In addition, each step by each thread in the program is guaranteed to preserve this invariant. As a result, each thread can rely on other threads to preserve the invariant:

```
relies even(x)
guarantees even(x)
```

These RG specifications are sufficient to verify that the program does not go wrong by failing the `even(u)` assertion in `client()`, but unfortunately the specification for `add()` is tightly-coupled, or *entangled*, with the `even(x)` data invariant from this particular client. A different client would necessitate revising and re-verifying the counter library, which makes modular verification more challenging and less scalable. For example, the second client in Figure 1 (right) enforces the data invariant `x >= 0`, but it cannot be verified with the `add()` specification entangled with the first client. Others have noted this limitation as well (see, for example, [14, 56]).

2.1 Disentangling RG Specifications: First Attempt

The goal of this paper is to support specifications for library functions like `add()` that are *not* specialized to one particular client. As a first attempt to achieve that goal, the code in Figure 2 (left) uses the following natural postconditions for `add()`, where `\old(x)` and `x` refer to the value of `x` upon function entry and exit, respectively:

```
ensures x == \old(x) + n
ensures \result == x
```

¹ Frame conditions, which specify the locations a function may read or modify, also play a key role in modular function specifications, but we do not consider them in this paper due to lack of space. Extending mover logic with frame conditions, perhaps using ideas from separation logic [47, 49], remains an important topic for future work.

Entangled Rely-Guarantee Specification

Counter Library

```
int x;
lock m;
```

relies even(x)
guarantees even(x)
requires even(x)
requires even(n)
ensures even(x)
ensures even(\result)

```
int add(int n) {
    acquire(m);
    int r = x;
    r = r + n;
    x = r;
    release(m);
    return r;
}
```

Verification Error

Library specification is not general enough to verify Second Client

Entangled Specification
 Library depends on
 Client's even(x) invariant

First Client

```
void main() {
    fork { client(); }
    fork { client(); }
}
```

relies even(x)
guarantees even(x)
requires even(x)
ensures even(x)

```
void client() {
    add(2);
    int u = add(2);
    assert even(u);
}
```

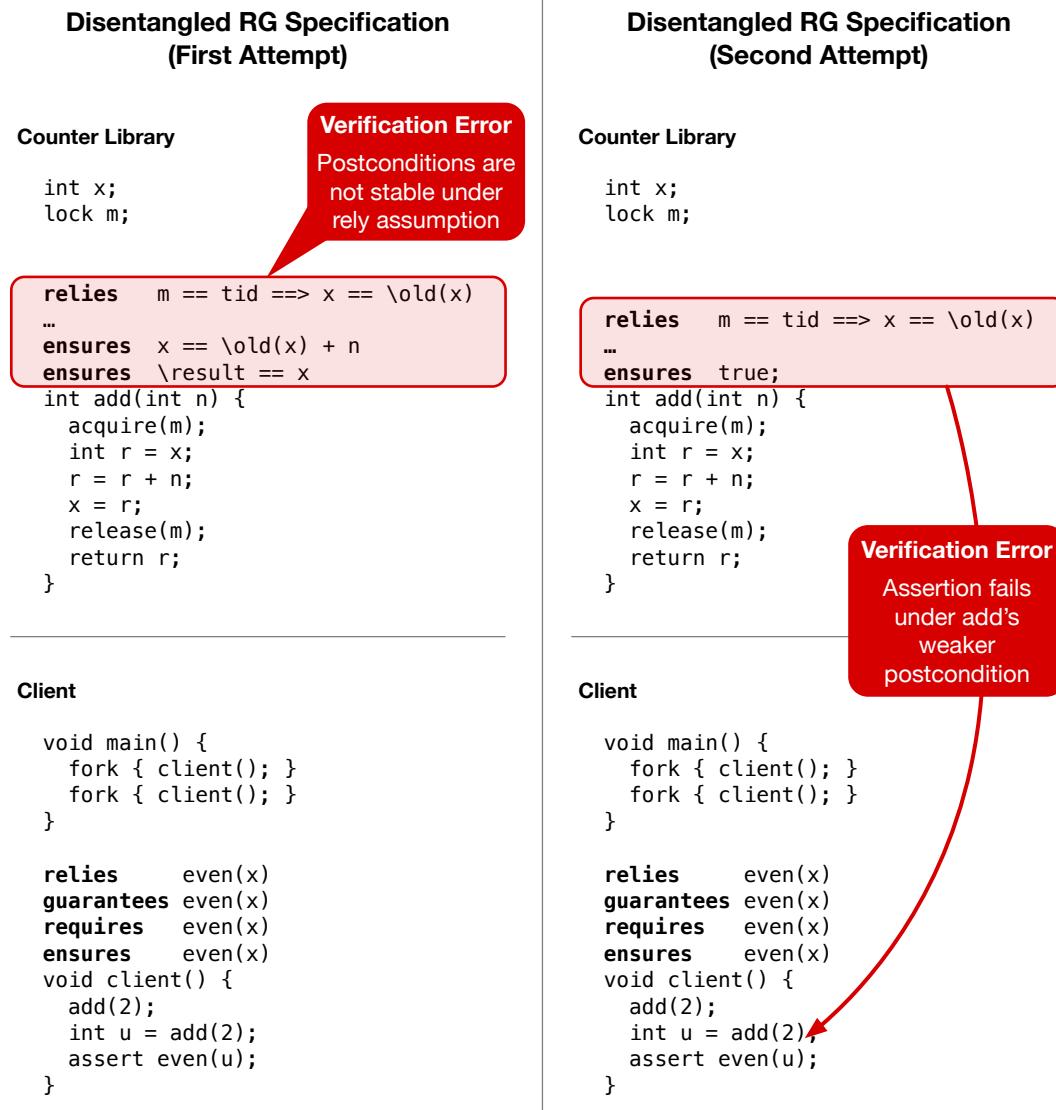

Second Client

```
void main() {
    fork { client(); }
    fork { client(); }
}
```

relies x >= 0
guarantees x >= 0
requires x >= 0
ensures x >= 0

```
void client() {
    add(2);
    int u = add(3);
    assert u >= 0;
}
```

Figure 1 Our idealized running example is an `add(n)` library function that atomically increases shared variable `x` by `n`. (**Left**) A rely-guarantee specification. The client's data invariant `even(x)` becomes entangled in the library specification. (**Right**) A second client that cannot be verified because the specification is insufficiently general.

■ **Figure 2 (Left)** An attempt to disentangle the library specification from the client that does not meet RG stability requirements. **(Right)** Another attempt that meets stability requirements but fails to verify the client.

In addition, if `add()` has no knowledge of its client, it must assume that other client threads could call `add()` with arbitrary arguments at any time, and so the natural rely assumption is that other threads may update `x` whenever the lock `m` is not held by the current thread. That assumption is most easily expressed as its contra-positive (where `tid` is the identifier of the current thread and lock `m` is held by that thread when `m == tid`):

```
relies m == tid ==> x == \old(x)
```

Here, `\old(x)` and `x` refer to the value of `x` before and after an interleaved action of another thread, respectively.

To account for interleaved steps of other threads, a central requirement of RG logic is that all store predicates (*e.g.* preconditions, postconditions, and invariants) used to reason about program behavior must be *stable* under this rely assumption R . This means that interleaved R -steps from other threads must not invalidate those predicates. In the case of `add` in Figure 2 (left), the postcondition `x == \old(x) + n && \result == x` is not stable under the rely assumption R , reflecting that `x` could be concurrently modified after the lock is released but before `add()` returns. Thus, Figure 2 (left) does not verify under RG logic.

2.2 Disentangling RG Specifications: Second Attempt

To ensure stability we must weaken the `add()` function's postcondition to be stable under the rely assumption, as shown in Figure 2 (right). Unfortunately, the resulting stable post condition is simply `true`, which no longer guarantees anything about the value of `x` and is too weak to verify the client.

2.3 Broken Invariants and Bidirectional Entanglement

As a more challenging example, consider the `add()` library variant in Figure 3 (left) that temporarily breaks the `even(x)` invariant while holding the lock. In this case, the invariant holds only when lock `m` is free:

```
m == 0 ==> even(x)
```

Stores at the program points in which the invariant is broken are not intended to be observable by clients. However, the revised RG specifications for `add()` and the client must now be based on this conditional invariant, resulting in two problems. First, the library specification is again specialized to the client's `even(x)` invariant. Second, the library's internal locking discipline leaks into the client's specification, limiting our ability to modify the library code without breaking clients. This example demonstrates that RG reasoning may force us to lose modularity between client and library.

3 Review of Lipton's Theory of Reduction

Our solution to this specification problem employs Lipton's theory of reduction [41], which classifies how steps of one thread commute with concurrent steps of another thread.

- A step is a *right-mover* (R) if it commutes “to the right” of any subsequent step by a different thread, in that performing the steps in the opposite order does not change the final store. A lock acquire is a right-mover because any subsequent step from another thread cannot modify that lock.

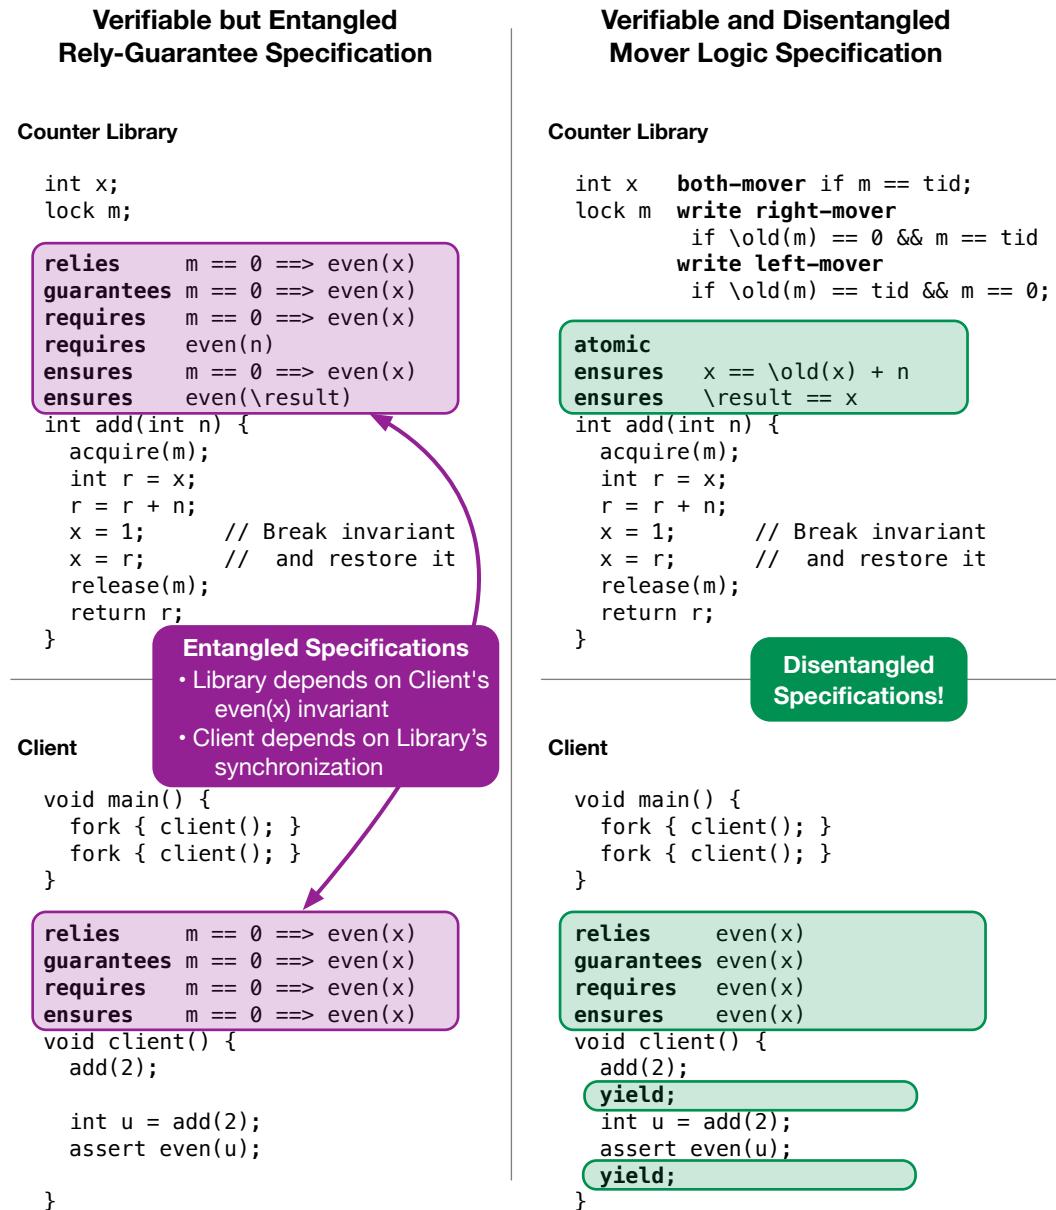

Figure 3 A second version of the counter library with a temporarily broken even(x) invariant. (**Left**) Under RG logic, the library specification is entangled with the client's even(x) invariant and the client specification is entangled with the library's synchronization discipline. (**Right**) Under mover logic, the specifications are cleanly disentangled.

16:8 Mover Logic

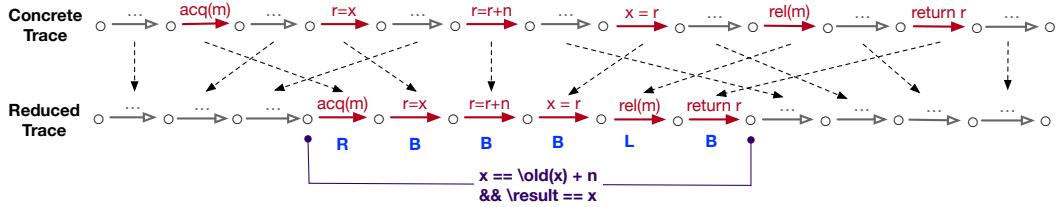

Figure 4 Reduction applied to an execution trace of `add()` from Figure 1.

- Conversely, a step is a *left-mover* (**L**) if it commutes “to the left” of a preceding step of a different thread. A lock release is a left-mover because any preceding step cannot modify that lock.
- A step is a *both-mover* (**B**) if it is both a left- and a right-mover, and it is a *non-mover* (**N**) if neither. A race-free memory access is a both-mover because there are no concurrent, conflicting accesses. An access to a race-prone variable is a non-mover since there may be concurrent writes.

A sequence of steps performed by a particular thread is *reducible* if it consists of (1) zero or more right-movers; (2) at most one non-mover; and (3) zero or more left-movers. That is, a sequence is reducible if the commutativity of the steps match the pattern **R***[**N**]**L***. Any interleaved steps of other threads can be “commuted out” to produce a serial execution.

Figure 4 illustrates this technique for a call to `add()` interleaved with steps of a second thread. In that figure and below, the solid and hollow arrow heads indicate steps from different threads, and arrows labeled “...” represent any number of steps by that thread. The steps of `add()` have the mover behavior **RBBBLB**, matching the reducible pattern **R*[N]L***. Thus we can reason about `add()` as if it executes sequentially and assign it the intuitive postcondition $x == \text{\old}(x) + n \ \&\& \ \text{\result} == x$.

4 Overview of Mover Logic

Mover logic extends RG logic to verify that certain functions are *atomic* and can therefore be assigned more precise (unstabilized) postconditions than under RG logic. Figure 3 (right) shows a mover logic specification for our library/client example. The declaration

```
int x  both-mover if m == tid;
```

means that accesses to `x` are both-movers provided that the current thread holds lock `m`. All other accesses are errors. The declaration for lock `m` specifies that acquires (which change `m` from 0 to the current thread’s identifier `tid`) are right-movers and releases (which change `m` from `tid` back to 0) are left-movers:

```
lock m  write right-mover
    if \old(m) == 0 && m == tid
write left-mover
    if \old(m) == tid && m == 0;
```

These mover specifications are sufficient to verify that `add` is atomic. Consequently, there is no need to apply the rely assumption at each intermediate store inside this atomic function. Instead, sequential reasoning suffices to establish the desired postcondition $x == \text{\old}(x) + n \ \&\& \ \text{\result} == x$.

The `client()` function in Figure 3 (right) is not atomic because steps of other threads could be interleaved between the two calls to `add(2)`. Mover logic uses a `yield` annotation to identify that thread interference may occur at that point, and the store invariants at `yields` must be stable under the rely assumption:

```
relies    even(x);
guarantees even(x);
```

Note that this thread guarantee does not need to summarize individual steps inside the callee `add()`, which would expose the broken invariant. Instead, it summarizes the entire atomic effect of `add()`, which preserves the `even(x)` invariant. With mover logic, the `client()` specification is independent of the internal synchronization discipline inside `add()`.

This library/client example illustrates several benefits of mover logic:

- Verifying that `add()` is atomic enables sequential reasoning inside `add()`.
- We thus avoid applying the rely assumption at each program point inside `add()`.
- As a result, `add()` satisfies the desired postcondition `x == \old(x) + n && \result == x`, which is independent of the client-specific data invariant `even(x)`.
- On the client side, the thread guarantee `even(x)` summarizes the entire behavior of `add()`, rather than the behavior of each individual step.
- Consequently, the client can be verified based on the illusion that `even(x)` always holds, with no loss of soundness.

Thus, mover logic disentangles the library specification from the data invariant of the client while also disentangling the client specification from the library synchronization discipline.

5 Additional Examples

5.1 Spin Lock

To further illustrate the benefits of disentangled specifications, Figure 5 (left) shows our counter library rewritten to employ a user-defined spin lock. The `spin_lock()` code employs a compare-and-set operation (`cas`) to attempt to change the lock 1 from 0 to the current thread's `tid`. The `cas` operation returns true if the update succeeds, and false otherwise. Thus, the function retries until the update is success, at which point the current thread holds the lock. The `spin_unlock()` function releases the lock by setting 1 back to 0.

Mover logic verifies that calls to `spin_lock()` and `spin_unlock()` are atomic right- and left-movers, respectively. That enables us to avoid entangled specifications for the spin lock and counter libraries, and the counter library's `add` specification is *identical* to the earlier implementation. It is still atomic and it guarantees the same post condition.

5.2 Lock-Free Queue

Figure 5 (top right) shows a lock-free single-element queue, where `buf` holds either the single enqueued `int` or `None` if the queue is empty, as indicated by the declared type `Optional[int]`.

The `enqueue(v)` function uses `cas` to switch `buf` from `None` to `v` and is atomic since failing `cas` operations are both-movers. The `dequeue()` function use the action `r ~= buf` to denote an *unstable read* of `buf` that can load any value into the local variable `r` [22]. Unstable reads can be treated as right-movers since they commute past steps by other

ensures head(top) == v
ensures tail(top) == \old(top)

```
void push(int v) {
    List t ~ top;
    List nu = v::t;
    while (!cas(top, t, nu)) {
        t ~ top;
        nu = v::t;
    }
}
```

atomic

ensures head(\old(top)) == \result
ensures tail(\old(top)) == top

```
int pop() {
    List t ~ top;
    while (t == Nil) { t ~ top; }
    List tl = tail(t);

    while (!cas(top, t, tl)) {
        t ~ top;
        while (t == Nil) { t ~ top; }
        tl = tail(t);
    }
    return head(t);
}
```

Figure 5 (Left) A new implementation of the counter library using a user-defined spin lock.
(Top Right) A single-element lock-free queue. **(Bottom Right)** A lock-free stack.

threads.² Consequently, the `dequeue()` function is atomic. All executions of that function consist of unstable reads (right-movers) and failed `cas` operations (both-movers) followed by a successful `cas` (non-mover). These sequences match the reducible pattern $R^*[N]L^*$. Moreover, the final `cas` ensures that `r` is equal to the pre-`cas` value of `buf`, which enables mover logic to establish the desired post-conditions `\result == \old(buf)` and `buf == None`.

5.3 Lock-Free Stack

Figure 5 (bottom right) shows a lock-free stack. This example uses immutable lists, where `Nil` is the empty list, `v::s` adds `v` to the front of the list `s`, and `head(s)` and `tail(s)` extract the first element and the rest of `s`, respectively.³

The `push(v)` function is atomic since it has only one non-mover operation, namely the successful `cas`. The unstable reads, list allocations `v::t`, and failed `cas` operations are both-movers or right-movers. Therefore, we can assign `push(v)` the following intuitive post-condition without needing to stabilize under the rely assumption of a particular caller.

```
ensures head(top) == v
ensures tail(top) == \old(top)
```

The `pop()` function is also atomic due to similar reasoning and satisfies the following post-condition without the need to stabilize it.

```
ensures head(\old(top)) == \result
ensures tail(\old(top)) == top
```

6 Mover Logic Language

We formalize mover logic for the idealized language MML (mover logic language), which we summarize in Figure 6. Section 7.3 below translates our running example into MLL. In MLL, threads manipulate a shared store σ that maps variables to values. Variables include x, y, z , and m . We often use the variable m as a lock, where m is the thread identifier (tid) of the thread holding the lock, or 0 if it is not held.

Thread-local variables r are supported by having each thread access a separate variable r_{tid} for each thread tid . The language includes reads and writes to global and local variables, acquires and releases of locks, local computations, etc. For generality and simplicity, we abstract all of these store-manipulation operations as $actions A \subseteq Tid \times Store \times Store$. Note that an action may depend on the current thread's identifier. We write actions as formulae in which $\text{\old}(x)$ and x to refer to the values of x in the pre-store and post-store, respectively. We write $\langle A \rangle_x$ to denote an action that only changes x :

$$\langle A \rangle_x \stackrel{\text{def}}{=} \{ (tid, \sigma, \sigma') \mid (tid, \sigma, \sigma') \in A \wedge \forall y \in Var. y \neq x \Rightarrow \sigma(y) = \sigma'(y) \}$$

² Unstable reads are a proof technique that trades off our ability to reason about the value stored in `r` for the ability to treat the unstable read as a right-mover. An implementation of unstable read may exhibit any a subset of the allowed behaviors, including simply performing a conventional read.

³ The duplicated code in this example could be removed in a language with richer control structures such as `break` statements.

16:12 Mover Logic

Syntax

(Statements)	$s ::= \text{skip} \mid \text{wrong} \mid A \mid s; s \mid \text{if } C \text{ s else } s$
	$\mid \text{while } C \text{ s } \mid f() \mid \text{yield}$
(Action)	$A \subseteq Tid \times Store \times Store$
(Thread Identifier)	$t, u \in Tid = \{1, 2, \dots\}$
(Conditional Action)	$C ::= A \diamond A$
(Variable Declaration)	$var ::= x \text{ var_spec}$
	$x, y, r, m \in Var$
(Function Declaration)	$fn ::= fn_spec \ f() \ \{ s \}$
	$f \in \text{FunctionName}$
(Declaration Table)	$D ::= \overline{var \mid fn}$
	(D is left implicit in the semantics for brevity)

Semantics

(Store)	$\sigma \in Var \rightarrow Value$
(State)	$\Sigma ::= s_1..s_n \cdot \sigma$
(Evaluation Context)	$E ::= \bullet \mid E; s$

$$s \cdot \sigma \xrightarrow{t} s' \cdot \sigma'$$

[E-SEQ]	$E[\text{skip}; s] \cdot \sigma \xrightarrow{t} E[s] \cdot \sigma$
[E-YIELD]	$E[\text{yield}] \cdot \sigma \xrightarrow{t} E[\text{skip}] \cdot \sigma$
[E-ACTION]	$E[A] \cdot \sigma \xrightarrow{t} E[\text{skip}] \cdot \sigma' \text{ if } (t, \sigma, \sigma') \in A$
[E-IF]	$E[\text{if } (A_1 \diamond A_2) \text{ s}_1 \text{ else } s_2] \cdot \sigma \xrightarrow{t} E[s_i] \cdot \sigma' \text{ if } (t, \sigma, \sigma') \in A_i, \text{ for } i \in 1, 2$
[E-WHILE]	$E[\text{while } C \text{ s}] \cdot \sigma \xrightarrow{t} E[\text{if } C \text{ (s; while } C \text{ s)} \text{ else skip}] \cdot \sigma$
[E-CALL]	$E[f()] \cdot \sigma \xrightarrow{t} E[s] \cdot \sigma \text{ if } fn_spec \ f() \ \{ s \} \in D$

$$\Sigma \rightarrow \Sigma'$$

$$\frac{\begin{array}{c} [\text{E-STATE}] \\ s_t \cdot \sigma \xrightarrow{t} s'_t \cdot \sigma' \end{array}}{s_1..s_t..s_n \cdot \sigma \rightarrow s_1..s'_t..s_n \cdot \sigma'}$$

Figure 6 Mover Logic Language.

We can then express assignments and locking operations as follows. Note that $\text{acquire}(m)$ blocks if the lock is already held, *i.e.* if $\text{old}(m) \neq 0$. We use the notation $expr[x := \text{old}(x)]$ to denote $expr$ with all occurrences of x replaced by $\text{old}(x)$.

$$\begin{aligned} \text{acquire}(m) &\stackrel{\text{def}}{=} \langle \text{old}(m) = 0 \wedge m = tid \rangle_m \\ \text{release}(m) &\stackrel{\text{def}}{=} \langle m = 0 \rangle_m \\ x = expr &\stackrel{\text{def}}{=} \langle x = expr[x := \text{old}(x)] \rangle_x \end{aligned}$$

The unstable read $r_{tid} \sim= x$ from Section 5.3 may store any value⁴ in the local variable r_{tid} :

$$r_{tid} \sim= x \stackrel{\text{def}}{=} \{ (tid, \sigma, \sigma[r_{tid} := v]) \mid v \in Value \}$$

⁴ In a language with types, this definition can be easily adapted to only store type-correct values into r_{tid} .

Mover Logic Language includes `if` and `while` statements that condition execution either on whether a Boolean test is true or on whether a store-manipulating operation, such as `cas`, succeeds. To handle these two cases uniformly, we introduce a *conditional action* $C = A_1 \diamond A_2$ where A_1 is an action capturing a true test or successful operation and A_2 is an action capturing a false test or failed operation. For generality, both cases may modify the store and both may be feasible on some pre-states.

We encode any state predicate $B \subseteq Store$ as the conditional action $\{(tid, \sigma, \sigma) \mid \sigma \in B\} \diamond \{(tid, \sigma, \sigma) \mid \sigma \notin B\}$ that distinguishes the true/false cases but never modifies the store. The following illustrates this encoding for the test $x \geq 0$.

$$x \geq 0 \stackrel{\text{def}}{=} \{(tid, \sigma, \sigma) \mid \sigma(x) \geq 0\} \diamond \{(tid, \sigma, \sigma) \mid \sigma(x) < 0\}$$

As a more interesting example, we encode `cas` as the following conditional action:

$$\text{cas}(x, v, v') \stackrel{\text{def}}{=} \langle \text{old}(x) = v \wedge x = v' \rangle_x \diamond I$$

where the identity action $I = \{(t, \sigma, \sigma) \mid t \in Tid \text{ and } \sigma \in Store\}$. This definition permits `cas` to non-deterministically fail from any pre-state, which enables us to treat failed `cas` operations as both movers [19].

Given $C = A_1 \diamond A_2$, the if statement `if C s1 else s2` may either: 1) evaluate the action A_1 and then s_1 , or 2) evaluate A_2 and then s_2 . The former is the “true” case and the latter is the “false” case, with the desired behavior regardless of whether C encodes a predicate test or a potentially-failing store update. To prevent the if statement from blocking, we require $(A_1 \cup A_2)$ to be total on the state, *i.e.* $\{\sigma \mid (t, \sigma, _) \in (A_1 \cup A_2)\} = State$.

The while statement `while C s` behaves similarly. It iterates as long as C succeeds. We may need to test the negation of a conditional action. The negation of $C = A_1 \diamond A_2$, written $\neg C$, is simply $A_2 \diamond A_1$. The language includes the statement `wrong` to indicate than an error occurred. The statement `assert B` abbreviates `if B skip else wrong`. The goal of mover logic is to verify that programs do not go wrong.

Global variable declarations have the form $x \ var_spec$ and are kept in a global declaration table D . Function declarations have the form $fn_spec f() \{ s \}$ and are also kept in D . Specifications for globals (var_spec) and functions (fn_spec) are described in Sections 7 and 8, respectively. For notational simplicity, D is left as an implicit argument to the evaluation judgments. To keep the core language as simple as possible, we elide formal parameters and return values. Instead, parameters and return values are passed in thread-local variables, as described below in Section 7.3.⁵

In our examples, we include types, curly braces, semicolons, and other standard syntactic forms to aid readability.

An execution state

$$\Sigma = s_1..s_n \cdot \sigma$$

consists of sequence of threads $s_1..s_n$ with a shared store σ . The evaluation relation $\Sigma \rightarrow \Sigma'$ is based on evaluation contexts $E[\dots]$, which identify the next statement to be evaluated. A state $\Sigma = s_1..s_n \cdot \sigma$ is *wrong* if any thread is about to execute `wrong`, *i.e.*, if $s_i = E[\text{wrong}]$. The semantics demonstrates that `yield` annotations have no effect at run time, but they are used in the mover logic described below.

⁵ Extending the language to include function arguments and results is straightforward, but it adds notational complexities that are orthogonal to our core contributions.

7 Mover Logic Effects and Specifications

Mover logic divides the execution of each thread into reducible code sequences that are separated by `yield` statements identifying where thread interference may be observed.

7.1 Effects

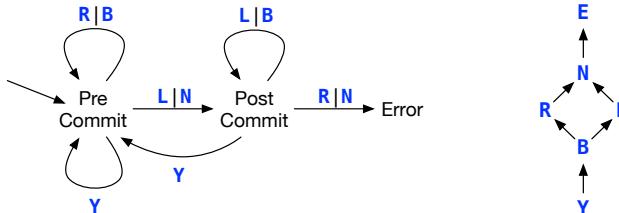

We use a language of effects to reason about reducible code sequences separated by `yields`:

$$e \in \text{Effect} ::= \text{Y} \mid \text{R} \mid \text{L} \mid \text{B} \mid \text{N} \mid \text{E}$$

where

- **Y** is the effect of a `yield` annotation;
- **R** describes right-mover actions;
- **L** describes left-mover actions;
- **B** describes both-mover actions that are both left- and right-movers;
- **N** describes non-mover actions that are neither left- nor right-movers; and
- **E** describes erroneous situations, such as the sequential composition of two non-mover actions without an intervening `yield`, which is not a reducible sequence.

Our strategy for verifying that `yields` correctly separate reducible sequences is based on the DFA [62] shown below (left). The DFA captures reducible sequences $\text{R}^*[\text{N}]\text{L}^*$ separated by yields **Y**, which resets the DFA to the initial “pre-commit” state on the left to start a new reducible sequence. The first left-mover or non-mover in a reducible sequence is often called the *commit* action and moves us from the pre-commit to the post-commit phase.

From this DFA, we derive the ordering $\text{Y} \sqsubseteq \text{B} \sqsubseteq \text{R}, \text{L} \sqsubseteq \text{N} \sqsubseteq \text{E}$, which is also shown above (right). For example, $\text{R} \sqsubseteq \text{N}$, since for any effect sequences α and β , if $\alpha \text{N} \beta$ is accepted by this DFA, the $\alpha \text{R} \beta$ is also accepted. We define a standard join operation \sqcup via this ordering.

We also define sequential composition $e_1; e_2$ and iterative closure e^* , as in [62]. For example, $\text{R}; \text{L} = \text{N}$ since to show $\alpha \text{R} \text{L} \beta$ is accepted by the DFA it is sufficient to show that $\alpha \text{N} \beta$ is accepted. Conversely, $\text{N}; \text{N} = \text{E}$ (error), since $\alpha \text{N} \text{N} \beta$ is never accepted by this DFA.

$e_1; e_2$	$\text{Y} \text{ B} \text{ R} \text{ L} \text{ N} \text{ E}$	e	e^*
Y	Y Y Y L L E	Y	Y
B	Y B R L N E	B	B
R	R R R N N E	R	R
L	Y L E L E E	L	L
N	R N E N E E	N	E
E	E E E E E E	E	E

7.2 Mover Specifications

In mover logic, the verification of a thread tid is performed in the context of a mover specification describing how each program action A starting in the store σ commutes with steps of other threads. Thus, mover specifications M have the type

$$M : Action \times Tid \times Store \rightarrow Effect \setminus \{Y\}$$

For example, if action A is a local computation that only accesses thread-local variables, we would naturally have

$$M(A, tid, \sigma) = B$$

Alternatively, if a global variable x is protected by a lock m , the write action $x = expr$ might have the mover specification

$$M(x = expr, tid, \sigma) = \begin{cases} B & \text{if } \sigma(m) = tid \\ E & \text{otherwise} \end{cases}$$

indicating that the write is a both-mover only if thread tid holds lock m . Otherwise, it is an error. We assume that $expr$ only accesses local variables, and that $M(A, tid, \sigma)$ is never Y since actions do not yield.

We write mover specifications in the source code using the following notation, which is inspired by earlier reduction-based verifiers [30, 19, 21]:

$$\begin{aligned} var_spec &::= var_clause^* \\ var_clause &::= \text{read } e \text{ if } P \mid \text{write } e \text{ if } P \end{aligned}$$

where $P \subseteq Tid \times Store \times Store$ is a two-store predicate describing the pre-store and post-store of the access to x in question. Further, P can depend on the current thread identifier tid . Similar to actions, we write these predicates as formulae in which $\text{old}(y)$ and y to refer to the values of y in the pre-store and post-store, respectively. To determine the mover effect of a variable access, we evaluate the specification clauses in order and take the effect of the first case where the condition P is satisfied. If no clauses apply, the access has the error effect E . More formally, given the specification for a variable x in the source code, we collect the sequence of clauses for reads and writes separately and then create the mover specification M for x as follows:

$$\begin{aligned} \left[\begin{array}{c} \text{read } e_1 \text{ if } P_1 \\ \vdots \\ \text{read } e_n \text{ if } P_n \end{array} \right] &\implies M(r_{tid} = x, tid, \sigma) = \begin{cases} e_1 & \text{if } P_1(tid, \sigma, \sigma) \\ \vdots & \vdots \\ e_n & \text{if } P_n(tid, \sigma, \sigma) \\ E & \text{otherwise} \end{cases} \\ \left[\begin{array}{c} \text{write } e_1 \text{ if } P_1 \\ \vdots \\ \text{write } e_n \text{ if } P_n \end{array} \right] &\implies M(x = expr, tid, \sigma) = \begin{cases} e_1 & \text{if } P_1(tid, \sigma, \sigma[x := \sigma(expr)]) \\ \vdots & \vdots \\ e_n & \text{if } P_n(tid, \sigma, \sigma[x := \sigma(expr)]) \\ E & \text{otherwise} \end{cases} \end{aligned}$$

where r_{tid} is a local variable, $expr$ only accesses thread-local variables, $\sigma(expr)$ is the result of evaluating $expr$ in the store σ , and the cases for M are evaluated in the order listed.

Counter Library	Client
<pre> int x both-mover if m == tid lock m write right-mover if \old(m) == 0 && m == tid write left-mover if \old(m) == tid && m == 0 atomic non-mover requires true ensures x == \old(x) + arg1_{tid} ensures result_{tid} == x add() { R (\old(m) == 0 & m == tid)_m B r_{tid} = x; B r_{tid} = r_{tid} + arg1_{tid}; B x = 1; B x = r_{tid}; L (m == 0)_m; B result_{tid} = r_{tid}; } </pre>	<pre> relies even(x) guarantees even(x) requires even(x) ensures even(x) client() { // even(x) arg1_{tid} = 2; // even(x) && arg1_{tid} == 2 add_{tid}(); // even(x) Y yield; // even(x) arg1_{tid} = 2; // even(x) && arg1_{tid} == 2 add(); // even(x) && even(result_{tid}) u_{tid} = result_{tid}; // even(x) && even(u_{tid}) if even(u_{tid}) skip else wrong; // even(x) Y yield; // even(x) } </pre>

Initial State Σ $(\text{yield}; \text{client}()).(\text{yield}; \text{client}()) \cdot [x := 0, m := 0]$

Figure 7 The example from Figure 3 (right) expressed in Mover Logic Language.

The declaration for a global variable x protected by a lock m is thus written as

```
int x  read  both-mover if m == tid
       write both-mover if m == tid
```

where **both-mover** is syntactic sugar for the effect **B**. (Similarly, we use **left -mover** for **L**, and so on.) In our examples, we abbreviate these identical read and write cases as follows.

```
int x  both-mover if m == tid
```

7.3 Motivating Example, Revisited

Figure 7 expresses our motivating example from Figure 3 (right) in our Mover Logic Language. As mentioned earlier, an access to a thread-local variable r actually accesses a (global) variable r_{tid} that is reserved for use by thread tid . We use thread-local variables to encode function arguments and results. The fork statements are converted into parallel threads in the initial state Σ . We insert a **yield** at the start of each thread in Σ so that the initial state is well-formed under the non-preemptive semantics we introduce in our formal development.

Given this mover specification, mover logic successfully verifies this code. Figure 7 also demonstrates the reasoning carried out by mover logic. The left margin shows the effect of each action and groups those effects into reducible sequences. The **add()** function is a single

reducible sequence, ensuring that we may treat it as atomic. The `client()` function consists of multiple reducible sequences separated by `yields`. We also show invariants demonstrating that `client()` is correct in comments at each program point.⁶

7.4 Additional Mover Specification Examples

Figure 3 (right) showed how mover specifications can capture the synchronization/commuting behavior of lock acquires, lock releases, and lock-protected variable accesses. Our mover specifications are inspired by the ANCHOR verifier, which used mover specifications to capture many synchronization idioms [19, 1].⁷

To illustrate how mover specifications capture more complex synchronization disciplines, suppose the variable `y` is *write-protected* by a lock `m`. That is, lock `m` must be held for all writes to `y` but not necessarily held for reads. Consequently, `y` should be declared volatile if the code is run under a weak memory model. Writes to `y` are non-movers (due to concurrent reads); lock-protected reads are both-movers (because there can be no concurrent writes); and reads without holding the lock are non-movers (due to concurrent writes). Mover specifications capture this synchronization discipline concisely as follows, where the last clause applies only when `m` is not `tid`.

```
int y write non-mover if m == tid
    read both-mover if m == tid
    read non-mover
```

The FASTTRACK dynamic race detector [18, 57] uses a combination of lock-protected and write-protected disciplines to synchronize accesses to some array pointers. We illustrate that discipline for an array pointer `vc`: initially, a `flag` is false and the pointer `vc` is guarded by `lock`; when `flag` becomes true, `vc` becomes write-guarded by `lock`. The mover specification for this discipline is captured by the first four lines in the specification for `vc`:

```
int vc[]      both-mover if !flag && lock == tid
              write non-mover if flag && lock == tid
              read both-mover if flag && lock == tid
              read non-mover if flag
[i]          both-mover if !flag && lock == tid
[i] read    both-mover if flag && (lock == tid || tid == i)
[i] write   both-mover if flag && (lock == tid && tid == i)
```

This idiom enables the algorithm to avoid using a lock to protect all accesses to `vc` but still replace `vc` with a larger array when necessary. The last three lines capture the synchronization discipline for accessing the array entry `vc[i]`, where we use the extended notation “[`i`] `var_clause`” to describe the synchronization cases for actions that access `vc[i]`. That entry is also initially guarded by `lock` when `flag` is false; when `flag` becomes true, the entry `vc[i]` can only be written by thread `i` while holding `lock`, read by any thread while holding the lock, or read by thread `i` without holding the lock. These reads and writes are all both-movers. These rules prevent all conflicting reads and writes, and thus all accesses to `vc[i]` are both-movers under this synchronization discipline.

⁶ In this example, the rely assumption `even(x)` is sufficient for reasoning about `yield` points. In code where live ranges for local variables span yield points, we would add to the rely assumptions the requirement that one thread does not change another thread’s local variables.

⁷ Our syntax for mover specifications is a syntactic variant of the ANCHOR syntax. In essence, our specifications are sequential `var_clauses`, whereas ANCHOR combines these clauses into a single binary decision tree using the syntax `bool_expr ? mover_spec : mover_spec`.

As a final example, consider a concurrent hashtable consisting of a `table` array and a `locks` array, which has length N . The entry `table[i]` is protected by `locks[i % N]`. The `table` reference itself may change when, for example, `table` is replaced with a larger array. To ensure such changes are done without interference, a write to `table` is permitted only when a thread holds *all* locks. In contrast, `table` can be read by a thread holding *any* lock. All such reads and writes are both-movers, as captured by the following mover specification:

```
Entry table[] write both-mover if  $\forall i \in [0, N]. \text{locks}[i] == \text{tid}$ 
      read both-mover if  $\exists i \in [0, N]. \text{locks}[i] == \text{tid}$ 
      [i] both-mover if  $\text{locks}[i \% N] == \text{tid}$ 
```

As illustrated in the previous two examples from the ANCHOR verifier [19], mover specifications can naturally capture synchronization disciplines that vary with the current program state.

A final example comes from the common iterative parallel algorithm pattern in which a synchronization barrier is used to divide the computation into a series of phases. In the even phases, the main thread (with `tid = 0`) updates shared data structures, and in odd phases, worker threads concurrently read data from those structures, as specified below.

```
int z  read both-mover if phase % 2 == 1
      both-mover if phase % 2 == 0 && tid == 0
```

8 Mover Logic

In this section, we show the proof rules for how mover logic handles statements (Section 8.1); function definitions, calls, and specifications (Sections 8.2–8.3); and run-time states (Section 8.4).

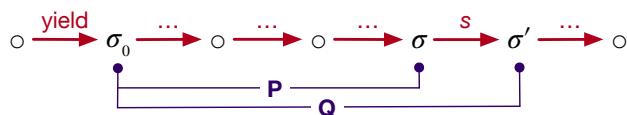

8.1 Mover Logic

Mover logic is defined via the judgments in Figures 8 and 9. The main judgment

$$R; G \vdash s : P \rightarrow Q \cdot e$$

verifies that, when starting from a store satisfying the precondition P , the statement s terminates only in stores satisfying the postcondition Q (*i.e.* partial correctness). In addition, the judgment uses the mover specification M to verify that s consists of reducible sequences separated by `yields`. At each yield point, the rely assumption $R \subseteq Tid \times Store \times Store$ is used to model potential interference from other threads. Conversely, the thread guarantee $G \subseteq Tid \times Store \times Store$ summarizes the behavior of each reducible code sequence between two yield points in s . The effect e summarizes how s commutes with steps of other threads.

In the rules, the precondition P can refer to the value of variable x in the initial store σ_0 of the current reducible code sequence via the notation `\old(x)`. Thus P is a two-store relation $P \subseteq Tid \times Store \times Store$ relating that initial store σ_0 to the pre-store σ for the execution of s . We show that requirement visually in the following trace, where $(tid, \sigma_0, \sigma) \in P$.

One-Store and Two-Store Predicates and Supporting Definitions

$$\begin{aligned}
 S, T &\subseteq Tid \times Store \\
 R, G, P, Q, A &\subseteq Tid \times Store \times Store \\
 Two(S) &\stackrel{\text{def}}{=} \{(t, \sigma, \sigma) \mid (t, \sigma) \in S\} & P; A &\stackrel{\text{def}}{=} \left\{ \begin{array}{l} (t, \sigma, \sigma') \in P \text{ and} \\ (t, \sigma', \sigma'') \in A \end{array} \right\} \\
 Post(P) &\stackrel{\text{def}}{=} \{(t, \sigma) \mid (t, _, \sigma) \in P\} & Yield(P, R) &\stackrel{\text{def}}{=} \left\{ \begin{array}{l} (t, \sigma', \sigma') \in P \text{ and} \\ (t, _, \sigma) \in R^* \end{array} \right\} \\
 I &\stackrel{\text{def}}{=} \{(t, \sigma, \sigma) \mid t \in Tid, \sigma \in Store\}
 \end{aligned}$$

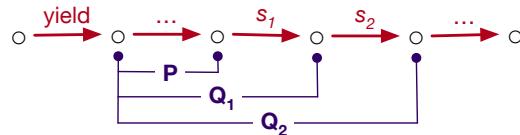

Mover Logic Proof Rules

Figure 8 Mover logic proof rules and supporting definitions.

The two-store postcondition $Q \subseteq Tid \times Store \times Store$ relates σ_0 to the post-store σ' of s .

Many of the mover logic rules are extensions of Hoare logic incorporating reduction effects. For example, the rule [M-SEQ] states that a sequential composition $(s_1; s_2)$ commutes as $e_1; e_2$, the sequential composition of the effects of its sub-statements, and that the precondition and postcondition are related as follows:

The rule [M-SKIP] indicates that `skip` has no effect, so its precondition and postcondition are identical. The rule [M-WRONG] verifies that `wrong` is never executed via the unsatisfiable precondition \emptyset . That is, this rule rejects any program that may execute `wrong` from any state.

Function Specification Syntax

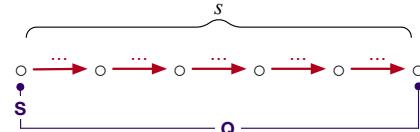

$$fn_spec ::= \begin{array}{l} \text{atomic } e \text{ requires } S \text{ ensures } Q \\ | \quad \text{relies } R \text{ guarantees } G \text{ requires } S \text{ ensures } T \end{array}$$

Proof Rules for Function Definitions and Calls

$\boxed{\vdash fn}$

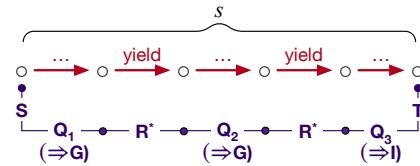

[M-DEF-ATOMIC]

$$\frac{f() \text{ is not (directly or indirectly) recursive} \quad \emptyset; \emptyset \vdash s : Two(S) \rightarrow Q \cdot e}{\vdash \text{atomic } e \text{ requires } S \text{ ensures } Q \quad f() \{ s \}}$$

[M-DEF-NON-ATOMIC]

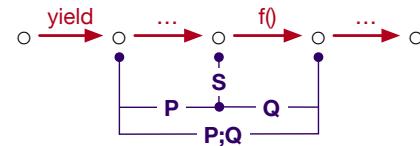

$$\frac{R; G \vdash s : Two(S) \rightarrow Two(T) \cdot R \quad G \neq \emptyset}{\vdash \text{relies } R \text{ guarantees } G \text{ requires } S \text{ ensures } T \quad f() \{ s \}}$$

$\boxed{R; G \vdash s : P \rightarrow Q \cdot e}$

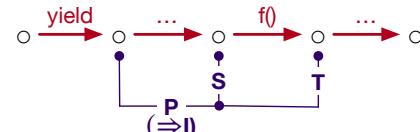

[M-CALL-ATOMIC]

$$\frac{\text{atomic } e \text{ requires } S \text{ ensures } Q \quad f() \{ s \} \in D \quad Post(P) \Rightarrow S}{R; G \vdash f() : P \rightarrow (P; Q) \cdot e}$$

[M-CALL-NON-ATOMIC]

$$\frac{\text{relies } R \text{ guarantees } G \text{ requires } S \text{ ensures } T \quad f() \{ s \} \in D}{R; G \vdash f() : Two(S) \rightarrow Two(T) \cdot R}$$

Verification of States

$\boxed{\vdash \Sigma}$

[M-STATE]

$$\frac{\forall fn \in D. \vdash fn \quad M \text{ is valid} \quad I \Rightarrow G \quad \forall t \in Tid. \left[\begin{array}{l} R; G \vdash s_t : P_t \rightarrow Q_t \cdot e_t \text{ and } e_t \neq E \text{ and } Q_t \Rightarrow G \\ \text{and } s_t \text{ is yielding and } (t, \sigma, \sigma) \in P_t \end{array} \right] \quad \forall t, u \in Tid. t \neq u \Rightarrow (G[tid := t] \Rightarrow R[tid := u])}{\vdash s_1..s_n \cdot \sigma}$$

Figure 9 Mover logic proof rules for function definition, calls, and run-time states.

The rule [M-ACTION] computes the effect of action A from states σ satisfying the current precondition P . That rule uses the function to compute this effect:

$$M(A, P) \stackrel{\text{def}}{=} \bigsqcup_{(t, _, \sigma) \in P} M(A, t, \sigma)$$

(Note that we are overloading M here.) The postcondition of A is then the precondition P sequentially composed with the action A , *i.e.* $P; A$. A key technical requirement of the reduction theorem is that once an atomic block $R^*[\mathbf{N}]L^*$ enters its post-commit (or left-mover part), then it must terminate. It cannot block or diverge [24].⁸ Hence, we require that A is total if it is a left-mover. We place similar restrictions on loops.

The rule [M-IF] requires both the true case $(A_1; s_1)$ and the false case $(A_2; s_2)$ to have the same post-condition Q . The effect e is the maximal effect of executing either A_1 followed by s_1 or A_2 followed by s_2 . The rule [M-WHILE] for `while` $A_1 \diamond A_2\; s$ checks that a successful test followed by the body preserves precondition P , which functions as a loop invariant. The postcondition of the loop is the postcondition of A_2 given the precondition P . The effect of a loop is the iterative closure of the effect of one iteration sequentially composed with the effect of the loop-terminating test A_2 .

Consider the loop in `spin_lock()` in Figure 5. The test `!cas(1, 0, tid)` is the conditional action $I \diamond (\text{\textbackslash old}(1) = 0 \wedge 1 = \text{tid})_1$ and the loop body is `skip`. Since $P; I = P$, rule [M-SKIP] concludes that $R; G \vdash \text{skip} : P \rightarrow P \cdot \mathbf{B}$. Further, $M(I, P) = \mathbf{B}$, because that action accesses no global variables, and the specification for 1 indicates that $M((\text{\textbackslash old}(1) = 0 \wedge 1 = \text{tid})_1, P) = \mathbf{R}$. Thus, $e = (\mathbf{B}; \mathbf{B})^*; \mathbf{R} = \mathbf{R}$. Also, the postcondition $P; A_2$ for the loop simplifies to the expected $P[1 := \text{tid}]$. To ensure the left-mover termination requirement, rule [M-WHILE] requires that $e \not\subseteq \mathbf{L}$. That is, the post-commit part of a reducible sequence cannot contain loops.

The rule [M-YIELD] for `yield` first checks that the thread guarantee G includes all possible behaviors P of the reducible sequence preceding the `yield` via the antecedent $P \Rightarrow G$. The reducible sequence following the `yield` starts with postcondition $Q = \text{Yield}(P, R)$ which incorporates repeated thread interference from other threads via the iterated rely assumption R^* and then resets each `\old(x)` value to be the current value of x at the start of the new reducible sequence.

The rule [M-CONSEQ] extends the consequence rule of RG logic to reduction effects.

8.2 Atomic Functions

Mover logic supports both atomic and non-atomic functions. An atomic function is one whose code body is reducible (*i.e.*, no `yield` statements) and has the following form:

```
atomic e
requires S ensures Q f() { s }
```

(We elide e in the surface syntax when it is \mathbf{N} , as in Figure 3 (right)). The precondition $S \subseteq Tid \times Store$ describes valid initial stores for the function call and must be established by the caller. The post condition $Q \subseteq Tid \times Store \times Store$ describes possible final stores, and it may refer to values of variables on function entry using the `\old(x)` notation. Since s is

⁸ To motivate this requirement consider the program `(x = 1; while (true) skip; yield) || (assert x != 1)`. This program can go wrong because the first thread writes 1 to x . However, the reducible block containing that write never terminates after performing that write, and that write is not included in the thread guarantee G . Thus, we require that once a reducible block commits, it must terminate.

atomic and `yield`-free, we elide the `rely` and `guarantee` components from atomic function specifications. We require atomic functions to be non-recursive to facilitate the “left-mover terminates” requirement mentioned above.

To ensure that the function body s conforms to the function’s specification, rule [M-DEF-ATOMIC] in Figure 9 first converts S into the two-store precondition $\text{Two}(S)$ (in which $\text{old}(x) = x$ for all variables x) and then verifies the function body s with respect to that precondition. We use the guarantee \emptyset to enforce that s is indeed yield-free. (Rule [M-YIELD] will always fail if G is \emptyset , provided that the `yield` is actually reachable, *i.e.* if $P \neq \emptyset$).

The rule [M-CALL-ATOMIC] for a corresponding call to $f()$ retrieves the above specification from the declaration table D and then ensures that the precondition P at the call site implies the callee’s precondition S . That rule uses $\text{Post}(P)$ to first convert P into a one-state predicate. The postcondition $(P; Q)$ combines the call precondition P with the two-store postcondition Q of the callee, as illustrated in the trace to the right of the rule.

8.3 Non-Atomic Functions

Non-atomic function definitions have the following form:

```
requires R guarantees G
requires S ensures T  f() { s }
```

We include thread rely R and guarantee G components in these function specifications since non-atomic function may include `yield` points where thread interference may occur. For simplicity, we require that non-atomic function calls and returns happen at the start of a reducible sequence. Consequently, the precondition $S \subseteq \text{Tid} \times \text{Store}$ and postcondition $T \subseteq \text{Tid} \times \text{Store}$ are both one-store predicates since there is no need to summarize the preceding reducible sequence.

The rule [M-DEF-NON-ATOMIC] checks that the function body s runs from the precondition $\text{Two}(S)$, possibly via multiple reducible sequences separated by `yields`, to terminate after a final `yield` s in a store satisfying T . Those requirements are enforced by using $\text{Two}(T)$ as the postcondition for s . Further, the body s should end in a `yield`, which from the definition of $e_1; e_2$ entails that the effect of s is at most R . At a call site, the rule [M-CALL-NON-ATOMIC] requires that the current reducible sequence is trivial/empty and meets the function’s one-store precondition S by requiring the precondition $\text{Two}(S)$ prior to the call. The rule also converts the function’s one-store postcondition T to the two-store predicate $\text{Two}(T)$.

8.4 Verifying States

We now define the verification judgment $\vdash \Sigma$ to verify program states $\Sigma = s_1..s_n \cdot \sigma$. The rule [M-STATE] for this judgment in Figure 9 ensures that:

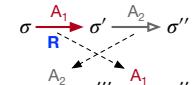

- each thread s_t verifies from a precondition P_t that includes the initial store σ ;
- any pending behavior Q_t at thread termination is published to G ;
- the thread guarantee G is reflexive;
- the guarantee of each thread is contained in the rely assumption of every other thread;
- each function definition in the global table D is verifiable; and
- that all threads start with a `yield` statement (to simplify the correctness proof).

A mover specification M makes claims about how steps of one thread commute with respect to steps of other threads, and mover logic needs to ensure that those claims are correct. Specifically, we define a mover specification to be *valid* if:

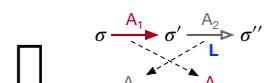

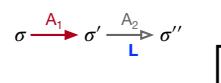

1. Right-moving actions can be moved later in a trace without changing the final store.
 2. Left-moving actions can be moved earlier in a trace without changing the final store.
 3. An action by one thread cannot change the effect of an action in another thread.
 4. An action by one thread cannot cause a left-moving action in another thread to block.
- We formalize these validity requirements as follows:

► **Definition 1** (Validity). M is valid if the following four conditions hold for all threads $t \neq u$ and $A_1, A_2, \sigma, \sigma'$:

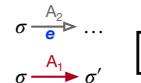

- (1) if $M(A_1, t, \sigma) \sqsubseteq R$ and $(t, \sigma, \sigma') \in A_1$ and
 $M(A_2, u, \sigma') \sqsubseteq L$ and $(u, \sigma', \sigma'') \in A_2$,
then there exists σ''' such that
 $(u, \sigma, \sigma''') \in A_2$ and $(t, \sigma''', \sigma'') \in A_1$.

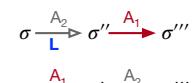

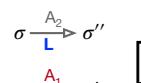

- (2) if $M(A_1, t, \sigma) \sqsubseteq N$ and $(t, \sigma, \sigma') \in A_1$ and
 $M(A_2, u, \sigma') \sqsubseteq L$ and $(u, \sigma', \sigma'') \in A_2$,
then there exists σ''' such that
 $(u, \sigma, \sigma''') \in A_2$ and $(t, \sigma''', \sigma'') \in A_1$.

- (3) if $M(A_1, t, \sigma) \sqsubseteq N$ and $(t, \sigma, \sigma') \in A_1$ and
 $M(A_2, u, \sigma) = e$ for some e ,
then $M(A_2, u, \sigma') = e$.

- (4) if $M(A_1, t, \sigma) \sqsubseteq N$ and $(t, \sigma, \sigma') \in A_1$ and
 $M(A_2, u, \sigma) \sqsubseteq L$ and $(u, \sigma, \sigma'') \in A_2$,
then there exists σ''' such that
 $(u, \sigma', \sigma''') \in A_2$ and $(t, \sigma'', \sigma''') \in A_1$.

8.5 Correctness

The central correctness theorem for mover logic is that verified programs do not go wrong by, for example, failing an assertion.

► **Theorem 2** (Soundness). If $\vdash \Sigma$ then Σ does not go wrong.

The proof appears in full in the extended version of this paper [20]. The basic structure is as follows.

1. We first develop an instrumented semantics that enforces the mover specification M and also that each thread consists of reducible sequences separated by yields.
2. In addition to the usual preemptive scheduler, we also develop a non-preemptive scheduler for the instrumented semantics that context switches only at yields.
3. We show that the instrumented semantics under the preemptive scheduler behaves the same as the standard semantics except that it may go wrong more often.
4. We use a reduction theorem to show that programs exhibit the same behavior under the preemptive and non-preemptive instrumented semantics.
5. Finally, we use a preservation argument [58] to show that verified programs do not go wrong under the non-preemptive instrumented semantics.
6. The steps above then imply that verified programs do not go wrong under the preemptive standard semantics.

9 Related Work

Modular Reasoning

Concurrent software verification introduces a number of scalability challenges that require a synthesis of various notions of modularity or abstraction to address. For example, *procedure-modular* reasoning tackles large code bases by verifying each procedure with respect to a specification of other procedures in the system. Rely-guarantee logic [33] augments procedure-modular reasoning with a notion of *thread-modular* reasoning that accommodates multiple threads by verifying each thread with respect to a specification of other threads in the system. As demonstrated in Section 2, systems like RG logic that support procedure-modular and thread-modular reasoning have great potential, but they are limited by entanglement between library and client specifications.

To address that limitation, mover logic augments procedure-modular and thread-modular reasoning with Lipton’s theory of reduction [41]. This complementary form of “interleaving” modularity limits the number of interleavings that must be considered and enables more precise procedure specifications for atomic functions.

In other work, separation logic combines procedure-modular reasoning with a notion of *heap-modular* reasoning [47, 49], which enables verification of sub-goals while ignoring irrelevant heap objects. Separation logic has been the foundation for a variety of verification tools [3, 32, 44]. Concurrent separation logics including, for example [53, 46, 5, 52], extend those ideas to a concurrent setting. While initially focused on noninterference via disjoint access and read-only sharing, later work [14, 13] supports more tightly-coupled threads.

Much of the work on concurrent separation logic focuses on *resources* (e.g., heap locations) and on ensuring threads access disjoint resources (hence ensuring noninterference). In contrast, mover logic focuses on commuting *actions*.

Concurrent separation logic and mover logic also differ in where thread interference specifications are placed. Concurrent separation logic conveniently merges interference (or resource footprint) specifications into each method’s precondition, thus enabling the logic to capture sophisticated resource usage idioms in a concise and elegant manner. Deny-guarantee reasoning [14] extends concurrent separation logic to focus more on actions rather than resources. In particular, a method’s precondition can include an “action map” specifying what actions the method (and its concurrent threads) may perform. This action map is analogous to our mover specifications. Several projects employ permissions or ownership, similar to separation logic, to reason about which memory locations are available to different threads. These include Viper [43] and VerCors [4]. These systems do not support reduction.

An important topic of future study is how to extend mover logic with a notion of heap modularity, perhaps similar to the core ideas of concurrent separation logic or dynamic frames [2, 51, 35]. This body of work may also provide insight into how to develop a compositional semantics based on mover logic.

Reduction-based Techniques

QED [15] is a program calculus and verification procedure for concurrent programs. It utilizes iterative reduction and abstraction refinement to increase the size of the blocks that can be considered serializable regions (at the abstract level). That approach has been shown to be quite successful for verifying complex concurrent code and has inspired a number of subsequent verification tools described below. Mover logic is a complementary approach in that the combination of RG reasoning and reduction enables direct verification of code

with `yield` points, without the need to create layers of abstractions. As part of that, mover logic supports specifying and reasoning about functions that are not atomic, which is not supported in QED. We also note that QED checks the commutativity properties of an action via a pairwise check with all other actions in the code, whereas mover logic uses the mover specification validity check for that purpose.

Several more recent verification tools utilize the same approach of writing a series of programs related by refinement, abstraction, and reduction. These include the CIVL verifier [30, 38, 40, 36, 37, 39] and the Armada verifier [42]. They are capable of handling sophisticated concurrent code, but do require the programmer to write and maintain multiple versions of the source code. The correctness arguments for these tools have typically been based on monolithic proofs.

Calvin-R [25] developed a number of early ideas related to reduction and thread-modular reasoning. The ANCHOR verifier [19] builds on ideas behind Calvin-R and CIVL to create a verification technique supporting an executable, object-oriented target language, a variety of synchronization primitives, and a new notation for specifying the interference between threads that is the foundation for our mover specifications. While effective at some verification tasks, ANCHOR’s correctness arguments are also challenging to understand and build upon. Further, ANCHOR is inherently limited to small programs because it inlines nested calls during verification, with no mechanism for procedure-modular reasoning. Mover logic may provide a useful foundation for a procedure-modular extension of ANCHOR.

The difficulty in assessing the strengths and weaknesses of the tools mentioned above without a robust underlying logic capturing what they do inspired this work. Mover logic may provide such a foundation, detached from any particular full-scale implementation, that it is accessible, general, and extensible. We hope implementations based on mover logic will follow, as the logic clarifies exactly what conditions must be met in reduction-based verifiers that attempt to integrate modular reasoning in the presence of interference.

Coq-based Techniques

Complementary approaches develop proof frameworks for verifying concurrent programs in Coq [12]. For example, CCAL [28] provides a compositional semantic model for composing and verifying the correctness of multithreaded components. CCAL focuses on only rely-guarantee reasoning [33] and not reduction. CSpec [7] is a Coq library for verifying concurrent systems modeled in Coq [12] using movers and reduction. While highly expressive, particularly because additional proof techniques can be added as additional Coq code, users must write significant Coq code for both specifications and proofs to use such a system. We have focused on a logic more amenable to fully automatic reasoning. Iris [34] uses higher-order separation logic to verify correctness of higher-order imperative programs.

Model Checking

An orthogonal approach to software verification utilizes explicit state, exhaustive model checking. Such approaches have lower programmer overhead than other techniques, but they are non-modular [16, 10, 11]. Specialized techniques, including reduction [29] and partial-order methods [27, 26, 48], have been used to limit state-space explosion while checking concurrent programs. A variety of concurrent software model checkers [8, 59, 45] have demonstrated the potential of these approaches in constrained settings.

10 Summary

Over the last two decades, several promising multithreaded program verifiers have leveraged reduction to verify sophisticated concurrent code including non-blocking algorithms, dynamic data race detectors, and garbage collectors by leveraging precise, reusable specifications for atomic functions. The reasoning used by these verifiers, including the notion of which programs are verifiable, and why the verification process is sound, is unfortunately rather complex. In contrast, Hoare logic [31] provides an accessible foundation for sequential verifiers, and RG logic [33] provides a similar foundation for some multithreaded verifiers.

In developing mover logic, we aim to facilitate future research on reduction-based verification. Mover logic provides a declarative and formal explanation of reduction-based verification, making it easier to understand which programs are verifiable, or not, and why; which functions can be specified as atomic; what atomic and non-atomic function specifications mean; which code blocks are reducible; where yield annotations are required, etc. The correctness proof for a reduction-based verifier need only show that the verifier follows the rules of mover logic, a significant simplification over existing proof techniques.

We hope that mover logic inspires the development of more expressive reduction-based logics and verification tools, potentially supporting features such as objects, data abstraction, dynamic allocation, dynamic thread creation, and precise frame conditions [2, 51, 35].

Abstract

Join patterns provide a promising approach to the development of concurrent and distributed message-passing applications. Several variations and implementations have been presented in the literature – but various aspects remain under-explored: in particular, how to specify a suitable notion of message matching, how to implement it correctly and efficiently, and how to systematically evaluate the implementation performance.

In this work we focus on actor-based programming, and study the application of join patterns with conditional guards (i.e., the most expressive and challenging version of join patterns in literature). We formalise a novel specification of *fair and deterministic join pattern matching*, ensuring that older messages are always consumed if they can be matched. We present a *stateful, tree-based join pattern matching algorithm* and prove that it correctly implements our fair and deterministic matching specification. We present a novel Scala 3 actor library (called `JoinActors`) that implements our join pattern formalisation, leveraging macros to provide an intuitive API. Finally, we evaluate the performance of our implementation, by introducing a systematic benchmarking approach that takes into account the nuances of join pattern matching (in particular, its sensitivity to input traffic and complexity of patterns and guards).

17.2 Fair Join Pattern Matching for Actors

We thank Omar Inverso for the technical support he provided for our experimental evaluation, Roland Kuhn for fruitful discussions on the shop floor use case, António Ravara for some useful suggestions, and Antoine Sébert for an implementation of join patterns using Scala 3 macros [25]. We thank the anonymous reviewers for their comments and suggestions.

1 Introduction

Programming concurrent and distributed message-passing applications is difficult, especially in scenarios where multiple concurrent processes need to synchronise and exchange data when complex conditions are satisfied. The join calculus [8] introduced *join patterns*, an intriguing construct for concurrent programming that can help address these scenarios. A *join pattern with conditional guard* is reminiscent of a clause in a typical pattern matching construct: it has the form “ $J \text{ if } \gamma \triangleright P$ ” – where J is a *message pattern* describing a combination of incoming messages and binding zero or more variables, and γ is a *guard*, i.e., a boolean expression that may use the variables bound in J . A program using join patterns can wait until a desired combination of messages arrives (in any order); when some of the messages are matched by the message pattern J and their payloads satisfy the guard γ , the process P is executed. We now illustrate programming with join patterns with an example emerging from an industrial case study where a monitoring program handles a variety of messages emitted by machines and devices deployed on a factory shop floor. (To illustrate our proposal, we only show a representative sample of the the actual monitoring application.)

```
1 def monitor() = Actor[Event, Unit] {
2     receive { (self: ActorRef[Event]) => {
3         case ( Fault(_, fid1, _, ts1),
4               Fix(_, fid2, ts2) ) if fid1 == fid2 =>
5             updateMaintenanceStats(ts1, ts2)
6             Continue
7
8         case ( Fault(mid, fid1, descr, ts1),
9               Fault(_, fid2, _, ts2),
10            Fix(_, fid3, ts3) ) if fid2 == fid3 && ts2 > ts1 + TEN_MIN =>
11             updateMaintenanceStats(ts2, ts3)
12             log(s"Fault ${fid1} ignored for ${(ts2 - ts1) / ONE_MIN} minutes")
13             self ! DelayedFault(mid, fid1, descr, ts1) // For later processing
14             Continue
15
16         case ( DelayedFault(_, fid1, _, ts1),
17                 Fix(_, fid2, ts2) ) if fid1 == fid2 =>
18             updateMaintenanceStats(ts1, ts2)
19             Continue
20
21         case Shutdown() => Stop
22     }
23 }
```

Listing 1 Simplified factory shop floor maintenance monitor, written using our Scala 3 library `JoinActors` (presented in Section 4).

Example: Monitoring a Factory Shop Floor. The Scala 3 Listing 1 is structured as an actor [1] that uses our join patterns library `JoinActors` (as introduced in Section 4). Its coding style is reminiscent of popular libraries like Akka and Pekko.¹ The constructor `Actor[Event, Unit]` (line 1) means that the actor’s mailbox receives messages of type `Event` (which has various subtypes), and whenever the actor stops running, it yields a `Unit` value. The “`receive { ... }`” block (lines 2–22) executes whenever messages are received, binding `“self”` to a reference to the monitor actor itself (usable to send messages to its mailbox).

The monitor actor in Listing 1 is used in a scenario where machines on the factory shop floor may occasionally require human intervention, so they may emit messages like `Fault(3, 42, "Motion sensor error", 10:31)` carrying information such as the machine and fault identifiers as well as a description and timestamp. When such an event occurs, a technician is expected to reach the machine and report that the fault is being fixed, by using a handheld device to emit a message like `Fix(35, 42, 10:33)` (carrying the worker id, fault id being fixed, and timestamp).

The key difference between the actor depicted in Listing 1 and a “standard” actor in libraries like Akka/Pekko lies in their message processing mechanisms. While the latter can only react to *individual* messages arriving in its mailbox, the actor in Listing 1 reacts whenever a *combination* of messages in its mailbox matches one of the *join patterns with guards* specified within its “`receive { ... }`” block.

- The case on lines 3–4 is triggered when the monitor detects in its mailbox both a `Fault` and a `Fix` message referring to the same fault (guard “`fid1 == fid2`”). In this case, the messages are removed from the mailbox, the monitor updates certain maintenance statistics (line 5), and then resumes execution by returning `Continue` (line 6).
- The case on lines 8–10 activates when the monitor sees *two* `Fault` message and a `Fix` message that handles the most recent fault, with the older fault being emitted more than 10 minutes earlier (guard “`fid2 == fid3 && ts2 > ts1 + TEN_MIN`”). In this case, the monitor also logs a warning and resends the unhandled fault to its own mailbox (as a `DelayedFault`) for later processing (lines 12–13);
- The case on lines 16–17 is similar to the first case above, except that it consumes the `DelayedFaults` emitted by the second case;
- The case on line 21 reacts to a `Shutdown` message by `Stopping` the monitor.

Notice that the join pattern matching cases do not depend on the order of messages in the mailbox: for instance, the first and second cases in Listing 1 (lines 3–4, 8–10) can be triggered even if, due to network delays or temporary partitions, the `Fix` message reaches the monitor mailbox *before* the corresponding `Fault`.²

The monitor in Listing 1 has a declarative and rather intuitive flavour – but writing it without a library (like ours) supporting join patterns is much harder. E.g., to just implement the first and second case (lines 3–4, 8–10), a programmer writing a “regular” Akka/Pekko actor would need to write code for processing one incoming message at a time, remembering how many `Faults` and/or `Fixes` it has seen thus far, and checking whether any combination creates a match with the newly-arrived message, and satisfies the guards; this handcrafted pattern matching logic should not “forget” any message combination, and should also support messages arriving out-of-order. As the number and complexity of message patterns increases, the handcrafted pattern matching code can become complicated, bug-prone, and inefficient.

¹ <https://akka.io/>, <https://pekko.apache.org/>

² The program in Listing 1 only assumes that each device has an accurate-enough clock, so message timestamps can be compared (with some tolerance) to determine which event happened first.

Open Problems. Although promising, join patterns are still subject of research and their adoption has yet to become “mainstream” in programming. In this work we tackle three aspects that, we believe, have been under-explored thus far.

1. *Formalising how a join pattern matching construct should select messages when multiple options are available.* Existing work (both theoretical and implementation-oriented, discussed in Section 2) leaves the message selection unspecified (i.e., allowing for non-determinism in the matching semantics), or follows a “first matching pattern wins” approach – which may cause older messages to be “forgotten” in the mailbox to the advantage of newer messages (we will discuss this in Section 3). This may yield “unfairness” towards the messages in the mailbox: a message in the box is perpetually neglected when “newer” messages are used in the matching.³
2. *Implementing join patterns with guards in a correct and efficient way.* Most existing implementations address message patterns without guards [9, 2, 23, 27, 16]. However, supporting guards is much harder: finding a combination of messages in a mailbox that satisfies a guard may require computing up to a factorial number of message combinations, and in order to reduce such computations, it becomes necessary to maintain the state of partial matches. Other authors have considered this issue [12, 20, 22] – but unlike us, they have either not provided a specific notion of matching nor demonstrated that their optimisation approaches (if any) *correctly* adhere to a desired matching specification (see problem 1 above). In fact, the papers [12, 20] do not define a notion of “preferred matching” while such a notion is mentioned in the doctoral thesis [21] without a formal definition nor proof of the properties of their algorithm.
3. *Systematically evaluating join pattern matching performance.* The performance of join pattern matching is highly dependant on the input message traffic and on the complexity of patterns and guards – but these aspects have not been systematically explored, and there is no standardised benchmarking suite for join pattern implementations (akin to Savina [13] for actor implementations). For instance, the measurements in [27] focus on classic synchronisation problems, with simple patterns, and without guards.

Contributions and Structure of the Paper. We address the aforementioned challenges by presenting a novel formalisation and implementation of join pattern matching with guards. After the background and related work (Section 2), we introduce our contributions.

- In Section 3, we present a formal specification of *fair and deterministic join pattern matching* guaranteeing that oldest messages are always consumed if they can be used (Defs. 3.8 and 3.10). We also introduce a *stateful tree-based matching algorithm* (Defs. 3.20 and 3.23), and we prove that it respects the formal specification of fair matching (Theorem 3.25).
- In Section 4 we present **JoinActors**, our Scala 3 library for actors with join patterns, including both a “brute-force” and a stateful tree-based implementation of our deterministic fair matching semantics. **JoinActors** uses macros to provide an intuitive API. **JoinActors** is the companion artifact of this paper.
- In Section 5 we evaluate the relative performance of the matching algorithms implemented in **JoinActors**, including (in Section 5.6) a comparison with an alternative implementation of our fair matching policy that uses the RETE algorithm [6]. Our evaluation explores variations of the input traffic and the complexity of join patterns and guards: we see this

³ This can be considered a form of *fairness of instruction* according to the terminology in [11].

as a step towards a standardised and systematic benchmarking approach for future join pattern implementations. Overall, our experiments show that the performance of our implementation of the stateful tree-based matching is suitable for applications like floor shop monitoring (described above) or smart house automation (described in Section 5.3).

We conclude and discuss our future work in Section 6 – including alternative matching policies. In this work we have chosen to formalise a “oldest messages first” matching policy because it fits many scenarios – in particular, our factory shop floor monitor (where, as in many application domains, a “first-arrived-first-served policy” is required, and non-deterministic matching would be inadequate), and the examples we could find in literature.

2 Background and Related Work

The Join calculus [8], emerging in the late 1990s as a variant of the asynchronous pi-calculus, aimed at enhancing the implementability of process calculi by introducing disciplined rules regarding locality and scoping. Its distinctive feature is the integration of restriction, recursion, and synchronization into a single language primitive: the *join definition*. A join definition comprises a list of *reaction rules* of the form $J \triangleright P$, where J is the *join pattern* and P is the process associated with the rule. Essentially, a join pattern specifies the message pattern necessary to activate the process P . For instance, in the construct $c_1(x) \wedge c_2(y) \triangleright P$, we have that c_1 and c_2 represent communication channels, and the process P is activated when messages are present in both channels. Hence, if messages like $c_1(m_1)$ and $c_2(m_2)$ are detected, they are consumed, and the process P is executed by substituting the variables x and y with the corresponding values m_1 and m_2 (i.e., P is executed as $P\{m_1, m_2/x, y\}$). A reaction rule can be seen as an evolution of a function definition in a concurrent message-passing setting: a function activates its body upon invocation from another function, through variable substitution – whereas a reaction rule $J \triangleright P$ activates P only when the join pattern J is “invoked” by one or more concurrent processes that send the required input messages; when this happens, P is executed through variable substitution.

Multiple reaction rules can be combined, such as: $c_1(x) \wedge c_2(y) \triangleright P_1 + c_1(z) \wedge c_3(w) \triangleright P_2$. When multiple rules share channels (as c_1 in the previous example), there may be conflicting synchronisations, as rules contend for messages. For example, if channels c_1 , c_2 , and c_3 in the previous example have a message available, either P_1 or P_2 can be activated. Significantly, all conflicting synchronisations are defined within the same combination of reaction rules: consequently, all consumers of messages within a channel are locally introduced by a definition, eliminating the need for global consensus in synchronisation.

Since its inception, the join calculus has inspired implementations in various programming languages [9, 7, 5, 14, 2, 23, 24, 27]. Early implementation approaches [5] were centered around *matching automata*, where join definitions are compiled into deterministic automata. In this cases, state corresponds to the state of message queues and transitions to the arrival of messages. Although the foundational principles of this approach have since been adopted in other implementations [2, 23, 24], newer methods have evolved to avoid the explicit construction of automata. Initially, most implementations relied on coarse-grained synchronization to guarantee the atomic consumption of messages. However, this strategy has been refined [27] by employing fine-grained concurrency for enhanced scalability. This involves the utilization of lock-free data structures and minimizing message enqueueing whenever possible. Subsequent optimizations have further been explored in implementations incorporating session types [10] to prune the size of matching automata.

The initial implementations adhere to the original join pattern model and not support pattern matching on consumed values. However, subsequent implementations expanded matching capabilities. This line of work has been started in [19], where join patterns were enriched with matching on constant values. This approach has been extended in [16] to incorporate pattern matching on algebraic data structures. An example of this extended approach involves message patterns such as $\text{pop}(e) \wedge \text{stack}(x :: xs)$ where the pattern associated with the channel *stack* expects a message containing a non-empty list. In such scenarios, efficient pattern satisfaction can be achieved by translating these extended join patterns into equivalent programs. These programs utilize conventional join patterns in their definitions while incorporating ML-style pattern matching in the processes executed after a join pattern match. Also, [16] showed that *linear* message patterns (i.e., where each bound variable occurs once) without guards can be implemented efficiently by checking bit flags.

The implementation of more expressive forms of pattern matching have been studied in [12, 20, 22]. These works are conceptually more similar to ours: unlike [16], these works support join patterns that include *conditional guards*, i.e., their reaction rules may look like $c_1(x) \wedge c_2(y) \text{ if } x < y \triangleright P$ (resembling pattern matching guards in Erlang or Scala); moreover, these works adapt join patterns to an actor-based setting: in the example above, P is activated when the mailbox of the running actor contains, e.g., the messages $c_1(1)$ and $c_2(2)$ (in any order, and possibly among other messages). The introduction of conditional guards significantly improves the usability of join patterns, but also significantly complicates the implementation of join pattern matching; these works adopt different approaches for finding and selecting a match among incoming messages. Both [12] and [20] adopt a “first-match” approach [26], i.e., given a combination of reaction rules, they select the first one that successfully matches the messages in the mailbox; to find that match, [12] adopts a “stateless brute force” approach (i.e., when the mailbox contains a set of messages that might potentially be matched by a join pattern, it tries all message combinations), while [20] maintains a state containing a cache of partial matches, to reduce unnecessary computations. Also, [22] reportedly adopts a variant of the RETE algorithm [6] to maintain a cache of partial matches (as a *discrimination network*) – but its implementation is not publicly available.

In the join calculus, join definitions have non-deterministic matching policies: when multiple message combinations or patterns are enabled (as we will show in Example 3.5), one option is chosen non-deterministically. Correspondingly, existing work and implementations based on join calculus leave matching policies unspecified, or pick the first pattern that completes a match. However, in scenarios where the message selection policy is critical (as in our factory automation example in Section 1, where earlier events must be handled first), the programmer has to encode the selection logic and maintain complex states to achieve the desired outcome. This paper addresses the issue by formalising *fair and deterministic* join pattern matching, inspired by matching mechanisms in functional languages. Drawing from our real-world factory automation use case, we propose an approach that ensures fair message consumption based on messages “age.” While other application scenarios may require different resolution policies, we argue that such policies should be enforced by library mechanisms. (We discuss some alternative policies in Section 6.) In contrast to prior work, we emphasise the formalisation of properties guaranteed by the matching mechanism: we introduce a formal specification of fair matching and prove that a stateful algorithm effectively implements that specification. We also contribute a comprehensive evaluation, as a first step toward a standard benchmark suite for join pattern implementations.

An interesting effect-handlers-based language is formalised in [3] to program different styles of matching across different message streams. Besides a common connection to the join calculus, a key design difference with our work is that we focus on matching messages within

an actor mailbox. The resulting features and applications are very different (e.g. a message in a mailbox may be matched at a later time, after other messages from the same emitter – which is not possible in a stream-based framework. Also, the work [3] does not address a notion of fair matching among juxtaposed “joins over asynchronously arriving events” that compete over the same input messages: in their modelling, no event binding takes precedence over the other, all iterations proceed independently and concurrently [3, page 67:14–15].

3 Formalisation

In this section we present the formalisation and properties of our approach to join pattern matching. In Section 3.1 we formalise the necessary notation, and in Section 3.2 we present a specification of *deterministic and fair matching*, covering both individual join patterns (Def. 3.8) and definitions (Def. 3.10). Then, in Section 3.3 we present a stateful matching algorithm that implements our fair matching specification (Theorem 3.25) while avoiding unnecessary computations.

3.1 Syntax

To abstractly represent messages, we assume a set \mathbb{C} of *constructors* equipped with a map arity assigning a natural number to each constructor; then, $\text{arity}(c) \geq 0$ is the *arity* of $c \in \mathbb{C}$ (c is a constant symbol if $\text{arity}(c) = 0$). A *message* is either a constructor of arity 0 or a term of the form $c(m_1, \dots, m_n)$ where $c \in \mathbb{C}$, $\text{arity}(c) = n > 0$, and m_i is a message (for $i \in 1..n$). For instance, for the example in Section 1, `Fault(3, 42, "Motion sensor error", 10:31)` is a message, with `Fault` being a constructor of arity 4 (numbers, strings, and timestamps are constant symbols represented in the usual way for readability). Through the paper we use *boolean guards* as pure expressions denoted with γ , using the syntax of boolean expressions of Scala; we also use *mailboxes* denoted as \mathcal{M} , as sequences of messages $m_1 \cdot \dots \cdot m_n$. We will also denote *variables* with the symbols y, w, z, \dots

Intuitively, a join pattern is a combination of “messages with variables” that binds the variables occurring therein. Multiple alternative join patterns can be composed in a *join definition*. In Def. 3.1 we formalise join patterns equipped with guards, and join definitions.

► **Definition 3.1** (Join patterns and join definitions). *The syntax of join patterns Π and join definitions D is given by the following grammar:*

$$\begin{aligned} \Pi &::= J \text{ if } \gamma & \text{where } J ::= \mu \mid \mu \wedge J \quad \text{and} \quad \mu ::= m \mid x \mid c(\mu_1, \dots, \mu_{\text{arity}(c)}) \\ D &::= \Pi \mid \Pi + D \end{aligned}$$

We postulate that J if γ must be well-formed, namely: (i) linear, i.e., no variable in J occurs more than once, and (ii) closed, i.e., each variable occurring in the guard γ also occurs in J . We will often simply write J as shorthand for J if `true`.

Assumption (i) in Def. 3.1 is quite standard: e.g., Scala and F# require linear use of pattern matching variables, and non-linear use can be simulated using guards (see Example 3.2 below). Assumption (ii) does not limit our results: in fact, if a guard contains variables bound elsewhere in the surrounding program, then all such variables would be substituted by values (thus “closing” the join pattern) *before* any match is attempted.

► **Example 3.2** (Well-formedness of join patterns). The join patterns shown in Example 3.4 (and also in Listing 1) are well-formed, since they are both linear and closed, whereas

$$\text{Fault}(mid_1, fid, descr_1, ts_1) \wedge \text{Fix}(wid_2, fid, ts_2)$$

is not-well formed, since the double occurrence of variable fid violates linearity. Intuitively, repeating fid can be a convenient way to state that the same fault id fid must appear in both messages. This is not supported by our formalisation – but the same effect can be obtained by linearising the join pattern: it is sufficient to rename the variables into fid_1 and fid_2 and introduce a guard $\text{fid}_1 = \text{fid}_2$, obtaining the first pattern shown in Example 3.4 below. \square

We write $\{m_1, \dots, m_n/x_1, \dots, x_n\}$ for a *substitution*, that is a map that replaces each variable x_i for message m_i . A substitution σ can be applied to join patterns and guards; for instance, the application of the substitution $\sigma = \{42/x\}$ to the join pattern $J = \text{Message}(x)$, written $J\sigma$, yields $\text{Message}(42)$. Similarly $(\text{isOdd}(x))\sigma = \text{isOdd}(42)$.

► Remark 3.3. A typical join pattern rule has the form $J \text{ if } \gamma \triangleright P$. Following the formalisation of ML-style pattern matching in [17], we omit the continuation process P to focus on the matching semantics. Adding continuations P to our formalisation is routine: it would be enough to apply substitutions σ produced by a match to the omitted process, as $P\sigma$.

Intuitively, a mailbox $M = m_1 \cdot \dots \cdot m_n$ yields a match for the join pattern $\Pi = \mu_1 \wedge \dots \wedge \mu_m \text{ if } \gamma$ in D if there is a substitution σ replacing all the variables in Π with some of the messages in the mailbox, such that $\gamma\sigma$ holds `true`; each message in M can be used at most once. A *variable* x matches any message, whereas a message constructor pattern like $\text{Fault}(x, 42, y, w)$ can only match a message built with a corresponding constructor, like $\text{Fault}(3, 42, \text{"Sensor error"}, 10:31)$ with the substitution $\{3, \text{"Sensor error"}, 123456/x,y,w\}$. (For the precise matching semantics, see in Section 3.2.) Observe that when all variables in a join pattern Π are substituted we obtain one or more \wedge -separated messages; likewise, when all variables in a guard γ are substituted, we can evaluate the boolean expression (e.g., a predicate like $\gamma\sigma = \text{isOdd}(42)$ might evaluate to `false`).

A join definition $D = \Pi_1 + \dots + \Pi_k$ specifies a pattern matching operation among one of the join patterns with guards $\Pi_1 \dots \Pi_k$. This formal notation abstracts the construct `receive { ... }` shown in Listing 1: each `case` in the `receive { ... }` is a join pattern in D .

► Example 3.4 (Syntax of join definitions). Assuming $\text{Fault}, \text{Fix} \in \mathbb{C}$ and adopting the syntax in Def. 3.1 and of boolean Scala expressions, the first two join patterns in Listing 1 are:

$$\begin{aligned} & \text{Fault}(mid_1, fid_1, descr_1, ts_1) \wedge \text{Fix}(wid_2, fid_2, ts_2) && \text{if } fid_1 = fid_2 \\ + \quad & \text{Fault}(mid_1, fid_1, descr_1, ts_1) \wedge \text{Fault}(mid_2, fid_2, descr_2, ts_2) \\ & \wedge \text{Fix}(wid_3, fid_3, ts_3) && \text{if } fid_2 = fid_3 \ \&\& \ ts_2 > ts_1 + \text{TEN_MIN} \end{aligned}$$

where `TEN_MIN` is a Scala constant representing 10 minutes; for readability, similar constants are silently assumed throughout our examples. \square

3.2 Fair and Deterministic Matching Semantics for Join Patterns

We now define the notion of pattern matching for a join pattern $\Pi = \mu_1 \wedge \dots \wedge \mu_n \text{ if } \gamma$. If we have $n = 1$ and a single message m , we can apply standard definitions from functional programming languages [17] and say that Π matches m if there is a substitution σ such that (i) $\mu_1\sigma = m$, and (ii) $\gamma\sigma$ evaluates to `true`. (Clearly, such a match can only happen if σ substitutes *all* variables occurring in μ .) Instead, if $n > 1$ and we have multiple messages available in a mailbox M , things are more difficult: there may be multiple ways for the message pattern $\mu_1 \wedge \dots \wedge \mu_n$ to match different subsets of messages in M while satisfying the guard γ ; moreover, a join definition D might contain several join patterns that match (part of) the mailbox contents. Example 3.5 illustrates this.

► **Example 3.5** (Multiple options for join pattern matching). Let $D = \Pi_1 + \Pi_2$ where:

$$\begin{aligned}\Pi_1 &= \text{Fault}(id_1, _) \wedge \text{Fix}(id_2) \text{ if } id_1 = id_2 \\ \Pi_2 &= \text{Fault}(_, t_1) \wedge \text{Fault}(id_2, t_2) \wedge \text{Fix}(id_3) \text{ if } id_2 = id_3 \&& t_2 > t_1 + \text{TEN_MIN}\end{aligned}$$

(observe that D corresponds to the first two cases in Listing 1 modulo the omission of unused messages and variables). Suppose we have the following mailbox, where subscripts show the arrival order of messages (the lower the subscript, the older the message):

$$M = \text{Fault}_1(1, 10:35) \cdot \text{Fault}_2(2, 10:39) \cdot \text{Fault}_3(3, 10:56) \cdot \text{Fix}_4(3)$$

Before message Fix_4 lands in the mailbox, none of the join patterns matches any message combination in the mailbox. Instead, when Fix_4 arrives, we have the following options:

- the first join pattern matches the messages Fault_3 and Fix_4 , via the substitution $\{3, 3 / id_1, id_2\}$
- the second join pattern matches both:
 - messages Fault_1 , Fault_3 , and Fix_4 , via the substitution $\{3, 3, 10:35, 10:56 / id_1, id_3, t_1, t_2\}$;
 - messages Fault_2 , Fault_3 , and Fix_4 , via the substitution $\{3, 3, 10:39, 10:56 / id_1, id_3, t_1, t_2\}$. \sqcup

Existing implementations of join patterns leave the resolution of non-deterministic choices unspecified, or pick the first matching pattern as the “winner.” Our approach is different: we formalise a deterministic matching policy to give programmers control over the selection process. Consequently, we specify how to deterministically choose the messages matched by a join pattern in Example 3.5, as well as deterministically decide which join pattern “wins” when both match messages in the mailbox.

Def. 3.8 below formalises a *deterministic* and *fair* notion of join pattern matching: when a join pattern can match multiple combinations of messages in the mailbox, we prioritise the combination that consumes the oldest messages. To this end, we first introduce some notation in Def. 3.6 that we will use to reason about mailbox contents.

► **Definition 3.6** (Sequence length, indexing, slicing, and ordering). *Given a set S and a sequence $\mathcal{S} = s_1 \cdot \dots \cdot s_n$ containing elements of S , we write $|\mathcal{S}|$ for the length of \mathcal{S} , ϵ for the empty sequence, and $\mathcal{S}[i]$ with $i \in 1..|\mathcal{S}|$ for the element at the i^{th} position of \mathcal{S} . An indexing sequence, denoted by \mathcal{I} , is a non-empty sequence of pairwise-distinct natural numbers greater than 0. Given a sequence \mathcal{S} and an indexing sequence $\mathcal{I} = i_1 \cdot \dots \cdot i_n$ such that $i_h \in 1..|\mathcal{S}|$ for each $h \in 1..n$, we write $\mathcal{S}[\mathcal{I}]$ for the \mathcal{I} -slice of \mathcal{S} , which is the sequence $\mathcal{S}[i_1] \cdot \dots \cdot \mathcal{S}[i_n]$.*

Let S be a set with a total order \sqsubseteq . Then, the lexicographic order \leq_{lex} is the relation on sequences in S^ inductively defined as: (note that \leq_{lex} only relates sequences of equal length)*

$$\frac{}{\epsilon \leq_{\text{lex}} \epsilon} \quad \frac{s \sqsubseteq s' \quad s \neq s'}{s \cdot \mathcal{S} \leq_{\text{lex}} s' \cdot \mathcal{S}'} \quad \frac{\mathcal{S} \leq_{\text{lex}} \mathcal{S}'}{s \cdot \mathcal{S} \leq_{\text{lex}} s \cdot \mathcal{S}'}$$

Letting $\text{sort}(\mathcal{S})$ be the function returning the sorted sequence of elements of \mathcal{S} based on the total order \sqsubseteq , we also define the sorted length-biased lexicographic order \leq_{slex} as:

$$\frac{n = |\mathcal{S}'| \leq |\mathcal{S}| \quad \text{sort}(\mathcal{S})[1 \cdot \dots \cdot n] \leq_{\text{lex}} \text{sort}(\mathcal{S}')}{\mathcal{S} \leq_{\text{slex}} \mathcal{S}'}$$

We also define $=_{\text{slex}}$ as $\leq_{\text{slex}} \cap \leq_{\text{slex}}^{-1}$. Note that \leq_{slex} is a preorder.

► **Example 3.7.** Using relations \leq_{lex} and \leq_{slex} in Def. 3.6 on sequences of integers, we have:

$$\begin{aligned}1 \cdot 2 \cdot 3 &\leq_{\text{lex}} 1 \cdot 3 \cdot 2 \leq_{\text{lex}} 2 \cdot 1 \cdot 3 \leq_{\text{lex}} 2 \cdot 3 \cdot 1 \leq_{\text{lex}} 3 \cdot 1 \cdot 2 \leq_{\text{lex}} 3 \cdot 2 \cdot 1 \\ 1 \cdot 2 \cdot 3 \cdot 4 &=_{\text{slex}} 4 \cdot 3 \cdot 2 \cdot 1 <_{\text{slex}} 1 \cdot 2 \cdot 3\end{aligned}$$

► **Definition 3.8** (Fair join pattern matching). We define the following judgements

$$\begin{array}{ll} \mathcal{M} \models_{\sigma} \Pi & \text{the join pattern } \Pi \text{ exactly matches mailbox } \mathcal{M} \text{ via substitution } \sigma \\ \mathcal{M} \models_{\mathcal{I}} \Pi & \text{the join pattern } \Pi \text{ sparsely matches mailbox } \mathcal{M} \text{ via slice } \mathcal{I} \\ \mathcal{M} \models \Pi \rightsquigarrow \mathcal{I} & \text{the join pattern } \Pi \text{ fairly matches mailbox } \mathcal{M} \text{ via slice } \mathcal{I} \end{array}$$

by the following inference rules:

$$\frac{\forall i \in \{1, \dots, n\} : \mu_i \sigma = m_i \quad \gamma \sigma \quad \mathcal{M}[\mathcal{I}] \models_{\sigma} \Pi \quad \mathcal{M} \models_{\mathcal{I}} \Pi \quad \forall \mathcal{I}' : \mathcal{M} \models_{\mathcal{I}'} \Pi \implies \mathcal{I} \leq_{\text{lex}} \mathcal{I}'}{\mathcal{M} \models \Pi \rightsquigarrow \mathcal{I}}$$

In Def. 3.8, the judgement $\mathcal{M} \models_{\sigma} J$ if γ holds if J exactly matches all the messages in \mathcal{M} in the same order they occur therein, through a substitution σ such that the guard $\gamma \sigma$ holds.

This exact matching is used in the premise of judgement $\mathcal{M} \models_{\mathcal{I}} J$ if γ , which matches a slice \mathcal{I} of the mailbox \mathcal{M} : i.e., the message patterns in J may only match a (possibly reordered) subsequence $\mathcal{M}[\mathcal{I}]$ of the mailbox \mathcal{M} . Notice that the slice \mathcal{I} and the pattern J contain the same number of messages. Finally, the judgement $\mathcal{M} \models J$ if $\gamma \rightsquigarrow \mathcal{I}$ selects the smallest slice \mathcal{I} of \mathcal{M} w.r.t the order \leq_{lex} in Def. 3.6 such that $\mathcal{M} \models_{\mathcal{I}} J$ if γ holds. The selected slice \mathcal{I} represents the “fairest” possible match: \mathcal{I} indexes the oldest messages in \mathcal{M} that match J and satisfy the guard γ . This matching policy ensures that no message is left indefinitely in the mailbox if it can be used to match the join pattern. Note that, if two slices \mathcal{I} and \mathcal{I}' in the premise of the judgement contain the same indexes in different order (i.e., they may be deemed “equally fair”), the ordering \leq_{lex} deterministically selects the slice which minimises reordering between messages in \mathcal{M} and message patterns in J .

► **Example 3.9** (Fair join pattern matching). Let Π_1 , Π_2 , and \mathcal{M} be as in Example 3.5. By Def. 3.8 we have that:

- There is a single match for Π_1 : $\mathcal{M}[3 \cdot 4] \models_{\sigma} \Pi_1$ via $\sigma = \{3, 3 / id_1, id_2\}$. Hence, we also have $\mathcal{M} \models_{[3 \cdot 4]} \Pi_1$ and we also get $\mathcal{M} \models \Pi_1 \rightsquigarrow [3 \cdot 4]$ (i.e., the fairest way to match the join pattern Π_1 is to consume messages $Fault_3$ and Fix_4).
 - There are two matches for Π_2 :
 - $\mathcal{M}[1 \cdot 3 \cdot 4] \models_{\sigma} \Pi_2$ via $\sigma = \{3, 3, 10:35, 10:56 / id_1, id_3, t_1, t_2\}$. Therefore, $\mathcal{M} \models_{[1 \cdot 3 \cdot 4]} \Pi_1$;
 - $\mathcal{M}[2 \cdot 3 \cdot 4] \models_{\sigma} \Pi_2$ via $\sigma = \{3, 3, 10:39, 10:56 / id_1, id_3, t_1, t_2\}$. Therefore, $\mathcal{M} \models_{[2 \cdot 3 \cdot 4]} \Pi_2$.
- Hence, since $1 \cdot 3 \cdot 4 \leq_{\text{lex}} 2 \cdot 3 \cdot 4$, we conclude $\mathcal{M} \models \Pi_2 \rightsquigarrow [1 \cdot 3 \cdot 4]$ (i.e., the fairest way to match the join pattern Π_2 is to consume messages $Fault_1$, $Fault_3$, and Fix_4). \square

Def. 3.10 concludes this section by extending the notion of fair join pattern matching (Def. 3.8) to join definitions. The idea is that if a mailbox \mathcal{M} allows for multiple fair matches on different patterns in a join definition D , we pick the i^{th} join pattern in D that matches \mathcal{M} via the slice \mathcal{I} with the highest number of oldest messages w.r.t. the alternatives; and if two patterns in D yield equally fair matches, we pick the first in D . Since join patterns in D may match slices of different length, we rank the matches using \leq_{slex} (Def. 3.6). This approach makes the choice of patterns deterministic, while ensuring fairness.

► **Definition 3.10** (Matching of join definitions). The judgement $\mathcal{M} \models D \rightsquigarrow \mathcal{I}, i$ (read: “ D fairly matches mailbox \mathcal{M} via slice \mathcal{I} by its i^{th} join pattern”) is defined as:

$$\frac{\begin{array}{c} \text{Matches} = \{(\mathcal{I}, i) \mid i \in \{1, \dots, n\} \text{ and } \mathcal{M} \models \Pi_i \rightsquigarrow \mathcal{I}\} \\ (\mathcal{I}, i) \in \text{Matches} \quad \forall (\mathcal{I}', i') \in \text{Matches} : \mathcal{I} <_{\text{slex}} \mathcal{I}' \text{ or } (\mathcal{I} =_{\text{slex}} \mathcal{I}' \text{ and } i \leq i') \end{array}}{\mathcal{M} \models \Pi_1 + \Pi_2 + \dots + \Pi_n \rightsquigarrow \mathcal{I}, i}$$

► **Example 3.11** (Selecting the fairest match across join definitions (1)). Continuing Example 3.9, we can now apply Def. 3.10 to determine the fairest match for the join patterns sum $D = \Pi_1 + \Pi_2$. Since we have both:

$$\mathcal{M} \models \Pi_1 \rightsquigarrow [3 \cdot 4] \quad \text{and} \quad \mathcal{M} \models \Pi_2 \rightsquigarrow [1 \cdot 3 \cdot 4]$$

we rank the selected slices as $1 \cdot 3 \cdot 4 <_{\text{slex}} 3 \cdot 4$ (by Def. 3.6), i.e., the slice matched by Π_2 is fairer than the slice matched by Π_1 . Therefore, we conclude $\mathcal{M} \models D \rightsquigarrow (1 \cdot 3 \cdot 4), 2$. \square

► **Example 3.12** (Selecting the fairest match across join definitions (2)). To see why the relation \leq_{slex} (Def. 3.6) considers the lexicographical ordering of *sorted* sequences, consider this variation of Example 3.5:

$$\begin{aligned} \text{Fault}(id_1, _) \wedge \text{Fix}(id_2) && \text{if } id_1 = id_2 \\ + \quad \text{Fix}(id_3) \wedge \text{Fault}(_, t_1) \wedge \text{Fault}(id_2, t_2) && \text{if } id_2 = id_3 \ \& \& \ t_2 > t_1 + \text{TEN_MIN} \end{aligned}$$

Let Π_1 and Π_2 be the two join patterns above. Take the same mailbox \mathcal{M} used in Example 3.5. Observe that the message pattern constructors in Π_2 are reordered w.r.t. Example 3.5 – and therefore, we now have $\mathcal{M} \models \Pi_2 \rightsquigarrow [4 \cdot 1 \cdot 3]$ (i.e., the fairest match of Π_2 now consumes the slice $4 \cdot 1 \cdot 3$ of \mathcal{M}). Intuitively, this slice is lexicographically greater than the fairest slice $3 \cdot 4$ matched by Π_1 – but the slice $4 \cdot 1 \cdot 3$ consumes the older message at index 1. For this reason, by Def. 3.6 we have $4 \cdot 1 \cdot 3 =_{\text{slex}} 1 \cdot 3 \cdot 4 <_{\text{slex}} 3 \cdot 4$ – and consequently, the fairest match of Π_2 is ranked fairer than the fairest match of Π_1 . As a result, we obtain $\mathcal{M} \models D \rightsquigarrow (4 \cdot 1 \cdot 3), 2$ (by Def. 3.10) – i.e., despite the reordering of the message pattern constructors in Π_2 , we match the same messages of Example 3.11 (albeit with a differently-ordered slice). \square

3.3 Stateful, Tree-Based Matching Semantics for Join Patterns

Def. 3.8 offers a high-level specification for our notion of “fair matching” – but this definition does not automatically lead to an efficient implementation. To the contrary, the direct implementation of Def. 3.8 is a “stateless” brute-force algorithm that, whenever a new message reaches the mailbox: (i) enumerates all possible matches; (ii) lexicographically sorts the matches satisfying the guard γ , depending on the messages they use; and (iii) picks the match on the smallest mailbox slice (using the lexicographical ordering \leq_{lex} in Def. 3.6). This may require computing up to $n!$ message combinations for a mailbox of length n , every time a new message arrives. A similar brute-force approach is adopted in previous implementations of join patterns in literature [12]. A source of inefficiency is that many message combinations may be uselessly recomputed and retried when a new message arrives, even if such combinations have previously failed by falsifying the guard γ . Furthermore, when a new message yields two or more possible matches, finding the fairest one may lead to redundant computations. These issues are illustrated in Examples 3.13 and 3.14 below.

► **Example 3.13** (Redundant matching computations). Consider the join pattern Π_1 from Example 3.5 (recall that $\Pi_1 = \text{Fault}(id_1, _) \wedge \text{Fix}(id_2)$ if $id_1 = id_2$), and the following mailbox, where a message Fix_1 (emitted by a factory worker’s handheld device) is delivered to the monitor before the corresponding Fault_4 (emitted by a machine):

$$\mathcal{M} = \text{Fix}_1(3) \cdot \text{Fault}_2(1, 10:35) \cdot \text{Fault}_3(2, 10:36) \cdot \text{Fault}_4(3, 10:37)$$

We have to search for a match every time a new message lands in the mailbox:

- Π_1 cannot match message Fix_1 alone;
- when the message Fault_2 is delivered, the Π_1 matches $\text{Fix}_1 \cdot \text{Fault}_2$ – but the guard $id_1 = id_2$ is not satisfied;

17:12 Fair Join Pattern Matching for Actors

- when the message Fault_3 is delivered, the Π_1 can match $\text{Fix}_1 \cdot \text{Fault}_2 \cdot \text{Fault}_3$ in two possible ways using the combinations $(\text{Fix}_1, \text{Fault}_2)$ and $(\text{Fix}_1, \text{Fault}_3)$, neither of which satisfies the guard – note that $(\text{Fix}_1, \text{Fault}_2)$ has already been attempted;
- when the message Fault_4 is delivered, the Π_1 matches $\text{Fix}_1 \cdot \text{Fault}_2 \cdot \text{Fault}_3 \cdot \text{Fault}_4$ in a third possible way besides the previous two: in fact, the combination $(\text{Fix}_1, \text{Fault}_4)$ satisfies the guard – again note that the two failing combinations were already attempted. \square

► **Example 3.14** (Redundant fairness computations). Consider Π_2 and mailbox \mathcal{M} from Example 3.5:

$$\begin{aligned}\Pi_2 &= \text{Fault}(_, t_1) \wedge \text{Fault}(id_2, t_2) \wedge \text{Fix}(id_3) \text{ if } id_2 = id_3 \wedge t_2 > t_1 + \text{TEN_MIN} \\ \mathcal{M} &= \text{Fault}_1(1, 10:35) \cdot \text{Fault}_2(2, 10:39) \cdot \text{Fault}_3(3, 10:56) \cdot \text{Fix}_4(3)\end{aligned}$$

When the message Fix_4 lands in \mathcal{M} , the join pattern Π_2 matches two combinations of messages (as previously shown in Example 3.9), and they should be compared to determine the fairest. However, as soon as we determine that the combination $(\text{Fault}_1, \text{Fault}_3, \text{Fix}_4)$ satisfies the guard, it is redundant to try and compare other combinations – because none of them consumes the message Fault_1 , hence they cannot possibly be fairer, by Def. 3.8. \square

We present an algorithm to tackle these inefficiencies based on a *stateful* solution. Our algorithm keeps track of how the messages in a mailbox \mathcal{M} can *partially* match a join pattern Π , through a tree structure whose nodes contains sets of message indexes in \mathcal{M} , decorated with information on how such messages may complete Π . The way the tree is incrementally constructed allows us to (1) avoid recomputing previously-failed matches, and (2) immediately produce the fairest match (if it exists) via a depth-first traversal.

We use *mailbox trees* (*m-trees*) (Def. 3.15) to arrange integers (representing the indexes of the messages in a mailbox) into sets that form the nodes of a tree, so that, for each branch (X, Y) in the tree, the child node Y is a superset of its parent node X and $\max X < \max Y$.

► **Definition 3.15** (Mailbox trees). A mailbox tree on a finite set of natural number I (*m-tree* on I for short) is a tree $\mathcal{T} = (N, E)$ where:

- $N \subseteq 2^I$ is the set of nodes and $\emptyset \in N$ is the root the tree
- the cardinality of each node equals its level in \mathcal{T} and, for nodes X and Y at the same level, $X \cap Y = \emptyset$ and X precedes Y if $\max X \leq \max Y$
- for each edge $(X, Y) \in E$, $X \subset Y$ and $\max Y \notin X$.

We write $X \in \mathcal{T}$ if X is a node of \mathcal{T} and $i \in \mathcal{T}$ if there is $X \in \mathcal{T}$ such that $i \in X$. An *m-tree* \mathcal{T} on I is consistent when, for each level $h > 0$ of \mathcal{T} , $\bigcup\{X \in \mathcal{T} \mid X \text{ is at level } h\} = I$.

The “ramification” operation (Def. 3.16 below) is used to incrementally extend an m-tree by adding the index i of a new messages that has landed in a mailbox.

► **Definition 3.16** (Ramification). Given a tree $\mathcal{T} = (N, E)$ where the elements of N are subsets of numbers, and given a natural number $i \notin \mathcal{T}$, let:

$$N' = N \cup \{\bar{X} \cup \{i\} \mid \bar{X} \in N\} \quad \text{and} \quad E' = E \cup \{(Y \setminus \{\max Y\}, Y) \mid Y \in N'\}$$

Then, we call $r(\mathcal{T}, i) = (N', E')$ the ramification of \mathcal{T} with i .

Note that the ramification of a tree \mathcal{T} has twice as many nodes as \mathcal{T} . Also, the construction of m-trees does not depend on the order in which messages indexes are added, as shown in Proposition 3.17 below. This allows us to abbreviate $r(\dots r(\mathcal{T}, i_1), \dots, i_n)$ as $r(\mathcal{T}, \{i_1, \dots, i_n\})$.

► **Proposition 3.17.** Ramification is a commutative internal operation on m-trees.

Proof. That ramification is internal on m-trees follows by construction given how edges are extended in Def. 3.16. Commutativity follows by induction on the structure of $\textcolor{teal}{T}$. \blacktriangleleft

In Def. 3.20 below we decorate each node $\textcolor{brown}{X}$ in an m-tree with *assignments* that use the messages indexed by $\textcolor{brown}{X}$ to fill the variables in a join pattern. But first, we need some auxiliary constructions.

Given a mailbox \mathcal{M} and a join pattern $\textcolor{green}{J} \text{ if } \gamma$ with $\textcolor{green}{J} = \mu_1 \wedge \dots \wedge \mu_p$, we define the function $c : \{1, \dots, p\} \rightarrow 2^{\{1, \dots, |\mathcal{M}|\}}$ that maps each $i \in \{1, \dots, p\}$ to the set of indexes of messages in \mathcal{M} that match μ_i ; formally,

$$c(i) = \left\{ j \in 1..|\mathcal{M}| \mid \text{there is a substitution } \sigma \text{ such that } \mu_i \sigma = \mathcal{M}[j] \right\} \quad (1)$$

Also, an \mathcal{M} -assignment for $\textcolor{green}{J}$ is an injective map $a : \{1, \dots, p\} \rightarrow \{1, \dots, |\mathcal{M}|\}$ such that $i \in c(i)$ for all $1 \leq i \leq p$. Let $\text{asgn}(\mathcal{M}, \textcolor{green}{J})$ be the set of all \mathcal{M} -assignments for $\textcolor{green}{J}$. (Note that $\text{asgn}(\mathcal{M}, \textcolor{green}{J}) = \emptyset$ if $|\mathcal{M}| < p$.) The next Proposition 3.18 ensures that each assignment has a unique substitution induced by the matching; such a substitution can be effectively computed since the proof of Proposition 3.18 is constructive.

► **Proposition 3.18.** *For each $a \in \text{asgn}(\mathcal{M}, \mu_1 \wedge \dots \wedge \mu_p)$ there is a unique substitution σ_a such that $\mathcal{M}[a(i)] = \mu_i \sigma_a$, for all $i \in \{1, \dots, p\}$.*

Proof. Since each variable occurs at most once in $\mu_1 \wedge \dots \wedge \mu_p$ (by well-formedness, Def. 3.1), it suffices to take $\sigma_a = \bigcup_{i \in \{1, \dots, p\}} \sigma_i$ where $\mathcal{M}[a(i)] = \mu_i \sigma_i$ for all $i \in \{1, \dots, p\}$. \blacktriangleleft

An assignment $a \in \text{asgn}(\mathcal{M}, \textcolor{green}{J})$ is *valid for the guard* γ if $\gamma \sigma_a$ evaluates to *true* (with σ_a from Proposition 3.18).

► **Example 3.19** (Assignments). Let Π_1 and \mathcal{M} as in Example 3.13. We have $c(1) = \{2, 3, 4\}$ and $c(2) = \{1\}$, the assignment a such that $a(1) = 4$ and $a(2) = 1$ belongs to $\text{asgn}(\mathcal{M}, \text{Fault}(id_1, _) \wedge \text{Fix}(id_2))$ and it is valid for the guard $id_1 = id_2$ while for $a[3/1]$ (the update of a mapping 1 to 3) we have $a[1 \mapsto 3] \in \text{asgn}(\mathcal{M}, \text{Fault}(id_1, _) \wedge \text{Fix}(id_2))$ and $a[1 \mapsto 3]$ is not valid for $id_1 = id_2$. \dashv

We are now ready to introduce *assignment trees*.

► **Definition 3.20** (Assignment trees, pattern resolution). *The assignment tree of a join pattern $\textcolor{green}{J} \text{ if } \gamma$ w.r.t. mailbox \mathcal{M} is the pair $(\textcolor{teal}{T}, \textcolor{teal}{a})$ where, letting $I = c(\{1, \dots, p\})$ with c as in (1),*

- $\textcolor{teal}{T} = (N, E)$ *is the subtree up-to level p of $r((\emptyset, \emptyset), I)$, the m-tree on I and*
- *the map of candidate assignments $\textcolor{teal}{a} : N \rightarrow 2^{\text{asgn}(\mathcal{M}, \textcolor{green}{J})}$ is such that, for each node $\textcolor{brown}{X} \in N$,*

$$\textcolor{teal}{a}(\textcolor{brown}{X}) = \{a \in \text{asgn}(\mathcal{M}, \textcolor{green}{J}) \mid a \text{ is valid for } \gamma \text{ and } \text{cod } a = \textcolor{brown}{X}\}$$

Let $t(\mathcal{M}, \textcolor{green}{J} \text{ if } \gamma)$ denote the assignment tree of $\textcolor{green}{J} \text{ if } \gamma$ w.r.t \mathcal{M} . Pattern $\textcolor{green}{J}$ is resolved in \mathcal{M} if there is a leaf $\textcolor{brown}{X}$ in $t(\mathcal{M}, \textcolor{green}{J} \text{ if } \gamma)$ such that $\textcolor{teal}{a}(\textcolor{brown}{X}) \neq \emptyset$.

Proposition 3.21 below is a soundness result: the assignment tree for mailbox \mathcal{M} and join pattern Π only contains combinations of message indexes from \mathcal{M} that can contribute to matching Π . Instead, Theorem 3.22 is a completeness result: it says that if an assignment matches a join pattern Π for mailbox \mathcal{M} , then the m-tree of \mathcal{M} contains a node made of exactly the messages used by that assignment. Taken together, these two results guarantee that, if we inspect assignment trees to find possible matches for Π in mailbox \mathcal{M} , we can only find possible matches (soundness), and we will not miss any possible match (completeness).

► **Proposition 3.21.** *The assignment tree $t(\mathcal{M}, \Pi)$ is consistent.*

Proof. The union of nodes of the same level but 0 yields $c(\{1, \dots, p\})$. ◀

► **Theorem 3.22.** *For all $a \in \text{asgn}(\mathcal{M}, J)$, $\text{cod } a \in t(\mathcal{M}, J \text{ if } \gamma)$.*

Proof. Assume $J = \mu_1 \wedge \dots \wedge \mu_p$ and proceed by induction on p using Def. 3.16. ◀

We now need to rank the assignments in an m-tree to align with our “fair matching” policy (Def. 3.8). To this end, we define the total order \preceq on $\text{asgn}(\mathcal{M}, J)$ as follows:

$$a \preceq a' \quad \text{if} \quad \langle a(1) \cdot \dots \cdot a(p) \rangle \leq_{\text{lex}} \langle a'(1) \cdot \dots \cdot a'(p) \rangle \quad \text{where} \quad J = \mu_1 \wedge \dots \wedge \mu_p \quad (2)$$

Now, Def. 3.23 below formalises how a join pattern is “fairly” resolved in an assignment tree. Observe that, crucially, Def. 3.23 only considers the first node in a depth-first traversal of the assignment tree that yields some candidate assignments. This allows our algorithm to find the fairest matches first, and avoid unnecessary traversals.

► **Definition 3.23** (Fair resolution). *Let X be the first node in a depth-first visit of the assignment tree $t(\mathcal{M}, J \text{ if } \gamma)$ at level p whose candidate assignment map a is non-empty. The fair resolution of $t(\mathcal{M}, J \text{ if } \gamma)$ is the minimal assignment in $a(X)$ w.r.t pre-order \preceq in (2).*

Note that Def. 3.23 univocally identifies a fair resolution when a join pattern matches multiple slices, as shown in Example 3.24 below.

► **Example 3.24.** Let Π_1 be as in Example 3.5 and consider the mailbox:

$$\text{Fault}_1(3, 10:35) \cdot \text{Fault}_2(2, 10:39) \cdot \text{Fault}_3(3, 10:56) \cdot \text{Fix}_4(3)$$

The assignments $a = \begin{cases} 1 \mapsto 1 \\ 2 \mapsto 4 \end{cases}$ and $a' = \begin{cases} 1 \mapsto 3 \\ 2 \mapsto 4 \end{cases}$ are valid (observe that $\sigma_a \neq \sigma_{a'}$), and their fair resolution is a , since $a \preceq a'$. □

Finally, Theorem 3.25 below shows that the tree-based algorithm correctly computes the fair join pattern matching according to Def. 3.8.

► **Theorem 3.25.** *Let $\Pi = J \text{ if } \gamma$ with $J = \mu_1 \wedge \dots \wedge \mu_p$, then $\mathcal{M} \models \Pi \rightsquigarrow \mathcal{I}$ if and only if the fair resolution a of $t(\mathcal{M}, \Pi)$ is such that $\mathcal{I} = a(1) \cdot \dots \cdot a(p)$.*

Proof. (\implies) Let $\mathcal{M}[\mathcal{I}] = m_1 \cdot \dots \cdot m_p$. By Def. 3.8, there is substitution σ such that $\gamma\sigma$ holds and $\mu_i\sigma = m_i$ for all $i \in \{1, \dots, p\}$ and any other slice with this property is greater than \mathcal{I} . Let a be the assignment such that $a(i) = \mathcal{I}[i]$ for all $i \in \{1, \dots, p\}$. By construction, $a \in \text{asgn}(\mathcal{M}, J)$, hence $\text{cod } a \in t(\mathcal{M}, J \text{ if } \gamma)$ by Theorem 3.22. Let a' be the resolution of $t(\mathcal{M}, J \text{ if } \gamma)$. By definition $a' \preceq a$ which, by (2), is equivalent to say that $\langle a'(1) \cdot \dots \cdot a'(p) \rangle \leq_{\text{lex}} \langle a(1) \cdot \dots \cdot a(p) \rangle$. We then have the thesis since $a = a'$ because we also have $\langle a(1) \cdot \dots \cdot a(p) \rangle \leq_{\text{lex}} \langle a'(1) \cdot \dots \cdot a'(p) \rangle$ by hypothesis.

(\impliedby) Let \mathcal{I}' be such that $\mathcal{M} \models \Pi \rightsquigarrow \mathcal{I}'$, map a be the resolution of $t(\mathcal{M}, \Pi)$, and $\mathcal{I}' = [a(1) \cdot \dots \cdot a(p)]$. We have $\mathcal{M} \models_{\mathcal{I}'} \Pi$ since $\mathcal{M}[\mathcal{I}] \models_{\sigma_a} \Pi$ by construction. Therefore $\mathcal{I}' \leq_{\text{lex}} \mathcal{I}$ by Def. 3.8 and the codomain of the assignment a' such that $a'(i) = \mathcal{I}'[i]$ for all $i \in \{1, \dots, p\}$ belongs to $t(\mathcal{M}, \Pi)$ by Theorem 3.22. Let $\mathcal{Y} \in t(\mathcal{M}, \Pi)$ containing this codomain and $X \in t(\mathcal{M}, \Pi)$ be such that $\text{cod } a \in X$. We have the following cases: either X precedes \mathcal{Y} , or \mathcal{Y} precedes X , or else $X = \mathcal{Y}$. In the first case, if $\max X < \max \mathcal{Y}$ then $\mathcal{I}' \neq \mathcal{I}$ and $\mathcal{I}' \leq_{\text{lex}} \mathcal{I}$, which contradicts the hypothesis $\mathcal{M} \models \Pi \rightsquigarrow \mathcal{I}$. In the second case, if $\max \mathcal{Y} < \max X$ then $\mathcal{I}' \neq \mathcal{I}$ and $\mathcal{I} \leq_{\text{lex}} \mathcal{I}'$, which contradicts the fact that a' is the resolution of $t(\mathcal{M}, \Pi)$. It must therefore be $X = \mathcal{Y}$ which implies $a' = a$. □

4 Implementation: the JoinActors Library

We now present `JoinActors`, our actor-based implementation of join patterns and fair matching algorithms in the Scala 3 programming language. `JoinActors` is the companion artifact of this paper, and its latest version is available at:

<https://github.com/a-y-man/join-actors>

In Section 4.1 we provide an overview of the join patterns API, and the main components of the library and motivation behind the choice of Scala 3. In Section 4.2 we present the implementation of the stateful tree-based matching, and in Section 4.3 we describe our prototype actor framework with fair join pattern matching.

4.1 Overview

The API of `JoinActors` allows programmers to write join patterns using (almost-)standard Scala pattern-matching syntax (as shown in the code snippet in Listing 1); at compile-time, the pattern matching code is transformed (using metaprogramming) into an internal data structure that is used by the matching algorithms to perform the join pattern matching. To use the library, the programmer calls the `receive` function (which is actually a macro) passing join patterns as regular Scala 3 pattern-matching expressions. This function also take as a parameter the type of matching algorithm to use. The syntax for join definitions is:

```
receive { (self: ActorRef[...]) =>
  case J1 if γ1 => RHS1
  case J2 if γ2 => RHS2 ... }
```

We selected Scala 3 for our join pattern library because its macros allow us to implement a straightforward API for join patterns, without necessitating specialized syntax or compiler extensions. This way, programmers can write join patterns using familiar language constructs, eliminating the need to learn a new language or syntax.

Our library uses a `Matcher` trait as a common interface to two matching algorithms:

- `BruteForceMatcher`: the brute-force matching algorithm; this is a translation of the declarative semantics with no state management, described in Section 3.2;
- `StatefulTreeMatcher`: the stateful tree-based matching algorithm described in Section 3.3.

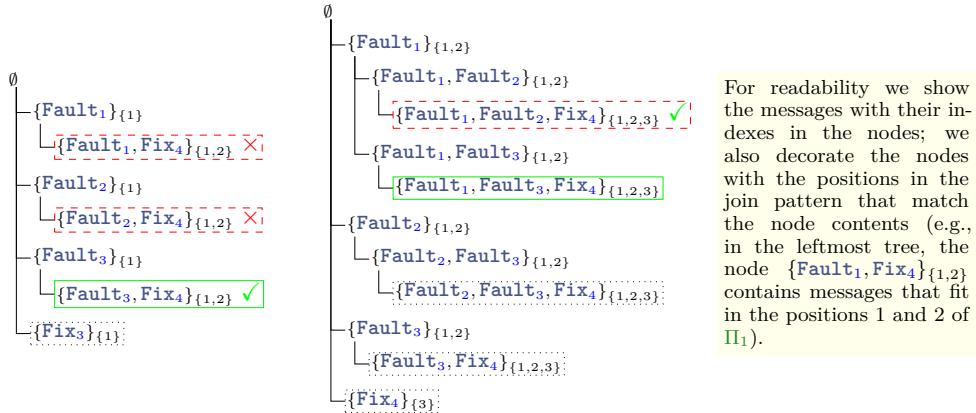

4.2 Implementing Stateful Tree-based Matching

M-trees (Def. 3.15) are the basic data structure of the our algorithm which are the cornerstone to build assignment trees (Def. 3.20). Given a join pattern $\Pi = J \text{ if } \gamma$ with $J = \mu_1 \wedge \dots \wedge \mu_p$ and a mailbox \mathcal{M} , our implementation *lazily* builds $t(\mathcal{M}, \Pi)$ using the ramification operation (Def. 3.16) starting from the tree (\emptyset, \emptyset) and incrementally extending it in depth-first order. When the messages of \mathcal{M} indexed by a leaf X at level p complete Π , we check the guard γ :

- if γ is satisfied by an assignment induced by X , we report the match, and remove the matched messages from \mathcal{M} and from the assignment tree (stopping its ramification);
- otherwise, we optimise the tree by pruning the leaf X , and continue its ramification.

If no match is found, we wait for a new message to land in the mailbox, and repeat.

► **Example 4.1** (Assignment tree construction). The assignment trees for Π_1 , Π_2 , and \mathcal{M} in Example 3.5 are pictorially shown below:

Leaves yielding a successful match (i.e., a combination of messages that complete the message pattern and satisfy its guard) are marked with green solid box and symbol \checkmark . Leaves where messages completes the join pattern without satisfying its guard are marked with red dashed boxes and symbol \times ; such leaves are immediately pruned from the tree once computed. Leaves in dotted boxes are other *potential* message matches – which are *not* actually computed, because an earlier successful match is found while lazily ramifying the tree (and the earlier match is fairer than the later potential match). \square

In the implementation, the M-trees are represented using the `TreeMap`⁴ data structure: it is a sorted map that takes an ordering on the keys, and for the ordering we use Def. 3.6. We use the following data structure types:

- `type PatternBins = TreeMap[PatternIdxs, MessageIdxs]` is a map from the positions of the patterns to the indices of the messages that match the pattern. These are the subscripts of the nodes in the trees of Example 4.1, where we associate the index of a message to the index of the pattern matching it. If a join pattern contains several messages with the same constructor (such as `Fault` in Π_2 in Example 4.1) then these messages will be grouped in the same bin where the key is the sequence of indices of the join pattern and the value will be the sequence of indices of the matched messages from the mailbox. For instance, the pattern bin of the leaf node with green solid box $\{Fault_1, Fault_2, Fix_4\}_{\{1,2,3\}}$ in the rightmost tree in Example 4.1 would be represented as $[1, 2] \mapsto [1, 2], [3] \mapsto [4]$.
- `type MatchingTree = TreeMap[MessageIdxs, PatternBins]` is a map from the indices of the messages that have been matched so far to the `PatternBins`. Thus, the leaf node with green solid box in the rightmost tree in Example 4.1 would have the matching tree $[1, 2, 4] \mapsto [[1, 2] \mapsto [1, 2], [3] \mapsto [4]]$.

Note that these data structures contain only the indices of the partially-matched messages and patterns. The guard is checked only when a leaf node is completed (as described above).

4.3 Prototype Actor Framework

To showcase our join patterns implementation in the actor concurrency model, `JoinActors` offers a prototype actor framework in Scala. Notably, our implementation requires Java 21 or later to run due to the use of *virtual threads*. We use `LinkedTransferQueues` as the mailbox implementation, and `ActorRef` objects for sending messages into a mailbox.

⁴ <https://scala-lang.org/api/3.x/scala/collection/immutable/TreeMap.html>

```

1 class Actor[M, T](private val matcher: Matcher[M, Result[T]]):
2   private val mailbox = LinkedTransferQueue[M]
3   val self           = ActorRef(mailbox)
4
5   def start(): (Future[T], ActorRef[M]) =
6     val promise = Promise[T]
7     ec.execute(() => run(promise))
8     (promise.future, self)
9
10  @tailrec
11  private def run(promise: Promise[T]): Unit =
12    matcher(mailbox)(self) match
13      case Continue    => run(promise)
14      case Stop(value) => promise.success(value)

```

■ **Listing 2** The `Actor` class implementation in the `JoinActors` library.

In Listing 2 (line 1) the actor’s constructor takes a `Matcher` instance as a parameter. The `run` method processes the messages in the mailbox using the `matcher` instance built by the `receive` macro, which may be either a `BruteForceMatcher` or a `StatefulTreeMatcher` instance. Depending on the result of the right-hand side of the join pattern, the actor either continues processing messages or stops and returns a result.

5 Evaluation

In this section we present the evaluation of our implementation of join patterns and the matching algorithms. In Section 5.1 we describe the methodology used to evaluate the performance of the algorithms. In Section 5.2 we present the results of the custom synthetic benchmarks. In Section 5.3 we present the results of a smart house benchmark. In Section 5.4 we present the results of a bounded buffer benchmark. In Section 5.5 we analyse the correlation between the size of the actor mailbox and the size of the m-trees. In Section 5.6 we compare our implementation of the tree-based fair matching algorithm with an alternative implementation based on the RETE algorithm. Overall, our experiments show that:

- Our stateful tree-based algorithm outperforms the brute force strategy in “noisy” workloads, where messages forming the fairest match are interspersed with random and non-matching messages. On the contrary, when the messages for the fairest match arrive consecutively, the brute force strategy outperforms the stateful tree-based one, since the latter incurs the overhead of building the matching tree. It is worth noticing that non-noisy workloads are unlikely in distributed or asynchronous scenarios.
- Compared to a RETE-based implementation of fair matching, our tree-based algorithm avoids unnecessary production of matches (as it directly picks the “fairest match”) and scales better when guards are computationally heavy. However, our tree-based algorithm implementation is an unoptimised proof-of-concept, and for simple guards may perform worse than an optimised RETE implementation (as the one we used).
- The number of matches per second measured in our experiments also shows that our implementation of the stateful tree-based matching is suitable for both our floor shop opening example and the smart house scenario – where the expected input traffic is in the order of tens of messages per second, with moderate “noise.”

5.1 Methodology

The lack of a standard benchmark suite for join patterns makes the performance evaluation non-trivial, as the performance of matching algorithms is highly sensitive to the inputs (i.e. amount and order of incoming messages), the size of the message patterns, and the complexity of the guards. Similar sensitivity has been documented e.g. in [15], which compares the matching algorithms RETE [6] and TREAT [18] in the realm of expert and rule-based multi-agent systems. Given that our stateful tree-based algorithm is influenced by RETE and TREAT, our evaluation methodology is inspired by the assessment conducted in [15].

We have devised a set of benchmarks to draw insights into the performance comparison between our stateful tree-based algorithm and the naïve brute-force algorithm. We also identify the trade-offs between the two algorithms in different scenarios, i.e., the overhead of maintaining state versus the overhead of reprocessing messages. To this end, we have created custom synthetic benchmarks and adapted some benchmarks from the literature, such as a producers-consumers bounded buffer from the Savina benchmark suite [13] and a smart house benchmark adapted from [22]. We ran the experiments on a computer with dual Xeon E5-2687W (8-core, 3.10GHz) and 128GB of memory, with 64-bit GNU/Linux 5.10.27. We used OpenJDK 21 with default settings, maximum heap size set to 16 GB, and Scala 3.3.3.

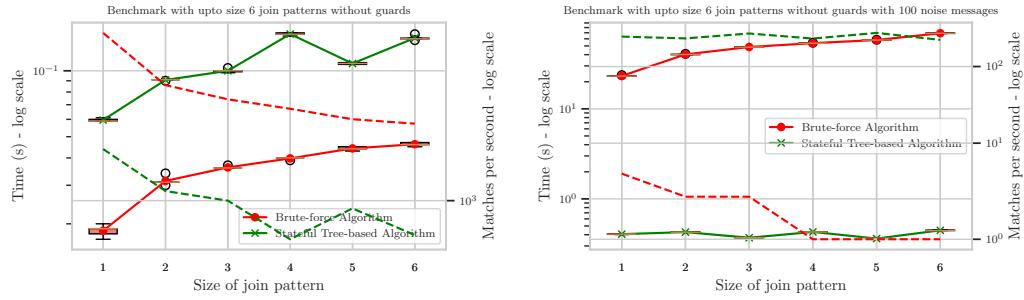

5.2 Synthetic Benchmarks

The general setup of each benchmark involves a program with a single actor, which consists of precisely one join definition, which receives message sent incrementally without delays. A benchmark execution finishes once the actor has processed all matches for the messages contained in its mailbox. We start measuring time just before the first message is sent and stop when the actor halts, so to disregard the time for setting up the actor. The benchmarks are implemented in Scala 3, and are included in the companion artifact of this paper.

Each experiment is repeated 5 times. The plots in Figs. 1 and 2 are to be read as follows: the x -axis represents the join pattern size (i.e., the number of messages in the pattern), and the error bars show the standard deviation of the measurements; the solid lines (measured on the left y -axis, log scale) show the benchmark completion time; the dashed lines (measured on the right y -axis, log scale) show the number of matches per second.

The benchmark suite has been crafted to encompass the following three aspects.

1. **Pattern size.** We have considered actors with pattern sizes ranging from 1 to 6: this mirrors scenarios found in the literature, where join patterns are usually not very long.
2. **Message workload profile.** We have benchmarked two kinds of input traffic workload: (1) a “clean” workload where the messages delivered to the mailbox precisely match the join pattern; (2) a spectrum of “noisy” workloads, where varying amounts of messages delivered to the mailbox will not match any pattern. The noise is uniformly interspersed with matchable messages. The rationale behind this choice is that the first scenario should favour the brute-force algorithm, as it may minimize the advantages of maintaining state, allowing us to measure the overhead of state maintenance. Conversely, the second scenario will require the brute-force algorithm to analyse unusable combinations of messages, thereby enabling us to measure the benefits of maintaining state.
3. **Guard effect.** We evaluated actors with join patterns, with and without guards. The inclusion of patterns with guards is particularly tailored to the main goal of this paper, which is to assess the benefits of state-based algorithms in the presence of guards.

■ **Figure 1** Pattern size without guards benchmark: without noise (left) and with noise (right).

5.2.1 Pattern Size and Workload without Guards

The first group of benchmarks compares the performance of brute-force and tree-based algorithms in cases where actors do not use guards. We consider actors with the following shape, for size 5 (i.e., a unique join pattern matching case for 5 messages). Note that messages have no payload, and the only rule has no guard.

```

1 Actor[SizeMsg, ...] {
2   receive { (_: ActorRef[SizeMsg]) =>
3     { case (A(), B(), C(), D(), E()) => ... }
4   } }
```

The corresponding benchmark evaluates the performance of such actor when fed with a stream of messages consisting on 100 repetitions of the sequence `A()`, `B()`, `C()`, `D()`, `E()`. Note that the mailbox is fed with messages in the exact order required for the match.

The results of the benchmark, considering actors of size 1 to 6, for both algorithms are shown in Fig. 1. The plot on the left of Fig. 1 shows that the brute-force approach significantly outperforms the stateful tree-based approach because the latter has the inherent overhead to build and to update trees – whereas the brute-force algorithm defers processing until a sufficient number of messages are received. Due to the nature of the traffic sent to the actor, the brute-force algorithm immediately finds a match every n messages, where n is the size of the pattern (e.g., 5 in the code snippet above). Instead, the stateful tree-based algorithm has to update its tree for each message, and only after n messages will it find a match and then prune the tree: hence, the retained state is only marginally utilised. However, as shown in the right plot of Fig. 1, if we change the shape of the messages sent to the actor, by augmenting the sequence of messages with noise (i.e. messages that do not match the pattern), the stateful tree-based algorithm outperforms the brute-force algorithm.

5.2.2 Pattern Size and Workload with Guards

The next benchmark addresses the effect of guards. Actors resemble the ones in Section 5.2.1, but now messages have payload and join patterns are augmented with guards, as follows:

```

1 Actor[SizeMsg, ...] {
2   receive { (_: ActorRef[SizeMsg]) => {
3     case (A(x), B(y), C(z), D(w), E(a))
4       if x == y && y == z && z == w && w == a => ... }
5   } }
```

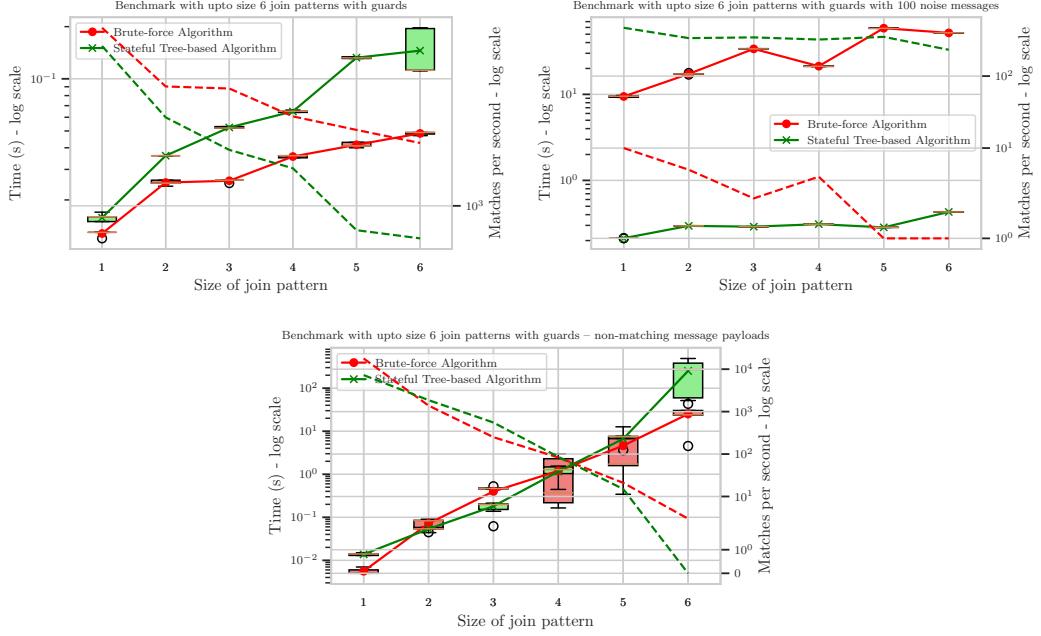

Figure 2 Benchmark results for varying pattern sizes with guards: without noise (top left), and with additional noise messages (top right) that cannot be matched by any join pattern. The bottom plot is a variation where the noise consists of messages that might be potentially matched by the join patterns, but whose payloads do not satisfy their guard.

As before, we first address the case of “perfect” workload, by feeding the actor with sequences of messages as `A(1)`, `B(1)`, `C(1)`, `D(1)`, `E(1)`, `A(2)`, `B(2)`, `C(2)`, `D(2)`, `E(2)`,

The results of the benchmark are shown in Fig. 2 (top-left). Similarly to the benchmark without guards, the brute-force algorithm outperforms the stateful tree-based algorithm on well-behaved input traffic. However, when we augment the sequence of “noise” messages, the results are similar to the benchmark without guards. Namely, the stateful tree-based algorithm outperforms the brute-force algorithm. This can be seen in Fig. 2 (top-right).

Moreover, we have performed a variation of this benchmark with a different type of noise: this time, the sequence of messages sent to the actor is augmented with payloads that do *not* satisfy the guard. An example of such a sequence of messages is:

`A(1)`, `A(-3)`, `B(1)`, `B(-4)`, `C(1)`, `C(-5)`, `D(1)`, `D(-6)`, `E(1)`, `E(-7)`, `A(2)`, ...

where only the messages highlighted in green match the pattern.

The benchmark results are shown in Fig. 2 (bottom). The performance of both algorithms is similar, which aligns with our expectations. Noise messages will always be reprocessed by both algorithms, as they persist as partial matches in the m-tree and as unprocessed messages in the brute-force algorithm. These noise messages can only be discarded if they satisfy the guard condition, which is not the case in this benchmark.

5.3 Smart House Benchmark

This benchmark is a real-world scenario adapted from [22]. In this setup, a single actor represents the smart house monitor and controller, tasked with managing various smart devices within a household. Specifically, the actor (1) activates the lights when someone enters and the ambient light is below 40 lux, and (2) detects arrivals or departures based on specific message sequences and reacts accordingly. The actor is shown in Listing 3.

```

1 Actor[Action, ...] {
2   receive { (selfRef: ActorRef[Action]) =>
3     case (
4       Motion(_: Int, mStatus: Boolean, mRoom: String, t0: Date),
5       AmbientLight(_: Int, value: Int, alRoom: String, t1: Date),
6       Light(_: Int, lStatus: Boolean, lRoom: String, t2: Date)
7     ) if bathroomOccupied(...) => ...
8     case (
9       Motion(_: Int, mStatus0: Boolean, mRoom0: String, t0: Date),
10      Contact(_: Int, cStatus: Boolean, cRoom: String, t1: Date),
11      Motion(_: Int, mStatus1: Boolean, mRoom1: String, t2: Date)
12    ) if occupiedHome(...) => ...
13     case (
14       Motion(_: Int, mStatus0: Boolean, mRoom0: String, t0: Date),
15       Contact(_: Int, cStatus: Boolean, cRoom: String, t1: Date),
16       Motion(_: Int, mStatus1: Boolean, mRoom1: String, t2: Date)
17     ) if emptyHome(...) => ...
18   ...
19 }
```

Listing 3 Smart house actor (arguments of predicates in the guards are omitted for readability). The type annotations in the join patterns are not necessary, but they are included for clarity.

Each of the mentioned scenarios is implemented as a separate join pattern with guards to ensure the correct behaviour is triggered. The performance evaluation of the implementation is conducted by measuring the time taken to process a number of messages that activate the patterns 1000 times, interspersed with a number of random messages intended to mimic various real-world workloads. When the number of random messages is 0, the smart house actor receives only exact matches: thus, for a join pattern size of 3, the actor will process 3000 such messages to get 1000 matches. Instead, in the case of 16 random messages, the actor receives 1000 sequences of messages, each one consisting of 16 random messages plus 3 matching messages distributed throughout the sequence. The benchmark concludes once the smart house actor has performed the expected 1000 matches.

Fig. 3 shows the results of our experiments: our implementation of the stateful tree-based algorithm quickly outperforms the naïve brute-force one, as it can quickly reuse partial matches and discard failed matches – whereas the brute-force algorithm has to compute all possible matches for each new incoming message. The plot also shows that the tree-based matching algorithm performs $\sim 10^5$ matches/sec. on non-noisy traffic (i.e., every input message is used in a join pattern match), and degrades to $\sim 10^2$ as more noise is injected in the input traffic, until $\sim 90\%$ of the messages are noise. This suggests that the implementation is suitable for a real-world application where a smart house controller may expect tens of messages per second with some amount of noise.

5.4 Producers-Consumers Bounded Buffer

This benchmark is an example of a multi-process synchronization problem. The benchmark involves producers and consumers represented by actors and a buffer actor. The buffer actor acts as a manager: (1) it monitors whether the data buffer is full or empty; (2) when consumers request work from an empty buffer, they are placed in a queue until work becomes

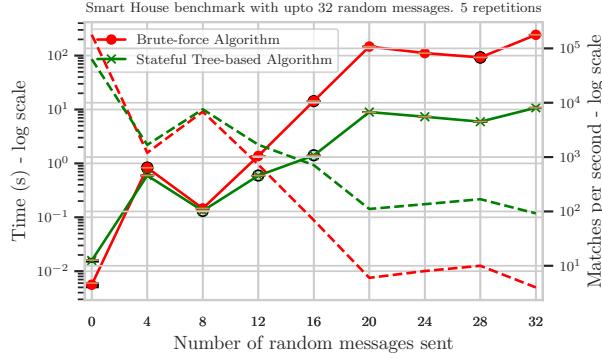

Figure 3 Smart House Benchmark. The x -axis represents the number of random “noise” messages sent with each group of 3 matchable messages; the solid lines (measured on the left y -axis, log scale) show the completion time; the dashed lines (measured on the right y -axis, log scale) show the number of matches per second. For each data point, the smart house actor performs 1000 matches, and the benchmark is repeated 5 times. The error bars show the standard deviation of the measurements.

available; (3) when producers are prepared to produce data but the buffer is full, they are queued until space opens up in the buffer; (4) it alerts producers to generate more work when space becomes available in the data buffer.

Fig. 4 shows the results of the benchmark for a buffer size of 1000. Since the join patterns of the bounded buffer are simple and without any guards and the messages are well-behaved, the brute-force algorithm outperforms the stateful tree-based algorithm. The overhead of maintaining state in the stateful tree-based algorithm is not justified in this case.

5.5 Analysis of Mailbox Size vs. Match Tree Size

We now focus on the relationship between the size of mailboxes and the size of the matching trees maintained in-memory by our stateful matching algorithm. Our analysis uses the smart house benchmark according to three different workload scenarios:

- **No noise:** each batch of 3 incoming messages triggers a match, emptying the mailbox after each match.
- **50% noise:** each batch consists of 3 messages suitable for matching and 3 “noise” messages that cannot be used in the matching, and thus, just accumulate in the mailbox.
- **66% noise:** each batch consists of 3 messages suitable for matching and 6 “noise” ones. For each scenario, we send 10 batches of messages, triggering 10 join pattern matches. The results are collected in Fig. 5, where the plots in the each row correspond to one of our scenarios. Despite the potential for m-trees to grow exponentially with mailbox size, the plots show a mostly flat and almost-linear correlation between mailbox size and m-tree size. For instance, the left plot in the first row of Fig. 5 illustrates the relationship between the number of messages processed by the actor and both the mailbox and m-tree sizes. Spikes indicate a join pattern match, leading to message removal and m-tree pruning. The right plot in the first row further explores the correlation between mailbox and m-tree sizes, demonstrating, for example, that a mailbox with two messages correlates to an m-tree size of 5-7 nodes, depending on the messages and applicable join patterns.

The results for the noise scenarios are respectively in the second and third row of Fig. 5: they show that mailbox and m-tree sizes decrease after each match similarly to the no-noise scenario. However, “noise” messages accumulate generating partial matches in the m-tree. Flat lines in the m-tree size plot signify unmatchable messages, leaving m-trees unchanged.

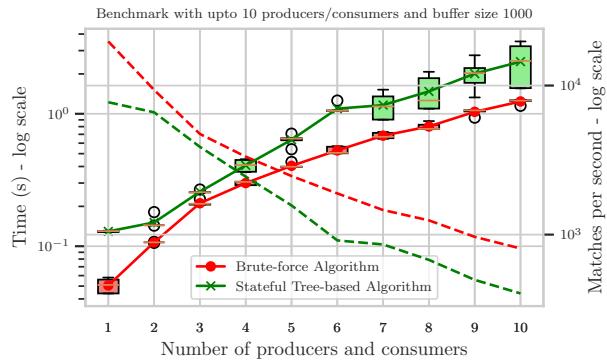

Figure 4 Producers-consumers bounded buffer benchmark: time to produce and consume data in a buffer of size 1000 against the number producers and consumers. The solid lines (measured on the left y -axis, log scale) show the benchmark completion time; the dashed lines (measured on the right y -axis, log scale) show the number of matches per second. The benchmark is repeated 5 times. The error bars show the standard deviation of the measurements.

5.6 Comparison with a RETE-based Fair Matching Implementation

In this section we compare our implementation of our stateful tree-based fair join pattern matching algorithm against an implementation based on the RETE algorithm. The use of RETE takes inspiration from [28], but here we use the Evrete library for Java.⁵ To implement an Evrete-based actor that realises our fair matching policy, we proceed as follows.

1. We set up an Evrete *session* where:
 - each incoming message is modelled as a *fact* with a unique id (denoting the order of arrival), and
 - each pattern matching case is encoded as a *rule* that Evrete will check against all combinations of “message facts” in the session. If a combination of “message facts” satisfies a rule, their message ids are stored in a collection of matches for that rule.
2. We implement an actor (as a JVM virtual thread) that, when a new message arrives:
 - a. stores the message as a “message fact” in the aforementioned Evrete session,
 - b. fires the session rules, and
 - c. if one or more successful matches are produced by any of the rules, then:
 - i. sorts the collections of successful matches (if any) by fairness (using Def. 3.6 on the “message fact” ids);
 - ii. finds the fairest match;
 - iii. removes from the session all the “message facts” used by such a fairest match; and
 - iv. clears the collections of successful matches.

A key difference between RETE and our stateful tree-based fair matching algorithm is that RETE exhaustively computes *all* possible matches when the rules are fired, and such matches must be sorted to find the fairest (see item 2(c)i above). Instead, our algorithm only computes matches “on demand” by finding the fairest first, through a lazy depth-first traversal of the match tree. This suggests that our tree-based fair matching algorithm is computationally less expensive than the RETE-based implementation outlined above. However, the comparative benchmarks are also influenced by multiple implementation differences:

⁵ <https://www.evrete.org>

17:24 Fair Join Pattern Matching for Actors

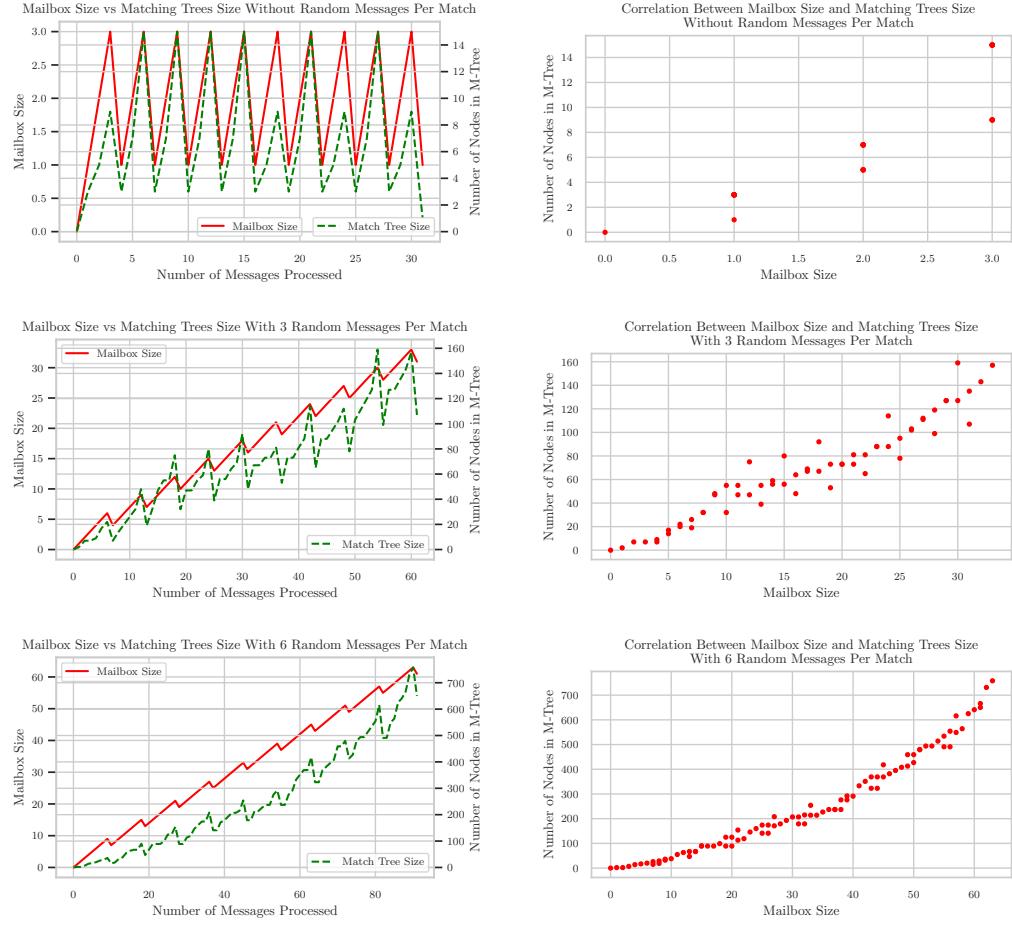

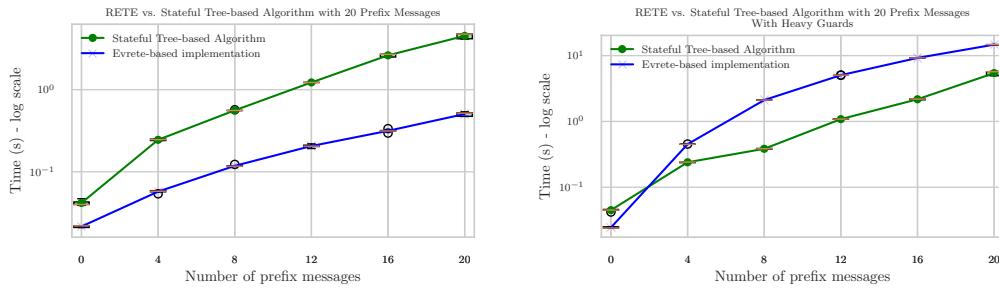

Figure 5 Mailbox size against the size of the matching tree: sizes based on the number of processed messages (left column) and mailbox/tree size correlation (right column).

- our implementation of tree-based fair matching is a proof-of-concept, is not optimised, is single-threaded, and is almost completely written in functional Scala. In particular, adding partial matches to the m-tree is a rather expensive operation, because the m-tree is currently implemented as an immutable data structure;
- instead, Evrete is being developed since 2020 and is significantly optimised, multi-threaded, and written in imperative Java using high-performance mutable data structures.

Consequently, Evrete can produce a significantly higher amount of matches-per-second w.r.t. our implementation – and thus, its exhaustive production of matches can be often faster than our “on-demand, fairest-first” production.

For these reasons, we have designed a benchmark (based on the “smart house” in Section 5.3) that discriminates the computational characteristics of our tree-based fair matching algorithm and the Evrete-based implementation, despite implementation differences:

1. we send n groups of “prefix” messages that create a partial match for a join pattern;
2. then, we send one message that can complete the join pattern with any of the previous “prefix” messages.

■ **Figure 6** Comparison of tree-based vs. Evrete-based implementation of fair matching. The x -axis shows the number of groups of “prefix” messages sent before a completing message. The y -axis shows the time taken to perform 10 matches.

E.g., for the pattern `Motion(...)` \wedge `AmbientLight(...)` \wedge `Light(...)`, we send n times the “prefix” messages `Motion(...)`, `AmbientLight(...)` (which partially match the pattern), and finally we send a message `Light(...)`, which can be combined with any previous “prefix” message to complete the pattern. In this situation, the Evrete-based implementation will compute all possible matches and then find the fairest – while our stateful tree-based fair matching algorithm will immediately produce the fairest match between `Light(...)` and the oldest `Motion(...)`, `AmbientLight(...)` messages. The benchmark measures the time taken to process up to n groups of messages followed by a completing message. In total, we send $(2n+1) \times 10$ messages, thus triggering 10 matches. We perform two variants of this benchmark:

- one with simple guards (the ones used in Section 5.3), and
- one where we artificially slow down the time necessary to evaluate the guards, simulating computationally-intensive “heavy guards” that take ~ 0.1 milliseconds to be computed.

The results are shown in Fig. 6. The plot on the left (with “simple” guards) shows that the Evrete-based implementation of fair matching outperforms our stateful tree-based implementation. The plot on the right shows that, with “heavy guards”, our stateful tree-based implementation outperforms the Evrete-based one: this is because our tree-based algorithm evaluates the “heavy guards” only once (after finding the fairest match), whereas Evrete computes the “heavy guards” repeatedly, for each possible match contained in the actor mailbox. Observe that the overall execution time of our algorithm in the plots of Fig. 6 does not change significantly. This suggest that our algorithm is less sensitive to “heavy guards” than the Evrete-based implementation.

6 Conclusion

We have addressed the problem of formalising and implementing join pattern matching for actor-based concurrent and distributed systems. We have contributed a novel specification of *fair and deterministic join pattern matching* guaranteeing that the oldest messages in an actor’s mailbox are eventually consumed, if allowed by the patterns. We have presented a novel *stateful tree-based join pattern matching algorithm* that avoids wasteful recomputations across matches, and we have proved that our algorithm correctly implements the fair matching specification. We have presented a novel actor library for Scala 3 that implements fair join pattern matching, with both stateless and stateful algorithms. We have presented a systematic benchmark suite for join-pattern-based systems, and we have applied it to evaluate our implementation. We have assessed the performance of our stateful tree-based algorithm in

comparison to the brute-force algorithm and a RETE-based implementation, under various conditions. The findings reveal a performance trade-off: the brute-force algorithm excels when dealing with well-behaved workloads, where maintaining state is an unnecessary overhead, whereas the stateful tree-based algorithm outperforms in scenarios with relative noise in the input messages (which is to be expected in many real-world applications) and complex guards, as evidenced in the smart house benchmark. The synthetic benchmarks in Sections 5.2.1 and 5.2.2 underscore the high sensitivity of the matching algorithms to their workload and guard complexity. These insights should be taken into account when choosing the matching algorithm, depending on the nature of the application and anticipated workload.

Future work. Our specification of fair join pattern matching includes several design decisions that may be fine-tuned depending on the application context. E.g., in some settings it may be better to select the pattern with the longest match, and in some settings it may be useful to match the *newest* messages in a mailbox (e.g., if the input traffic volume is too high for processing every message in real-time). We can specify and implement these alternative policies with minimal adjustments to our definitions, results, and library implementation: we plan to study them, and explore other possibilities. Also, ensuring “fair choice” when multiple join patterns are enabled is another intriguing notion of fairness that would require a significantly different formalisation of matching semantics; we leave this as future work.

We plan to study the problem of *join pattern unreachability*, i.e., whether a pattern will always be preempted by its alternatives. E.g., if a join definition contains the two join patterns $A(x) + A(x) \wedge B(y)$, the former may be always preferred to the latter, or not, depending on the nuances of the matching policy across patterns (e.g., first-match vs. longest-match). We plan to study how to statically verify whether a join pattern is unreachable, and extend our Scala 3 implementation to issue a compile-time warning when this occurs.

Our evaluation shows that selecting the best-performing strategy for join pattern matching is not trivial: depending on the expected input traffic and the complexity of the patterns and guards, stateful matching may be faster than stateless matching, or *vice versa*. Our Scala 3 library `JoinActors` can be easily tweaked to allow programmers choose a specific matching strategy *per pattern*; it could also be extended to switch matching strategy “on the fly” (i.e., between matches), and it could be interesting to study how to automatically switch strategy depending on input traffic observations. We plan to adapt `JoinActors` to let programmers select a suitable matching strategy based on a custom heuristic.

`JoinActors` is a proof-of-concept prototype, and we plan to heavily optimise it – in particular, by using a more efficient mutable data structure to represent m-trees, allowing for faster updates when new messages arrive, and faster traversals for finding the fairest match. The need for such optimisations is highlighted by the results shown in Section 5.6, and we plan to study the internals of the Evrete library to inspire future improvements.

We see our evaluation in Section 5 as a first necessary step towards establishing a standard, comprehensive benchmark suite for existing and future join pattern implementations, in the spirit of Savina [13] for actor implementations. We will study how to further improve our benchmark suite, and we welcome feedback and suggestions from the community.

Abstract

In object-oriented languages, the traditional CFL-reachability formulation for k -callsite-sensitive pointer analysis (k CFA) focuses on modeling field accesses and calling contexts, but it relies on a separate algorithm for call graph construction. This division can result in a loss of precision in k CFA, a problem that persists even when using the most precise call graphs, whether pre-constructed or generated on the fly. Moreover, pre-analyses based on this framework aiming to improve the efficiency of k CFA may inadvertently reduce its precision, due to the framework's lack of native call graph construction, essential for precise analysis.

Addressing this gap, this paper introduces a novel CFL-reachability formulation of k CFA for Java, uniquely integrating on-the-fly call graph construction. This advancement not only addresses the precision loss inherent in the traditional CFL-reachability-based approach but also enhances its overall applicability. In a significant secondary contribution, we present the first precision-preserving pre-analysis to accelerate k CFA. This pre-analysis leverages selective context sensitivity to improve the efficiency of k CFA without sacrificing its precision. Collectively, these contributions represent a substantial step forward in pointer analysis, offering both theoretical and practical advancements that could benefit future developments in the field.

1 Introduction

Pointer analysis is fundamental to numerous static analyses, including program understanding, program verification, security analysis, compiler optimization, and symbolic execution. Over the past two decades, k -callsite-sensitivity [49], which distinguishes method contexts on their k -most-recent callsites, has emerged as a prevalent context abstraction in both whole-program [5, 60, 40] and demand-driven [53, 48, 62] pointer analyses for Java programs.

¹ The first two authors contributed equally to this work.

Traditionally, k -callsite-sensitive pointer analysis, abbreviated to k CFA (Control-Flow Analysis) [49], is either inclusion-based [1] or founded on context-free language (CFL) reachability [44]. The inclusion-based formulation for k CFA [22, 57] has been incorporated into several pointer analysis frameworks for Java [40, 59, 60, 5, 17]. In this approach, a program’s statements are represented as points-to set constraints. The methods’ calling contexts are delineated by parameterizing these constraints with context abstractions. Often, the call graph for the program is constructed dynamically, i.e., on the fly to maximize precision and efficiency [11, 47, 26, 27, 50]. Conversely, the CFL-reachability formulation for k CFA [53] plays a pivotal role in the development of a diverse array of pointer analysis algorithms. These include demand-driven pointer/alias analysis [53, 64, 62, 48], context transformations [57], library-code summarization [48], and selective context-sensitivity [33]. In this approach, a program’s points-to information is determined by resolving a graph reachability problem within a specifically constructed *pointer assignment graph* (PAG) [26]. This CFL-reachability formulation involves analyzing the intersection of two context-free languages (CFLs), denoted as $L_{FC} = L_F \cap L_C$, where L_F describes field accesses as balanced parentheses and L_C enforces callsite-sensitivity by matching method calls and returns, also represented through balanced parentheses [53]. However, this formulation employs a distinct, external algorithm for call graph construction, further elaborated in Section 2.

In comparison to the inclusion-based approach, the L_{FC} -based CFL-reachability formulation for k CFA suffers from two major limitations, primarily due to its reliance on a separate algorithm for call graph construction. Firstly, this segregation can lead to a decrease in precision within k CFA, a problem that persists regardless of whether the call graphs are pre-constructed or generated on the fly. Secondly, certain pre-analyses, such as SELECTX [33], aim to enhance k CFA’s efficiency through the L_{FC} -based CFL-reachability formulation. However, these pre-analyses might unintentionally compromise its precision, undermining the overall effectiveness of the pointer analysis.

The primary contribution of this research lies in addressing the aforementioned limitations by introducing a new CFL-reachability formulation of k CFA. This novel formulation, for the first time, demonstrates the feasibility of specifying k CFA entirely through CFL-reachability, eliminating the need for a separate call graph algorithm. Our approach utilizes three CFLs, $L_{DCR} = L_D \cap L_C \cap L_R$, within a new PAG framework. Here, L_D extends beyond field accesses (as in L_F) to include dynamic dispatch, L_C maintains callsite-sensitivity as per previous formulation [53], and L_R introduces support for parameter passing required by its built-in on-the-fly call graph construction. Theoretically, we demonstrate for the first time that k CFA can be characterized as a specific type of context-sensitive language – the intersection of multiple CFLs. This is a notable distinction, as not all context-sensitive languages can be expressed in this manner [31, 25], underscoring the uniqueness of our approach. The subsequent sections will delve into the challenges of designing L_{DCR} and provide insights into our formulation’s underpinnings.

As a secondary contribution of this research, we demonstrate the practical utility of L_{DCR} by introducing P3CTX, the first precision-preserving pre-analysis designed to accelerate k CFA in Java programs. Given the critical importance of precision in tasks such as software security analysis, our approach distinguishes itself as the preferable option. It provides a speed advantage without sacrificing precision. P3CTX employs an L_{DCR} -enabled selective context-sensitivity technique, further substantiating the correctness of L_{DCR} . In contrast, SELECTX [33], developed based on L_{FC} [53], invariably encounters precision loss, thus underscoring the superiority of our approach.

Figure 1 Inclusion-based formulation (M is the containing method of the statement being analyzed).

In summary, this paper makes the following two major contributions:

- A new CFL-reachability formulation of *kCFA* with built-in call graph construction.
- An *L_{DCR}*-enabled precision-preserving pre-analysis for accelerating *kCFA* with selective context-sensitivity. Compared with two state-of-the-art pre-analyses [33, 29], our pre-analysis enables better efficiency-precision trade-offs in several application scenarios.

The rest of this paper is organized as follows. Section 2 provides background knowledge and motivates the development of *L_{DCR}* by highlighting several design challenges. Section 3 introduces *L_{DCR}*, explaining how these challenges are addressed and offering insights into its design. Section 4 presents and evaluates, P3CTX, our *L_{DCR}*-enabled pre-analysis for accelerating *kCFA*. Section 5 discusses related work and Section 6 concludes the paper.

2 Background and Motivation

We start by reviewing the inclusion-based and traditional CFL-reachability *L_{FC}* formulations of *kCFA* (Section 2.1). Next, we use an example to illustrate their approaches to call graph construction, discuss *L_{FC}*'s limitations, and highlight the necessity of and challenges faced in designing *L_{DCR}*, a new CFL-reachability formulation with an integrated on-the-fly call graph construction (Section 2.2).

In our formalization, we consider a simplified Java language with six types of statements: New for object creation (“`x = new T // O`”); Assign for variable assignments (“`x = y`”); Load for retrieving field values (“`x = y.f`”); Store for assigning values to fields (“`x.f = y`”); Virtual Calls for instance method calls (“`x = r.m(a1, ..., an) // c`”); and Static Calls for static method calls (“`x = m(a1, ..., an) // c`”). Here, O identifies the unique abstract object created by a particular New statement, x and y are local variables, and c identifies a callsite. For a virtual call `r.m(a1, ..., an)`, we write `thism'`, `pim'` and `retm'` as its “this” variable, *i*-th parameter and return variable for a virtual method *m'* invoked at this callsite, respectively. For a static call `m(a1, ..., an)`, only `pim` and `retm` are relevant. In scenarios where method calls do not return a value, the flow from `retm` to x is disregarded.

$$\begin{array}{c}
\frac{x = \mathbf{new} \ T \ // \ O}{O \xrightarrow{\text{new}} x} [\mathbf{P-NEW}] \quad \frac{x = y}{y \xrightarrow{\text{assign}} x} [\mathbf{P-ASSIGN}] \quad \frac{x = y.f}{y \xrightarrow{\text{load}[f]} x} [\mathbf{P-LOAD}] \\
\\
\frac{x.f = y}{y \xrightarrow{\text{store}[f]} x} [\mathbf{P-STORE}] \quad \frac{x = m(a_1, \dots, a_n) \ // \ c}{\forall i \in [1, n] : a_i \xrightarrow[\hat{c}]{\text{assign}} p_i^m \quad \text{ret}^m \xrightarrow[\check{c}]{\text{assign}} x} [\mathbf{P-SCALL}] \\
\\
\frac{x = r.m(a_1, \dots, a_n) \ // \ c \quad m' \text{ is a target of this callsite}}{r \xrightarrow[\hat{c}]{\text{assign}} \text{this}^{m'} \quad \text{ret}^{m'} \xrightarrow[\check{c}]{\text{assign}} x \quad \forall i \in [1, n] : a_i \xrightarrow[\hat{c}]{\text{assign}} p_i^{m'}} [\mathbf{P-VCALL}]
\end{array}$$

Figure 2 Rules for building the PAG required by L_{FC} .

2.1 Background

2.1.1 Inclusion-based Formulation

Figure 1 gives the rules for such a formulation [22, 51, 57], where several auxiliary functions are used: (1) `MethodCtx` maintains the contexts used for analyzing a method, (2) `dispatch` resolves a virtual call to a target method, and (3) `PTS` records the points-to information found context-sensitively for a variable or an object’s field. In k CFA, context sensitivity is achieved by parameterizing variables and objects with contexts as modifiers. A calling context of a method is abstracted by its last k callsites. Given a context $ctx = [c_1, \dots, c_n]$ and a context element c , $c :: ctx$ stands for $[c, c_1, \dots, c_n]$ and $[ctx]_k$ stands for $[c_1, \dots, c_k]$.

Let us examine the six rules in Figure 1. In **[I-NEW]**, hk represents the (heap) context length for a heap object, typically set as $hk = k - 1$ [51, 58, 20, 30]. **[I-ASSIGN]**, **[I-LOAD]**, and **[I-STORE]** address standard assignments and field accesses. **[I-SCALL]** and **[I-VCALL]** handle static and virtual calls, respectively. Let us explain **[I-VCALL]** only. In this rule, m' is a target method dynamically resolved for a receiver object O (based on its dynamic type $t = \text{DynTypeOf}(O)$) at callsite c . Thus, this rule is also responsible for performing on-the-fly call graph construction during the pointer analysis. In its conclusion, $ctx' \in \text{MethodCtx}(m')$ reveals how the contexts of a method are introduced. Initially, for the program being analyzed, its entry methods have only the empty context, e.g., $\text{MethodCtx}(\text{"main"}) = \{[]\}$. Importantly, the receiver variable r and the other arguments a_1, \dots, a_n are handled differently: a receiver object flows only to the method it dispatches, while the objects pointed to by $a_i (i \in [1, n])$ flow to all methods dispatched at this callsite.

2.1.2 L_{FC} -based CFL-Reachability Formulation

In L_{FC} [53], k CFA is solved by reasoning about CFL-reachability on a PAG representation [26]. Figure 2 gives six rules for building the PAG. For a PAG edge, its label above indicates whether it is an assignment or field access. There are two types of `assign` edges: *intra-procedural* (for modeling regular assignments without a below-edge label) and *inter-procedural* (for modeling parameter passing with a below-edge label representing a callsite).

In L_{FC} , passing arguments to parameters at both static and virtual callsites is modeled identically by using inter-procedural `assign` edges (**[P-SCALL]** and **[P-VCALL]**). For example, in **[P-VCALL]**, \hat{c} (\check{c}) signifies an inter-procedural value-flow entering into (exiting from) m' at callsite c , where m' represents a virtual method discovered by a separate call graph construction algorithm (either in advance [9, 2, 55] or on the fly [54, 53]). Therefore, \hat{c} (\check{c}) is also known as an *entry* (*exit*) *context*.

```

1 class A {
2   void foo(D p) {
3     Object v = p.f;
4   }
5 }
6 class B extends A {
7   void foo(D q) { }
8 }
9 class C extends A {
10  void foo(D r) {}
11 }
12 class D { Object f; }
13 class O { }

14 static void bar(A x, O o) {
15   D d = new D(); // D1
16   d.f = o;
17   x.foo(d); // c3
18 }
19 static void main() {
20   O o1 = new O(); // O1
21   O o2 = new O(); // O2
22   A a = new A(); // A1
23   A b = new B(); // B1
24   bar(a, o1); // c1
25   bar(b, o2); // c2
26 }

```

Figure 3 A motivating example.

For a PAG edge $x \xrightarrow[c]{\ell} y$, its *inverse edge*, which is omitted in Figure 2 but required by L_{FC} , is defined as $y \xrightarrow[\bar{c}]{\bar{\ell}} x$. For a below-edge label \hat{c} or \check{c} , $\bar{\hat{c}} = \check{c}$ and $\bar{\check{c}} = \hat{c}$, implying that the concepts of entry and exit contexts for inter-procedural assign edges are swapped if they are traversed inversely.

L_{FC} is defined as the intersection of two distinct CFLs, $L_{FC} = L_F \cap L_C$, with L_F pertaining to the PAG's above-edge labels and L_C to its below-edge labels. L_F , a CFL over Σ_{L_F} , is created from above-edge labels. For each path p in the PAG, $L_F(p)$ is a string in $\Sigma_{L_F}^*$, made by sequentially concatenating p 's above-edge labels. A node v is L_F -reachable from node u if a path p , termed L_F -path, exists from u to v such that $L_F(p) \in L_F$. L_C follows a similar definition, but with Σ_{L_C} comprising below-edge labels.

We give L_F and L_C below and illustrate both with an example in Section 2.2. L_F enforces field-sensitivity for field accesses by matching stores and loads as balanced parentheses:

$$\begin{array}{lcl}
\text{flowsto} & \longrightarrow & \text{new flows}^* \\
\text{flows} & \longrightarrow & \underline{\text{assign}} \mid \text{store}[f] \text{ alias load}[f] \\
\text{alias} & \longrightarrow & \text{flowsto flowsto} \\
\underline{\text{flowsto}} & \longrightarrow & \overline{\text{flows}}^* \text{ new} \\
\text{flows} & \longrightarrow & \underline{\text{assign}} \mid \text{load}[f] \text{ alias store}[f]
\end{array} \tag{1}$$

Note that u alias v iff $u \xrightarrow{\text{flowsto}} O \xrightarrow{\text{flowsto}} v$ for some object O . In addition, $O \xrightarrow{\text{flowsto}} v$ iff $v \xrightarrow{\text{flowsto}} O$, meaning that flowsto actually represents the standard points-to relation.

L_C enforces callsite-sensitivity by matching “calls” and “returns” as balanced parentheses:

$$\begin{array}{lcl}
\text{realizable} & \longrightarrow & \text{exit entry} \\
\text{exit} & \longrightarrow & \text{exit balanced} \mid \text{exit } \check{c} \mid \epsilon \\
\text{entry} & \longrightarrow & \text{entry balanced} \mid \text{entry } \hat{c} \mid \epsilon \\
\text{balanced} & \longrightarrow & \text{balanced balanced} \mid \hat{c} \text{ balanced } \check{c} \mid \epsilon
\end{array} \tag{2}$$

A path p in the PAG of the program is *realizable* iff p is an L_C -path.

Finally, a variable v points to an object O iff there exists an L_{FC} -path p from O to v , such that $L_F(p) \in L_F$ (p is a *flowsto-path*) and $L_C(p) \in L_C$ (p is a *realizable-path*). Ignoring all balanced contexts, the contexts for v and O can be directly read off from p (Section 3.2.2).

 **Table 1** Points-to results for the program in Figure 3 computed by 2CFA according to Figure 1.

	$\langle v, [c3, c1] \rangle$	$\{\langle O1, [] \rangle\}$		$\langle D1.f, [c2] \rangle$	$\{\langle O2, [] \rangle\}$

2.2 Motivation

We begin with a motivating example (Section 2.2.1) and an inclusion-based framework featuring on-the-fly call graph construction (Section 2.2.2). We explore the limitations of L_{FC} without this feature (Section 2.2.3) and the challenges of developing L_{DCR} with it (Section 2.2.4). Transitioning from L_{FC} to L_{DCR} requires a new PAG representation specific to L_{DCR} .

2.2.1 Example

In Figure 3, classes A, B, C, D, and O are defined. B and C, subclasses of A, override the `foo()` method from A. The notation `T:m()` represents method `m()` in class `T`. The method `bar()` is a wrapper, storing the object pointed to by `o` in `D1.f`, and then invoking `A:foo()`, `B:foo()`, or `C:foo()` based on the dynamic type of object `x` points to. In `main()`, `O1`, `O2`, `A1`, and `B1` are created, in which `A1` and `O1` (`B1` and `O2`) are passed into `bar()` as its two arguments at callsite `c1` (`c2`).

2.2.2 Inclusion-based Formulation

Table 1 lists the points-to results computed for the program in Figure 3 by 2CFA following the rules in Figure 1. For `main()`, analyzed under `[]`, its points-to relations are obtained trivially. As for `bar()`, there are two calling contexts, `[c1]` and `[c2]`. Under `[c1]`, we have $PTS(x, [c1]) = \{\langle A1, [] \rangle\}$, $PTS(d, [c1]) = \{\langle D1, [c1] \rangle\}$, and $PTS(D1.f, [c1]) = PTS(o, [c1]) = \{\langle O1, [] \rangle\}$. Then `A:foo()` is found to be the target invoked by `x.foo()` at callsite `c3` in line 17 ([I-VCALL]). Thus, $PTS(p, [c3, c1]) = \{\langle D1, [c1] \rangle\}$ and $PTS(v, [c3, c1]) = \{\langle O1, [] \rangle\}$. Similarly, when `bar()` is analyzed under `[c2]`, we have $PTS(x, [c2]) = \{\langle B1, [] \rangle\}$. Thus, `x.foo()` at callsite `c3` is now resolved to `B:foo()`. Note that [I-VCALL] supports on-the-fly call graph construction during the analysis and 2CFA is precise enough by not resolving `C:foo()` as a spurious target at `c3`.

2.2.3 L_{FC} -based Formulation

L_{FC} addresses k CFA using a separate call graph construction algorithm. This approach separates, both conceptually and algorithmically, the parameter passing at a virtual callsite from the dynamic dispatch process. The limitations arising from this separation are explored below, considering whether the call graph is pre-constructed or constructed on the fly.

In Figure 3, L_{FC} uses a PAG as shown in Figure 4, constructed with CHA [9], an imprecise yet fast and sound call graph algorithm. In this scenario, `C:foo()` is conservatively marked as a target method at callsite `c3` (line 17). However, as explained later, L_{FC} would exclude such spurious targets when employing a more precise call graph in its analysis.

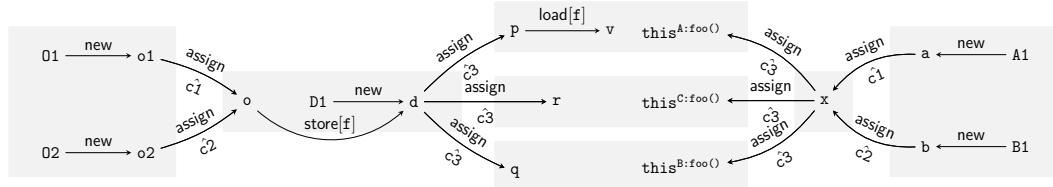

Figure 4 The PAG operated on by L_{FC} for the program given in Figure 3.

We analyze a specific traversal path leading to d , an argument in the call to $\text{foo}()$ at callsite c_3 (line 17), originating from o_1 in $\text{bar}(a, o_1)$ under $[c_1]$ or o_2 in $\text{bar}(b, o_2)$ under $[c_2]$. The subsequent task is to assign d to the appropriate parameter, based on the target method identified at this callsite: p for $A:\text{foo}()$, q for $B:\text{foo}()$, or r for $C:\text{foo}()$.

2.2.3.1 Using a Call Graph Constructed in Advance

Even if L_{FC} uses the most precise pre-built call graph, $k\text{CFA}$ can still lose precision. For instance, at callsite c_3 (line 17) in Figure 3, both $A:\text{foo}()$ and $B:\text{foo}()$ are identified as possible target methods. This means $A:\text{foo}()$ is always considered a target method, whether the call is from $\text{bar}(a, o_1)$ under $[c_1]$ or $\text{bar}(b, o_2)$ under $[c_2]$. As a result, this scenario leads to the identification of two L_{FC} -paths:

$$o_1 \xrightarrow{\text{new}} o_1 \xrightarrow[\hat{c}_1]{\text{assign}} o \xrightarrow{\text{store}[f]} d \xrightarrow{\text{new}} D_1 \xrightarrow{\text{new}} d \xrightarrow[\hat{c}_3]{\text{assign}} p \xrightarrow{\text{load}[f]} v \quad (3)$$

$$o_2 \xrightarrow{\text{new}} o_2 \xrightarrow[\hat{c}_2]{\text{assign}} o \xrightarrow{\text{store}[f]} d \xrightarrow{\text{new}} D_1 \xrightarrow{\text{new}} d \xrightarrow[\hat{c}_3]{\text{assign}} p \xrightarrow{\text{load}[f]} v \quad (4)$$

Thus, in this L_{FC} -based pointer analysis, v is concluded to point to both o_1 and o_2 , despite v actually pointing only to o_1 as per 2CFA (Table 1), meaning that o_2 is spurious.

L_{FC} 's precision loss stems from its approach to parameter passing at virtual callsites ([P-VCALL]), treating them similarly to static callsites ([P-SCALL]) using inter-procedural `assign` edges, without accounting for CFL-reachability for specific receiver objects. As a result, this causes L_{FC} to overlook that the L_{FC} -path in Equation (3) and the L_{FC} -path in Equation (4) are relevant only when x points to A_1 at $[c_1]$ and B_1 at $[c_2]$, respectively.

If L_{FC} uses a less precise call graph, which is pre-built by, say, CHA [9], then $C:\text{foo}()$ will also be identified as a target method at callsite c_3 (line 17), leading to r pointing to D_1 spuriously due to $D_1 \xrightarrow{\text{new}} d \xrightarrow[\hat{c}_3]{\text{assign}} r$. However, r 's points-to set is actually empty as per 2CFA (not listed in Table 1).

2.2.3.2 Using a Call Graph Constructed On the Fly

When d is reached at callsite c_3 in line 17 of Figure 3, using a call graph constructed on the fly as in demand-driven analyses [53, 62, 48], where methods invoked at a virtual callsite are context-specific, enables us to discern that the path in Equation (3) is an L_{FC} -path, while that in Equation (4) is not. This precision ensures that v points only to o_1 . In the first path, x points to A_1 under context $[c_1]$, identifying $A:\text{foo}()$ as the target at c_3 . The path $\xrightarrow[\hat{c}_3]{\text{assign}} p \xrightarrow{\text{load}[f]} v$ confirms that v points to o_1 . In the second path, reaching d under $[c_2]$ leads to $B:\text{foo}()$ at c_3 (with x pointing to B_1), blocking the same path.

While L_{FC} can address $k\text{CFA}$ on-demand more accurately than a pre-built call graph, precision loss may still occur in scenarios where a callsite has multiple dispatch targets under a common context. For example, in Figure 5 (where classes E, F, and G are renamed

```

1 class E {
2   void foo(G p) {
3     Object v = p.g;
4   }
5 class F extends E {
6   void foo(G q) { }
7 }
8 class G { Object g; }
9 G w = new G(); // G1
10 if (...) {
11   E e1 = new E(); // E1
12   w.g = e1;
13 } else {
14   F f1 = new F(); // F1
15   w.g = f1;
16 }
17 E x = w.g;
18 x.foo(null); // c

```

Figure 5 A small example.

from classes A, B, and D in Figure 3 to prevent name collisions), using a separate call graph construction algorithm to identify all potential target methods at “`x.foo(null)`” under any context results in the discovery of both `E:foo()` and `F:foo()`. Subsequent analysis of CFL-reachability with L_{FC} yields:

$$E1 \xrightarrow{\text{new}} e1 \xrightarrow{\text{store}[g]} w \xrightarrow{\text{new}} G1 \xrightarrow{\text{new}} w \xrightarrow{\text{load}[g]} x \xrightarrow[\hat{c}]{\text{assign}} \text{this}^{E:\text{foo}()} \quad (5)$$

$$F1 \xrightarrow{\text{new}} f1 \xrightarrow{\text{store}[g]} w \xrightarrow{\text{new}} G1 \xrightarrow{\text{new}} w \xrightarrow{\text{load}[g]} x \xrightarrow[\hat{c}]{\text{assign}} \text{this}^{E:\text{foo}()} \quad (6)$$

Therefore, both `E1` and `F1` will flow to `thisE:foo()` although `F1` is spurious by [I-VCALL]. Similarly, both `E1` and `F1` will flow to `thisF:foo()` with `E1` being spurious.

L_{FC} ’s precision loss stems from treating the receiver variable the same as other arguments ([P-VCALL] in Figure 2), in contrast to the inclusion-based approach ([I-VCALL] in Figure 1). Attempting to eliminate spurious receiver objects like `F1` for `E:foo()` informally, outside the specifications of L_{FC} or any call graph construction algorithm, is an ad hoc solution. This problem has persisted in the L_{FC} on-demand algorithm for kCFA [53], released as part of the SOOT compiler [59] and used by many other researchers [61, 48], in the last 15 years.

2.2.3.3 Discussion

In addressing kCFA, L_{FC} depends on an external algorithm for call graph construction. This approach not only leads to the precision loss in kCFA as previously mentioned, but also presents another limitation: L_{FC} is unable to track all value-flow paths involved in method dispatch, whether the call graph is constructed beforehand or generated on-the-fly.

In analyzing “`x.foo(d)`” in line 17 of Figure 3, for parameter passing of `d` at the callsite as per [I-VCALL], it is necessary to first identify methods dispatched on the receiver objects that `x` points to, then proceed with parameter passing (from `d` to `p` for `A:foo()`, and `d` to `q` for `B:foo()`). However, in L_{FC} , parameter passing, achieved through inter-procedural assign edges ([P-VCALL]), is conceptually and algorithmically detached from dynamic dispatch at the callsite. It does not relate this process via CFL-reachability to its receiver objects, a limitation also evident in the PAG shown in Figure 4.

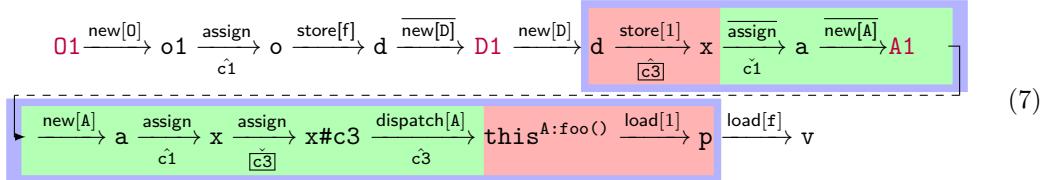

The limitations of L_{FC} indicate that its pre-analyses, designed to boost kCFA efficiency, can unintentionally compromise its precision. For example, SELECTX [33] aims to accelerate kCFA through selective context-sensitivity with L_{FC} , often leading to reduced precision.

2.2.4 L_{DCR} : Challenges and Our Solution

In developing L_{DCR} , it is crucial to facilitate CFL-reachability for parameter passing in line with k CFA. For a virtual call $\text{r.m}(a_1, \dots, a_n)$ at callsite c , passing an argument, denoted a , to its corresponding parameter p in a yet-to-be-discovered target method m' under context \mathbf{C} involves establishing a CFL-reachability path in a PAG representation, starting from a , through receiver variable r for dynamic dispatch (based on the dynamic type of the object pointed to by r under \mathbf{C}), and ending at p . Linking a to r , especially when $a \neq \text{r}$, is complex. Additionally, in CFL-reachability, some context elements in \mathbf{C} are consumed, i.e., matched during dynamic dispatch and must be restored for passing a to p under the same context \mathbf{C} . We identify three key challenges in handling this complex parameter-passing task:

- **CHL1.** How do we precisely pass r to the “this” variable of a target method m' invoked at callsite c , avoiding the precision loss as illustrated in Figure 5?
- **CHL2.** How do we establish a CFL-reachability path in a PAG representation of the program from a_i to p_i , passing through r to trigger dynamic dispatch during parameter passing, where p_i is the i -th parameter of a target method m' discovered at callsite c under \mathbf{C} ?
- **CHL3.** How do we ensure the passage of a_i to p_i for the target method m' invoked at callsite c with a context abstraction that accurately characterizes parameter passing for callsite c under \mathbf{C} ?

In our approach, illustrated using our motivating example (Figure 3), L_{DCR} is applied to a novel PAG representation depicted in Figure 7, distinct from the PAG used by L_{FC} (Figure 4). In this new formulation, we demonstrate that v points exclusively to 01 , attributable to a unique path from 01 to v :

The technical specifics of this path will be further elaborated in Section 3.

This path represents the flow of 01 to v through two calls, $c1$ (line 24) and $c3$ (line 17). Focusing on parameter passing of d at $c3$ under context $\mathbf{C} = [c1]$, where $A:\text{foo}()$ is the sole target, L_{DCR} employs a more indirect approach than L_{FC} 's direct inter-procedural assign edge $d \xrightarrow[c3]{\text{assign}} p$. L_{DCR} dynamically identifies dispatch targets in the path from d to p using a sequence of PAG edges. To address **CHL1**, we match $\text{new}[A]$ with $\text{dispatch}[A]$. For **CHL2**, d is stored in a special field of x to initiate dynamic dispatch, then loaded from the same field of $this^{A:\text{foo}()}$ into p (highlighted in \blacksquare). Afterwards, dynamic dispatch under $\mathbf{C} = [c1]$ is performed similarly to L_{FC} (highlighted in \blacksquare). To tackle **CHL3**, d is passed to p under context $[c3, c1]$, where $c3$ denotes the callsite and $c1$ the context for $A1$ flowing into x (highlighted in \blacksquare). The importance of the two boxed below-edge labels, $\hat{c3}$ and $\check{c3}$, in meeting **CHL3** will be elaborated upon in Section 3.

3 L_{DCR} : Design and Insights

When tackling a CFL-reachability problem, the selection of CFLs and their corresponding graph representations are closely interconnected and thoughtfully designed. To separate this interdependency, we first introduce a new PAG representation for a program, which supports

$$\begin{array}{c}
\frac{x = \mathbf{new} T // O}{O \xrightarrow{\mathbf{new}[T]} x} [\mathbf{C-NEW}] \quad \frac{M \text{ is an instance method}}{\mathbf{this}^M \xrightarrow{\mathbf{load}[i]} p_i^M} [\mathbf{C-PARAM}] \quad \frac{M \text{ is an instance method}}{\mathbf{ret}^M \xrightarrow{\mathbf{store}[0]} \mathbf{this}^M} [\mathbf{C-RET}] \\
\\
\frac{x = r.m(a_1, \dots, a_n) // c \quad t <: \text{DeclTypeOf}(r) \quad m' = \text{dispatch}(c, t)}{\forall i \in [1, n] : a_i \xrightarrow[\boxed{\hat{c}}]{\mathbf{store}[i]} r \quad r \xrightarrow[\boxed{\check{c}}]{\mathbf{load}[0]} x \quad r \xrightarrow{\mathbf{assign}} r\#c \quad r \xrightarrow[\boxed{\hat{c}}]{\mathbf{assign}} r\#c \quad r\#c \xrightarrow[\boxed{\check{c}}]{\mathbf{dispatch}[t]} \mathbf{this}^{m'}} [\mathbf{C-VCALL}]
\end{array}$$

Figure 6 Rules for building the PAG required by L_{DCR} . **[C-ASSIGN]**, **[C-LOAD]**, **[C-STORE]** and **[C-SCALL]** mirror those in Figure 2 and are excluded here to conserve space.

on-the-fly call graph construction (Section 3.1). Following this, we elaborate on L_{DCR} by detailing our solutions to the three challenges (**CHL1 – CHL3**) and providing insights into its design (Section 3.2).

3.1 Pointer Assignment Graph

For representing a program in L_{DCR} , we employ the rules specified in Figure 6 to construct a PAG. The inverse of a PAG edge $x \xrightarrow[c]{\ell} y$, implicitly defined, is $y \xrightarrow[\bar{c}]{\bar{\ell}} x$, mirroring the approach in L_{FC} (Section 2.1.2). However, our approach uniquely allows below-edge labels to be also either $\boxed{\hat{c}}$ or \check{c} , where $\boxed{\hat{c}} = \check{c}$ and $\check{c} = \boxed{\hat{c}}$, with c denoting a callsite. To initiate dynamic dispatch at a callsite c , edges with boxed below-edge labels symbolize a novel type of inter-procedural value-flow entering (indicated by $\boxed{\hat{c}}$) or exiting (marked by \check{c}) a method at c . These specific boxed below-edge labels are introduced solely for addressing **CHL3**, and their significance will be explained in Section 3.2.2.

Our PAG, designed for L_{DCR} , primarily differs from the one for L_{FC} (Figure 2) in handling virtual callsites. Consequently, **[C-ASSIGN]**, **[C-LOAD]**, **[C-STORE]**, and **[C-SCALL]** are the same as **[P-ASSIGN]**, **[P-LOAD]**, **[P-STORE]**, and **[P-SCALL]**, respectively. The additional rules in Figure 6 construct PAG edges that facilitate on-the-fly call graph construction at virtual callsites, addressing **CHL1** and **CHL2**.

In **[C-NEW]**, $O \xrightarrow{\mathbf{new}[T]} x$ specifically encodes T , the dynamic type of O , to facilitate dynamic dispatch on O and enable its use as a receiver object, avoiding precision loss as depicted in Figure 5.

For **[C-PARAM]** and **[C-RET]**, we treat the i -th (non-**this**) parameter of an instance method M (denoted as p_i^M , with i starting from 1) and its return variable \mathbf{ret}^M as special fields of \mathbf{this}^M , identified by offset i and 0, respectively. This allows the initialization of $\mathbf{this}^M.0$ with a store $\mathbf{ret}^M \xrightarrow{\mathbf{store}[0]} \mathbf{this}^M$ and a non-**this** parameter p_i^M with a load $\mathbf{this}^M \xrightarrow{\mathbf{load}[i]} p_i^M$.

In **[C-VCALL]**, we uniquely handle virtual calls like “ $x = r.m(a_1, \dots, a_n) // c$ ” differently from **[P-VCALL]** (Figure 2), using $r\#c$ to uniquely identify r at callsite c . There are two edges between r and $r\#c$: the edge $r \xrightarrow{\mathbf{assign}} r\#c$, which is essential for passing the receiver variable, and the edge $r \xrightarrow[\check{c}]{\mathbf{assign}} r\#c$, which is crucial for passing other arguments during parameter passing, as will be explained shortly. We initially over-approximate target methods at c using CHA ([9]), similar to L_{FC} , for later refinement by L_{DCR} . For each target method m' , the argument a_i is passed to the corresponding parameter $p_i^{m'}$ ($1 \leq i \leq n$) via a store $a_i \xrightarrow[\boxed{\hat{c}}]{\mathbf{store}[i]} r$ and a matching load $\mathbf{this}^{m'} \xrightarrow{\mathbf{load}[i]} p_i^{m'}$ (**[C-PARAM]**). CFL-reachability under L_{DCR} involves traversing this store edge to find the dynamic type of each receiver object pointed by r (marked by $\boxed{\hat{c}}$). The sequence $r \xrightarrow[\check{c}]{\mathbf{assign}} r\#c \xrightarrow[\check{c}]{\mathbf{dispatch}[t]} \mathbf{this}^{m'}$ indicates finding the dynamic type t (marked by \check{c}), enabling dispatch of m' with \hat{c} as its entry context (i.e.,

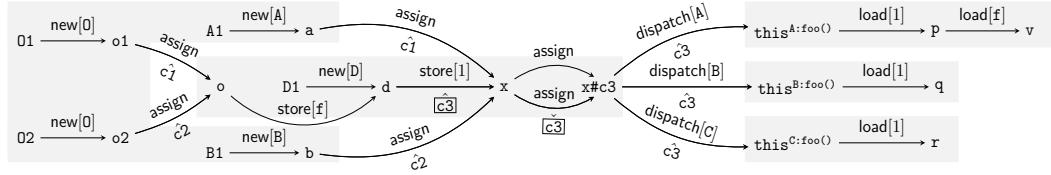

Figure 7 The PAG for L_{DCR} constructed for the program given in Figure 3.

$m' = \text{dispatch}(c, t)$ as desired). A **dispatch** edge also functions as an **assign** edge. For the receiver variable r , we simply use $r \xrightarrow{\text{assign}} r\#c$ (without the need for relating r to itself). Finally, x is assigned $\text{ret}^{m'}$ (stored in $\text{this}^{m'}.0$ ([**C-RET**])) via a load $r \xrightarrow{\text{load}[0]} x$, with \boxed{c} marking the conclusion of the dynamic dispatch at callsite c .

Figure 7 illustrates the PAG leveraged by L_{DCR} for our motivating example, as presented in Figure 3. This PAG, uniquely tailored to support L_{DCR} 's integrated call graph construction, shows notable differences from the PAG employed by L_{FC} , as depicted in Figure 4.

3.2 L_{DCR} : A New CFL-Reachability Formulation for k CFA

L_{DCR} combines three CFLs ($L_{DCR} = L_D \cap L_C \cap L_R$) for addressing **CHL1 – CHL3**. L_D , detailed in Section 3.2.1, deals with field accesses and dynamic dispatch, catering to **CHL1** and **CHL2**. L_C , defined in Equation (2), ensures callsite-sensitivity using below-edge labels Σ_{L_C} , which include \hat{c} and \check{c} , and treats L_{DCR} 's unique boxed labels $\hat{\square}$ and $\check{\square}$ as ϵ . L_R , presented in Section 3.2.2, facilitates parameter passing in on-the-fly call graph construction, addressing **CHL3**. The focus will predominantly be on L_D and L_R , concentrating on parameter passing, with method returns being similarly handled.

Basic Idea. L_{DCR} , a CFL-reachability formulation, differs from L_{FC} mainly in managing parameter passing at virtual callsites, enabling L_{DCR} 's built-in call graph construction compared to L_{FC} 's reliance on a separate algorithm (Sec. 2.2.3.2). At a virtual callsite “ $r.m(a_1, \dots, a_n); //c$ ” under context C , handling the receiver variable r (pointing to receiver objects) involves addressing **CHL1**: passing a receiver object to $\text{this}^{m'}$ for dispatch on m' . In addition, for an argument a_i , **CHL2** and **CHL3** are met by storing a_i in $r.i$, verifying if any object pointed by r under C matches dynamic type t , dynamically dispatching to m' ($m' = \text{dispatch}(c, t)$), and assigning $\text{this}^{m'}.i$ to $p_i^{m'}$ at callsite c under context C . Method returns are handled in a similar fashion.

► **Example 1.** Revisiting our motivating example (Figure 3) and its PAG (Figure 7), L_{DCR} ensures a unique path from **01** to v , as shown in Equation (7), so that v points only to **01** when $\text{bar}()$ is invoked at **c1**. The sub-path from **01** to d shows that **01** is stored into $d.f$, with d pointing to **D1**. The sub-path from d to p indicates parameter passing at callsite **c3** to p for $A:\text{foo}()$, dynamically identified by L_{DCR} under $C = [c1]$. We have discussed addressing **CHL1 – CHL3** at this callsite in Section 2.2.4. We wish to emphasize that $\hat{\square}$ and $\check{\square}$ signify dynamic dispatch's start and end at callsite **c3** for d . CFL-reachability traversal between these markers confirms that x points to **A1** under $[c1]$, necessitating a return to x under $[c1]$. With receiver object **A1**, $A:\text{foo}()$ is dispatched via $x\#c3 \xrightarrow[\hat{c3}]{\text{dispatch}[A]} \text{this}^{A:\text{foo}()}$, allowing d to pass to p under $[c3, c1]$. Unlike L_{FC} [53] that uses $[c3]$, L_{DCR} specifies $[c3, c1]$ to indicate this occurs only when x points to **A1** under $[c1]$. $C:\text{foo}()$, present in the PAG due to CHA [9], is filtered out by L_{DCR} 's on-the-fly call graph construction.

Let L_{FC}^{dd} be a demand-driven formulation of L_{FC} that is identical in all aspects except for one modification. This version continues to utilize a separate algorithm for on-the-fly call graph construction, but it has been specifically enhanced to accurately handle parameter passing for receiver variables, effectively avoiding the precision loss discussed in Section 2.2.3.2.

When developing L_{DCR} , we treat soundness fundamentally as an issue of precision.

► **Definition 2** (Soundness and Precision of On-the-Fly Call Graph Construction). *For any given callsite and context C , let T be the set of target methods identified under C through L_{FC}^{dd} . Suppose L is a language differing from L_{FC}^{dd} solely in managing parameter passing at virtual callsites. We regard L as sound if it facilitates parameter passing under C for at least the methods in T , and as precise (besides being sound) if it enables parameter passing under C for precisely the target methods in T .*

We write $L_{DC} = L_D \cap L_C$ as the intersection of L_D and L_C . A path p qualifies as an L_{DCR} -path if $L_D(p) \in L_D$, $L_C(p) \in L_C$, and $L_R(p) \in L_R$. An L_{DC} -path is defined similarly. As we will discuss further, L_{DC} is sound yet imprecise, whereas L_{DCR} is precise.

3.2.1 The L_D Language

This CFL captures both field-sensitive accesses, similar to L_F in Equation (1), and dynamic dispatch within its language framework:

$$\begin{aligned}
\text{flowsto} &\longrightarrow \text{new}[t] (\text{flows} \mid \text{dispatch}[t])^* \\
\text{flows} &\longrightarrow \text{assign} \mid \text{store}[f] \text{ alias } \text{load}[f] \\
\text{alias} &\longrightarrow \overline{\text{flowsto}} \text{ flowsto} \\
\overline{\text{flowsto}} &\longrightarrow (\text{dispatch}[t] \mid \overline{\text{flows}})^* \overline{\text{new}[t]} \\
\overline{\text{flows}} &\longrightarrow \overline{\text{assign}} \mid \overline{\text{load}[f]} \text{ alias } \overline{\text{store}[f]}
\end{aligned} \tag{8}$$

Here, Σ_{L_D} includes all above-edge labels in the program's PAG. L_D extends L_F from Equation (1) [54, 53] by retaining its balanced parentheses approach for field accesses and adding support for dynamic dispatch, which facilitates on-the-fly call graph construction. Next, we describe how L_D is specifically designed to address **CHL1** and **CHL2**.

3.2.1.1 CHL1

To address **CHL1** regarding parameter passing at a virtual callsite, it is crucial that a receiver object O , pointed to by its receiver variable, is only passed to the `this` variable of a method dispatchable on O . For instance, in `x.foo(null)` from Figure 5, where `x` might point to both `E1` and `F1`, L_{FC} might incorrectly pass both `E1` and `F1` to `thisE:foo()`, as shown in Equations (5) and (6), despite `F1` being spurious. Note that L_{FC}^{dd} , introduced just before Definition 2, was specifically conceptualized to mitigate such precision loss.

In L_D , we explicitly specify the dynamic types of objects in four terminals: `new[t]`, `new[\overline{t}]`, `dispatch[t]`, and `dispatch[\overline{t}]`. This modification alters the two L_{FC} -paths discussed in Equations (5) and (6) for Figure 5 as follows:

$$E1 \xrightarrow{\text{new}[E]} e1 \xrightarrow{\text{store}[g]} w \xrightarrow{\overline{\text{new}[G]}} G1 \xrightarrow{\text{new}[G]} w \xrightarrow{\text{load}[g]} x \xrightarrow{\text{assign}} x\#c \xrightarrow[\epsilon]{\text{dispatch}[E]} \text{this}^{E:\text{foo}()} \tag{9}$$

$$F1 \xrightarrow{\text{new}[F]} f1 \xrightarrow{\text{store}[g]} w \xrightarrow{\overline{\text{new}[G]}} G1 \xrightarrow{\text{new}[G]} w \xrightarrow{\text{load}[g]} x \xrightarrow{\text{assign}} x\#c \xrightarrow[\epsilon]{\text{dispatch}[E]} \text{this}^{E:\text{foo}()} \tag{10}$$

During a `flowsto` ($\overline{\text{flowsto}}$) traversal, the type in `dispatch[t]` ($\overline{\text{dispatch}[t]}$) must align with its corresponding `new[t]` ($\overline{\text{new}[t]}$). Thus, the path in Equation (9) qualifies as an L_D -path, as $\text{new}[E] \text{ flows}^* \text{ dispatch}[E] \in L_D$, but the path in Equation (10) does not as $\text{new}[F] \text{ flows}^* \text{ dispatch}[E] \notin L_D$. Hence, in L_D , **F1** cannot spuriously flow to `thisE:foo()`. Similarly, in Equation (7), only **A1** can be passed to `thisA:foo()`, as `A:foo()` is dispatchable on **A1**.

► **Lemma 3.** *Consider a virtual callsite $x = r.m(a_1, \dots, a_n)$. In L_D , every receiver object pointed to by r flows only to the `this` variable of a method that can be dispatched on the receiver object.*

Proof Sketch. Follows from the definition of L_D . ◀

3.2.1.2 CHL2

To meet **CHL2** and trigger dynamic dispatch at virtual callsites during parameter passing, we use $L_{DC} = L_D \cap L_C$. Re-examining the L_{DCR} -path in Equation (7) without $\hat{c3}$ and $\check{c3}$, we assess if **01** flows into v starting from $c1$. Parameter passing for d at “`x.foo(d); // c3`” under $C = [c1]$ involves traversing the sub-path from d to p of `A:foo()`. Starting with $d \xrightarrow{\text{store}[1]} x$, a `flowsto` traversal is initiated via $x \xrightarrow[\check{c1}]{\text{assign}} a \xrightarrow{\text{new}[A]} \text{A1}$ under $C = [c1]$, returning to x via $\text{A1} \xrightarrow{\text{new}[A]} a \xrightarrow[\check{c1}]{\text{assign}} x$, dispatching at $c3$ through $x \xrightarrow{\text{assign}} x\#c3 \xrightarrow[\hat{c3}]{\text{dispatch}[A]} \text{this}^{A:\text{foo}()}$, and finally passing d to p via $\text{this}^{A:\text{foo}()} \xrightarrow{\text{load}[1]} p$. Unlike L_{FC} 's direct passage of d to p in Equation (3), L_{DCR} uses a series of edges under $[c3, c1]$, indicating dispatch occurs only when x points to **A1** under $[c1]$.

► **Lemma 4.** *L_{DC} is sound in handling parameter passing at virtual callsites.*

Proof Sketch. Consider a virtual callsite $r.m(a_1, \dots, a_n); // c$, where parameter passing for an argument occurs under context C . Let T represent the set of target methods identified on the fly for this callsite under C by applying a separate call graph algorithm as in L_{FC}^{dd} . As r is handled similarly as in L_{FC}^{dd} , it suffices to consider parameter passing for a non-this argument a_i . Focusing on a_i , L_{DC} initiates dynamic dispatch by locating receiver objects pointed to by r under also C . Since L_{DC} differs from L_{FC}^{dd} only in handling parameter passing at virtual callsites, the set of target methods found by L_{DC} must include T . In addition, for each target $m' \in T$, there always exists a PAG path q :

$$a_i \xrightarrow{\text{store}[i]} r \xrightarrow{\text{flowsto}} O \xrightarrow{\text{flowsto}} r \xrightarrow{\text{assign}} r\#c \xrightarrow{\text{dispatch}[-]} \text{this}^{m'} \xrightarrow{\text{load}[i]} p_i^{m'} \quad (11)$$

Here, if u represents “ $r \xrightarrow{\text{flowsto}} O$ ”, then “ $O \xrightarrow{\text{flowsto}} r$ ” is its inverse \bar{u} . This ensures a_i flows p_i by L_D and $L_C(q) \in L_C$ by L_C . Moreover, $L_C(q)$ forms a sequence of contexts feasible under C , as u is traversed under C . Therefore, by Definition 2, L_{DC} is sound. ◀

3.2.2 The L_R Language

L_{DC} , though sound, is not precise. This is illustrated in examples from Figures 8 and 9, highlighting L_{DC} 's limitations and underscoring the importance of L_R in L_{DCR} .

```

1 static void main() {
2   H h = new H(); // H1
3   I i1 = new I(); // I1
4   I i2 = new I(); // I2
5   h.m(i1); // c4
6   h.n(i2); // c5
7 }
8 class I {}
9 class H {
10  void m(Object p) { ... }
11  void n(Object q) { ... }
12 }

```

Figure 8 An example for illustrating the imprecision of L_{DC} caused by an incorrect dispatch site.

```

1 static void main() {
2   J j1 = new J(); // J1
3   K k1 = new K(); // K1
4   K k2 = new K(); // K2
5   K v1 = wid(j1, k1); // c6
6   K v2 = wid(j1, k2); // c7
7 }
8 class K {}
9 class J {
10  K id(K p) {
11    return p;
12 }
13 static K wid(J j, K k) {
14  K v = j.id(k); // c8
15  return v;
16 }

```

Figure 9 An example for showing the imprecision of L_{DC} caused by an incorrect dispatch context.

L_{DC} 's precision loss can occur from a spurious dispatch callsite, shown by the following two L_{DC} -paths for Figure 8, temporarily ignoring the boxed labels $\hat{c4}$, $\check{c4}$, and $\check{c5}$:

$$\text{I1} \xrightarrow{\text{new[I]}} \text{i1} \xrightarrow[\hat{c4}]{\text{store[1]}} \text{h} \xrightarrow{\text{new[H]}} \text{H1} \xrightarrow{\text{new[H]}} \text{h} \xrightarrow[\check{c4}]{\text{assign}} \text{h}\#c4 \xrightarrow{\text{dispatch[H]}} \text{this}^m \xrightarrow{\text{load[1]}} \text{p} \quad (12)$$

$$\text{I1} \xrightarrow{\text{new[I]}} \text{i1} \xrightarrow[\hat{c4}]{\text{store[1]}} \text{h} \xrightarrow{\text{new[H]}} \text{H1} \xrightarrow{\text{new[H]}} \text{h} \xrightarrow[\check{c5}]{\text{assign}} \text{h}\#c5 \xrightarrow{\text{dispatch[H]}} \text{this}^n \xrightarrow{\text{load[1]}} \text{q} \quad (13)$$

Both L_{DC} -paths track **I1**'s flow in the program's PAG. The first path correctly leads **I1** to **p**. However, the second path spuriously directs **I1** to **q**, as the flowsto traversal to identify **a**'s receiver object starts at **c4** but concludes at **c5** spuriously. L_R addresses this precision issue by requiring matched boxed edge labels. As a result, the first path in Equation (12) is a valid L_{DCR} -path (with $\hat{c4}$ matched by $\check{c4}$), while the second path in Equation (13) is invalidated (due to the mismatch of $\hat{c4}$ and $\check{c5}$).

L_{DC} may also experience precision loss due to a spurious dispatch context. Consider the following two L_{DC} -paths in the PAG of Figure 9 (by ignoring the boxed labels $\hat{c8}$ and $\check{c8}$ for now):

$$\begin{aligned} & \text{K1} \xrightarrow{\text{new[K]}} \text{k1} \xrightarrow[\hat{c6}]{\text{assign}} \text{k} \xrightarrow{\text{store[1]}} \text{j} \xrightarrow[\check{c6}]{\text{assign}} \text{j1} \xrightarrow{\text{new[J]}} \text{J1} \xrightarrow{\text{new[J]}} \text{j1} \xrightarrow[\hat{c6}]{\text{assign}} \text{j} \xrightarrow[\check{c8}]{\text{assign}} \text{j}\#c8 \xrightarrow{\text{dispatch[J]}} \text{this}^{\text{id}} \xrightarrow{\text{load[1]}} \\ & \text{p} \xrightarrow{\text{store[0]}} \text{this}^{\text{id}} \xrightarrow[\hat{c8}]{\text{dispatch[J]}} \text{j}\#c8 \xrightarrow[\check{c8}]{\text{assign}} \text{j} \xrightarrow[\hat{c6}]{\text{assign}} \text{j1} \xrightarrow{\text{new[J]}} \text{J1} \xrightarrow{\text{new[J]}} \text{j1} \xrightarrow[\hat{c6}]{\text{assign}} \text{j} \xrightarrow[\check{c8}]{\text{load[0]}} \text{v} \xrightarrow[\hat{c6}]{\text{assign}} \text{v1} \end{aligned} \quad (14)$$

$$\begin{aligned} & \text{K1} \xrightarrow{\text{new[K]}} \text{k1} \xrightarrow[\hat{c6}]{\text{assign}} \text{k} \xrightarrow{\text{store[1]}} \text{j} \xrightarrow[\check{c6}]{\text{assign}} \text{j1} \xrightarrow{\text{new[J]}} \text{J1} \xrightarrow{\text{new[J]}} \text{j1} \xrightarrow[\hat{c7}]{\text{assign}} \text{j} \xrightarrow[\check{c8}]{\text{assign}} \text{j}\#c8 \xrightarrow{\text{dispatch[J]}} \text{this}^{\text{id}} \xrightarrow{\text{load[1]}} \\ & \text{p} \xrightarrow{\text{store[0]}} \text{this}^{\text{id}} \xrightarrow[\hat{c8}]{\text{dispatch[J]}} \text{j}\#c8 \xrightarrow[\check{c8}]{\text{assign}} \text{j} \xrightarrow[\hat{c7}]{\text{assign}} \text{j1} \xrightarrow{\text{new[J]}} \text{J1} \xrightarrow{\text{new[J]}} \text{j1} \xrightarrow[\hat{c7}]{\text{assign}} \text{j} \xrightarrow[\check{c8}]{\text{load[0]}} \text{v} \xrightarrow[\hat{c7}]{\text{assign}} \text{v2} \end{aligned} \quad (15)$$

These two L_{DC} -paths in Figure 9 vary only by context: Equation (15) is similar to Equation (14), but replaces **c7** with **c6** and **v2** with **v1**. Both track where **K1** flows, starting from “**wid(j1,k1); // c6**”. According to Equation (14), **v1** points to **K1** as expected. However, Equation (15) inaccurately allows **K1**, passed at **c6**, to flow into **v2** at **c7**, spuriously indicating

v2 points to K1. Focusing on dynamic dispatch at callsite c8 in line 14 due to the call at c6 in line 5 (Figure 9), Equation (14) shows that j initially pointing to J1 under [c6] and maintains this during both flowsto and flowsto traversals from c6. However, Equation (15) starts similarly but ends with j pointing to J1 under [c7], which is inconsistent with the call at c6.

In general, L_{DC} may lack precision as it sometimes includes spurious sub-paths for dynamic dispatch. Consider a generic virtual callsite $r.m(a_1, \dots, a_n) // c$, L_{DC} initiates dynamic dispatch by executing the following alias-related traversal on its receiver variable r:

$$\dots \xrightarrow[\hat{c}]{\text{store}[i]} r \xrightarrow{\text{flowsto}} O \xrightarrow{\text{flowsto}} r' \xrightarrow[\check{c}']{\text{assign}} r' \# c' \xrightarrow{\hat{c}'} \dots \quad (16)$$

Such a *dispatch path*, which starts from \hat{c} and ends at \check{c}' , is *valid* if two conditions are met:

- **DP-C1:** $c = c'$ (implying that $r = r'$), and
- **DP-C2:** O is pointed by both r and r' under exactly the same context.

However, L_{DC} can ensure that r and r' are aliases but cannot guarantee the validity of this dispatch path. For example, Equation (13) contains a dispatch path violating **DP-C1**, and Equation (15) violates **DP-C2**. To exclude such invalid dispatch paths in L_{DC} -paths, L_R is designed to utilize all below-edge labels in the PAG (i.e., \hat{c} , \check{c} , \hat{C} , and \check{C}) as terminals:

$$\begin{aligned} \text{recoveredCtx} &\longrightarrow \text{recoveredCtx } \hat{c} \mid \text{recoveredCtx } \check{c} \mid \text{recoveredCtx siteRecovered} \mid \epsilon \\ \text{siteRecovered} &\longrightarrow \hat{C} \text{ ctxRecovered } \check{C} \\ \text{ctxRecovered} &\longrightarrow \text{matched ctxRecovered} \mid \text{ctxRecovered matched} \mid \check{c} \text{ ctxRecovered } \hat{c} \mid \epsilon \\ \text{matched} &\longrightarrow \text{matched matched} \mid \hat{c} \text{ matched } \check{c} \mid \text{siteRecovered} \mid \epsilon \end{aligned} \quad (17)$$

Here, Σ_{L_R} includes all below-edge labels in the program's PAG. The start symbol `recoveredCtx` would define a language that contains L_C if its third alternative “`recoveredCtx siteRecovered`” were changed to “`recoveredCtx`”. Thus, L_R is engaged during a dispatch path traversal. The `siteRecovered` production enforces **DP-C1**, and the `ctxRecovered` and `matched` productions collectively enforce **DP-C2**. This design enables L_R to address **CHL3** by reinstating the context of r.

By incorporating L_R into L_{DC} , the composite language $L_{DCR} = L_D \cap L_C \cap L_R$ achieves precision in managing parameter passing at virtual callsites. Reexamining the paths in Equations (14) and (15), with the inclusion of \hat{C} and \check{C} , it is clear that the first path qualifies as an L_{DCR} -path, while the second does not. In the first path, the dynamic dispatch starts at callsite c8 under context [c6] and returns to the same callsite under the same context, signified by \hat{C} and \check{C} . Conversely, the second path, while also starting dispatch at callsite c8 under context [c6], mistakenly returns under a different context, [c7], making it invalid for L_{DCR} . As a result, L_{DCR} correctly determines that K1 is pointed to by v1, but not by v2, effectively preventing v2 from pointing to K1 spuriously.

Below, we give a formal development of L_R , followed by a proof of L_{DCR} 's precision.

To determine the points-to set of a variable v , $\text{PTS}(v, c_v)$, using L_{DC} , consider an L_C -path p with label $L_C(p) = \ell_1, \dots, \ell_n$, where each ℓ_i is a context label on an inter-procedural assign edge. The inverse of p , \bar{p} , has a label $L_C(\bar{p}) = \bar{\ell}_n, \dots, \bar{\ell}_1$. Splitting p into sub-paths p^{ex} and p^{en} , we define $L_C^{\text{ex}}(p) = L_C(p^{\text{ex}})$ and $L_C^{\text{en}}(p) = L_C(p^{\text{en}})$, with $L_C(p) = L_C^{\text{ex}}(p)L_C^{\text{en}}(p)$. Here, $L_C^{\text{ex}}(p)$ and $L_C^{\text{en}}(p)$ are derived from exit and entry in L_C 's grammar (Equation (2)). For $s \in L_C$, $\mathcal{B}(s)$ returns s's canonical form with balanced contexts removed. If c is a string of exit contexts like $\check{c}_1 \dots \check{c}_n$, $\mathcal{E}(c) = [c_1, \dots, c_n]$ converts it into a context representation, noting $\mathcal{E}(\epsilon) = []$.

For an L_{DC} -path p from an object O to a variable v , we can clearly deduce the following points-to relationship, including the specific contexts of O and v :

$$\langle O, \mathcal{E}(\mathcal{B}(L_C^{\text{ex}}(p))) \rangle \in \text{PTS}(v, \mathcal{E}(\overline{\mathcal{B}(L_C^{\text{en}}(p))})) \quad (18)$$

► **Example 5.** Let us take $p_{\text{O1},v}$, the L_{DC} -path from Equation (7), by ignoring $\hat{[\text{c3}]}$ and $\check{[\text{c3}]}$. By definition, $L_C(p_{\text{O1},v}) = \hat{[\text{c1c1c1c3}]}$, where $p_{\text{O1},v}^{\text{ex}}$ denotes the sub-path from O1 to A1 and $p_{\text{O1},v}^{\text{en}}$ denotes the sub-path from A1 to v . Thus, $L_C^{\text{ex}}(p_{\text{O1},v}) = \hat{[\text{c1c1}]}$ and $L_C^{\text{en}}(p_{\text{O1},v}) = \hat{[\text{c1c3}]}$. Since $\mathcal{E}(\mathcal{B}(\hat{[\text{c1c1}]}) = []$ and $\mathcal{E}(\mathcal{B}(\hat{[\text{c1c3}]}) = [\text{c3}, \text{c1}]$, we have: $\langle \text{O1}, [] \rangle \in \text{PTS}(v, [\text{c3}, \text{c1}])$.

To enforce **DP-C1**, the production $\text{siteRecovered} \rightarrow \hat{[\text{c}]} \text{ ctxRecovered } \check{[\text{c}]}$ ensures that a dispatch process starting at a callsite (indicated by $\hat{[\text{c}]}$) concludes at the same callsite (marked by $\check{[\text{c}]}$). In the dispatch path from Equation (16), this guarantees $c = c'$ and $r = r'$. Thus, matching $\hat{[\text{c}]}$ with $\check{[\text{c}]}$ allows c to be reinstated at the next dispatch edge, ensuring dynamic dispatch occurs specifically at callsite c .

To enforce **DP-C2**, the ctxRecovered - and matched -productions are crucial, with ctxRecovered

$\rightarrow \check{[\text{c}]} \text{ ctxRecovered } \hat{[\text{c}]}$ being central. This is best understood through a generic dispatch path in Equation (16). **DP-C2** can be rephrased as follows. Let $p_{r,O}$ be the flowsto path from r to O , and its inverse $\overline{p_{r,O}}$ a flowsto path. Consider $p_{O,r'}$ as the flowsto path from O to r' . The path from r to r' is composed of $p_{r,O} p_{O,r'}$ or equivalently $p_{r,O}^{\text{ex}} p_{r,O}^{\text{en}} p_{O,r'}^{\text{ex}} p_{O,r'}^{\text{en}}$. Applying Equation (18), we deduce:

$$\begin{aligned} \langle O, \mathcal{E}(\mathcal{B}(L_C^{\text{ex}}(\overline{p_{r,O}}))) \rangle &\in \text{PTS}(r, \mathcal{E}(\overline{\mathcal{B}(L_C^{\text{en}}(\overline{p_{r,O}}))})) \\ \langle O, \mathcal{E}(\mathcal{B}(L_C^{\text{ex}}(p_{O,r'}))) \rangle &\in \text{PTS}(r', \mathcal{E}(\overline{\mathcal{B}(L_C^{\text{en}}(p_{O,r'}))})) \end{aligned} \quad (19)$$

As r and r' are aliases, they must always point to O with exactly the same heap context, i.e., $\mathcal{E}(\mathcal{B}(L_C^{\text{ex}}(\overline{p_{r,O}}))) = \mathcal{E}(\mathcal{B}(L_C^{\text{ex}}(p_{O,r'})))$. Thus, $\mathcal{B}(\mathcal{B}(L_C^{\text{ex}}(\overline{p_{r,O}})) \mathcal{B}(L_C^{\text{ex}}(p_{O,r'}))) = \epsilon$ holds, implying the edge labels on path $p_{r,O}^{\text{en}} p_{O,r'}^{\text{ex}}$ must be balanced. Besides, r and r' are required to have the same context, i.e., $\mathcal{E}(\mathcal{B}(L_C^{\text{en}}(\overline{p_{r,O}}))) = \mathcal{E}(\mathcal{B}(L_C^{\text{en}}(p_{O,r'})))$. Thus, the following must be true:

$$\mathcal{B}(\mathcal{B}(L_C^{\text{en}}(p_{O,r'})) \overline{\mathcal{B}(L_C^{\text{en}}(\overline{p_{r,O}}))}) = \epsilon \quad (20)$$

implying that the edge labels in path $p_{O,r'}^{\text{en}} p_{r,O}^{\text{ex}}$ must be balanced out.

Both the ctxRecovered - and matched -productions in L_R play key roles during dispatch path traversal, as illustrated in Equation (16). The production $\text{ctxRecovered} \rightarrow \check{[\text{c}]} \text{ ctxRecovered } \hat{[\text{c}]}$ enforces **DP-C2** (see Equation (20)), while $\text{matched} \rightarrow \text{siteRecovered}$ initiates traversal of another dispatch path. The other productions help bypass matched contexts and callsites. In simple terms, for a traversal from r to O (r flowsto O), writing down all unmatched exit contexts as $\check{[\text{c}_1]}, \dots, \check{[\text{c}_n]}$ implies that the unmatched entry contexts seen on the return from O to r' (O flowsto r') should be $\hat{[\text{c}_1]}, \dots, \hat{[\text{c}_n]}$.

Revisiting the two L_{DC} -paths from Equations (14) and (15), as introduced in Section 3.2.2, the L_{DC} -path in Equation (14) qualifies as an L_{DCR} -path due to its valid dispatch paths. However, the L_{DC} -path in Equation (15) does not, as its initial dispatch path at callsite c8 from j to $j\#\text{c8}$ is invalid. With $\mathcal{B}(L_C^{\text{en}}(p_{j,\text{J1}})) = \check{[\text{c6}]}$ and $\mathcal{B}(L_C^{\text{en}}(p_{\text{J1},j})) = \hat{[\text{c7}]}$, we find $\mathcal{B}(\mathcal{B}(L_C^{\text{en}}(p_{\text{J1},j})) \mathcal{B}(L_C^{\text{en}}(p_{j,\text{J1}}))) = \hat{[\text{c7}]} \check{[\text{c6}]} \neq \epsilon$, indicating the path is invalid as $\check{[\text{c6}]} \hat{[\text{c7}]}$ does not balance out according to $\text{ctxRecovered} \rightarrow \check{[\text{c}]} \text{ ctxRecovered } \hat{[\text{c}]}$.

► **Theorem 1.** L_{DCR} is precise in handling parameter passing for virtual callsites.

Proof. Drawing from Lemmas 3 and 4, it suffices to show that for every virtual callsite “ $r.m(a_1, \dots, a_n); // c$ ” under context \mathbf{C} , L_{DCR} precisely handles parameter passing for the same target method set T identified at this callsite under \mathbf{C} by L_{FC}^{dd} ’s call graph algorithm. This holds as L_R filters out only those L_{DC} -paths with invalid dispatch paths. \blacktriangleleft

L_{DCR} achieves the same level of precision as L_{FC}^{dd} , thereby ensuring both soundness and precision in computing points-to information. We now employ L_{DCR} to determine points-to information in our motivating example (Figure 3), with Equation (18) being relevant but focusing solely on L_{DCR} -paths in the program’s PAG. Although CHA [9] in the PAG (Figure 7) broadly predicts target methods at virtual callsites, L_{DCR} ’s on-the-fly call graph construction process efficiently filters out spurious target methods like $\mathbf{C}:foo()$.

Finally, let us compare L_{DCR} , a CFL-reachability-based pointer analysis, with k CFA (Figure 1). While L_{DCR} , like L_{FC} [53], is suited for demand-driven analysis, k CFA is for whole-program analysis. Their key difference is the starting point: k CFA begins with entry methods M , including `main()`, and L_{DCR} with query variables V . Thus, k CFA may not compute points-to information for variables in V not reachable from M . In terms of precision, if k CFA determines $PTS(v, c)$ for variable v from M under context c , L_{DCR} can obtain exactly the same points-to set for v under c according to Equation (18). However, k CFA may overlook points-to information in the code unreachable from M .

3.3 Time Complexities

The PAG construction shown in Figures 2 and 6 scales linearly with the number of program statements. Yet, the L_{DCR} -reachability problem, like the L_{FC} -reachability problem [53], is undecidable due to being an intersection of three interwoven CFLs (L_D , L_C , L_R), making the combinations of $L_D \cap L_C$, $L_D \cap L_R$, and $L_C \cap L_R$ also undecidable [45]. For any individual CFL language $L \in \{L_D, L_C, L_R\}$, the reachability problem’s time complexity can reach up to $O(m^3n^3)$, where m is the grammar size and n is the number of nodes in the PAG.

Similar to k CFA (Figure 1), which introduces k -limiting to L_C in L_{FC} , resulting in a complexity of $O(n^3)$, we can also render the L_{DCR} -reachability problem computable within polynomial time for practical applications by applying k -limiting to both L_C and L_R .

4 P3Ctx : An Application of L_{DCR}

In our secondary contribution, we demonstrate the effectiveness of L_{DCR} through P3Ctx, the first pre-analysis tool powered by L_{DCR} for accelerating k CFA with selective context-sensitivity, always maintaining its precision. This also confirms L_{DCR} ’s correctness. Conversely, SELECTX [33], an L_{FC} -enabled pre-analysis does not guarantee precision preservation.

4.1 Selective Context-Sensitivity

Selective context sensitivity enhances the efficiency of context-sensitive analyses, maintaining much of their precision. It applies context-sensitivity selectively to crucial program variables and objects, treating the rest context-insensitively. SELECTX [33], a recent method for selective context-sensitive pointer analysis in k CFA, is built on L_{FC} , an incomplete formulation dependent on an external call graph construction algorithm. As a result, SELECTX inaccurately categorizes some vital variables and objects, causing precision loss. To remedy this, we introduce P3Ctx, a new L_{DCR} -based pre-analysis technique for selective context-sensitivity in k CFA, ensuring precision. P3Ctx is developed following the fundamental approach used in [33] for creating SELECTX.

4.1.1 CFL-Reachability-Guided Selections

Applying L_{FC} to develop SELECTX [33] is straightforward. For a flowsto path $p_{O,n,v}$ in L_{FC} , starting from an object O to a variable v via n (a variable or object in method M), consider $p_{O,n}$ as the segment from O to n , and $p_{n,v}$ from n to v . Then n requires context-sensitivity in $kCFA$ to avoid potential precision loss *only if* three conditions are met:

$$\begin{aligned} \text{CS-C1} : L_F(p_{O,n,v}) &\in L_F \\ \text{CS-C2} : L_C(p_{O,n}) &\in L_C \wedge L_C(p_{n,v}) \in L_C \\ \text{CS-C3} : L_C^{\text{en}}(p_{O,n}) &\neq \epsilon \wedge L_C^{\text{ex}}(p_{n,v}) \neq \epsilon \end{aligned} \quad (21)$$

where L_C^{en} and L_C^{ex} are from Section 3.2.2. O from outside M flows into n along $p_{O,n}$ context-sensitively and n flows out of M into v along $p_{n,v}$ context-sensitively, via M 's parameters (or return variable) along each path. Note that $p_{O,n,v}$ itself is not required to be an L_{FC} -path.

By replacing L_F with L_D in Equation (21), P3CTX also determines n to be context-sensitive *if* CS-C1–CS-C3 are met. Viewing these conditions as sufficient (rather than merely necessary) makes both SELECTX and P3CTX conservative, potentially marking some n as context-sensitive even when $kCFA$ would not lose precision with context-insensitive analysis. While SELECTX could lead to precision loss due to L_{FC} 's incompleteness, P3CTX, in contrast, always preserves precision. This is because L_{DCR} works with a PAG that clearly includes dispatch paths for all virtual callsites in the program.

► **Example 6.** In our motivating example (Figure 3), whether v spuriously points to D2 hinges on the context sensitivity of d , o , x , and D1 in $\text{bar}()$. Using L_{FC} and analyzing the PAG in Figure 4, SELECTX deems all four as context-insensitive, causing v to erroneously point to D2 because they cannot flow out of $\text{bar}()$ via its parameter x , failing to meet CS-C3. In L_{FC} 's PAG, which relies on an external call graph construction algorithm, there are no dispatch paths for these variables/objects to flow out of $\text{bar}()$ through x .

In L_{DCR} , the parameter passing of d at $x.\text{foo}(d)$ (line 17) directly relates to x via CFL-reachability (Figure 7). Consider $p_{\text{D1},n,v}$ in Equation (7), which is an L_{DCR} -path. For $n \in \{d, o, x, \text{D1}\}$, P3CTX designates each n as context-sensitive. This decision is because $p_{\text{D1},n,v}$ qualifies as an L_D -path (CS-C1), with both $p_{\text{D1},n}$ and $p_{n,v}$ being L_C -paths (CS-C2). Furthermore, $L_C^{\text{en}}(p_{\text{D1},n}) = \hat{c}1 \neq \epsilon$ and $L_C^{\text{ex}}(p_{n,v}) = \check{c}1 \neq \epsilon$, satisfying CS-C3.

4.1.2 Regularization

To make P3CTX as lightweight as possible so that we can efficiently make context-sensitivity selections without losing the performance benefits obtained from a subsequent main pointer analysis, we have decided to keep L_C unchanged as done in several earlier pre-analyses [35, 32, 33] but regularize L_D and L_R . We first regularize L_R to L_R^r as follows:

$$\text{recoveredCtx} \longrightarrow \text{recoveredCtx } \hat{c} \mid \text{recoveredCtx } \check{c} \mid \text{recoveredCtx } \hat{\square} \mid \text{recoveredCtx } \check{\square} \mid \epsilon \quad (22)$$

Thus, $L_D \cap L_C \cap L_R^r = L_D \cap L_C = L_{DC}$. By noting further that the boxed edge labels in L_R^r (i.e., $\hat{\square}$ and $\check{\square}$) are irrelevant to context-sensitivity selections and the regular entry/exit context labels in L_R^r (i.e., \hat{c} and \check{c}) have already been included in L_C , we conclude that L_R^r (i.e., L_R) can be ignored safely (or conservatively). As $L_{DC} \supseteq L_{DCR}$ (i.e., L_{DC} captures all the possible value-flows that are captured by L_{DCR} for a given program) according to Lemma 4, it suffices to use L_{DC} in place of L_{FC} in Equation (21) in developing our precision-preserving pre-analysis. Like the L_{FC} -reachability problem, the L_{DC} -reachability

problem is also undecidable [45]. Following [33], we regularize L_D into L_{D^r} and subsequently over-approximate L_{DC} to obtain $L_{D^r C} = L_{D^r} \cap L_C$. In Section 4.1.3, we present an algorithm to verify CS-C1–CS-C3 using $L_{D^r C}$ efficiently.

We start with $L_0 = L_D$. We first over-approximate L_0 by disregarding its field-sensitivity requirement and thus obtain L_1 given below:

$$\begin{array}{lcl} \text{flowsto} & \longrightarrow & \text{new } (\text{flows} \mid \text{dispatch})^* \\ \text{flows} & \longrightarrow & \text{assign} \mid \text{store } \overline{\text{flowsto}} \text{ flowsto load} \\ \overline{\text{flowsto}} & \longrightarrow & (\overline{\text{dispatch}} \mid \overline{\text{flows}})^* \text{ new} \\ \overline{\text{flows}} & \longrightarrow & \overline{\text{assign}} \mid \overline{\text{load}} \text{ flowsto store} \end{array} \quad (23)$$

In the absence of field-sensitivity, a `dispatch` ($\overline{\text{dispatch}}$) edge behaves just like an `assign` ($\overline{\text{assign}}$) edge and can thus be interpreted this way. As a result, we obtain L_2 below:

$$\begin{array}{lcl} \text{flowsto} & \longrightarrow & \text{new flows}^* \\ \overline{\text{flowsto}} & \longrightarrow & \overline{\text{flows}}^* \text{ new} \\ \text{flows} & \longrightarrow & \text{assign} \mid \text{store } \overline{\text{flowsto}} \text{ flowsto load} \\ \overline{\text{flows}} & \longrightarrow & \overline{\text{assign}} \mid \overline{\text{load}} \text{ flowsto store} \end{array} \quad (24)$$

Our approximation goes further by treating a `load` ($\overline{\text{load}}$) edge as also an `assign` ($\overline{\text{assign}}$). As a result, we will no longer require a `store` ($\overline{\text{load}}$) edge to be matched by a `load` ($\overline{\text{store}}$) edge. This will give rise to L_3 below:

$$\begin{array}{lcl} \text{flowsto} & \longrightarrow & \text{new flows}^* \\ \overline{\text{flowsto}} & \longrightarrow & \overline{\text{flows}}^* \text{ new} \\ \text{flows} & \longrightarrow & \text{assign} \mid \text{store } \overline{\text{flowsto}} \text{ flowsto} \\ \overline{\text{flows}} & \longrightarrow & \overline{\text{assign}} \mid \overline{\text{flowsto}} \text{ flowsto store} \end{array} \quad (25)$$

Finally, we obtain $L_{D^r} = L_4$ given below by no longer distinguishing a `store` edge from its inverse, `store` edge, so that we can represent both types of edges as a `store` edge:

$$\begin{array}{lcl} \text{flowsto} & \longrightarrow & \text{new flows}^* \\ \overline{\text{flowsto}} & \longrightarrow & \overline{\text{flows}}^* \text{ new} \\ \text{flows} & \longrightarrow & \text{assign} \mid \text{store } \overline{\text{assign}}^* \text{ new new} \\ \overline{\text{flows}} & \longrightarrow & \overline{\text{assign}} \mid \overline{\text{new}} \text{ new assign}^* \text{ store} \end{array} \quad (26)$$

► **Lemma 1.** $L_D \subseteq L_{D^r}$.

Proof. Follows from the fact that $L_i \subseteq L_{i+1}$. ◀

While L_{D^r} is identical to L_R regularized from L_F in SELECTX [33], our PAG (Figure 6), which makes dynamic dispatch paths explicitly, differs fundamentally from the one operated by L_{FC} (Figure 2). This distinction ensures that P3CTX preserves precision, unlike SELECTX.

Let $G = (N, E)$ be the PAG of a program. We use Andersen's algorithm [1] instead of CHA [9] to build its call graph in order to sharpen the precision of P3CTX.

We use a simple DFA shown in Figure 10 to accept L_{D^r} exactly. P3CTX runs inter-procedurally in linear time of the number of the PAG edges in G . To deal with L_C , we use summary edges added into the PAG (facilitated by the dotted transition labeled as `balanced`).

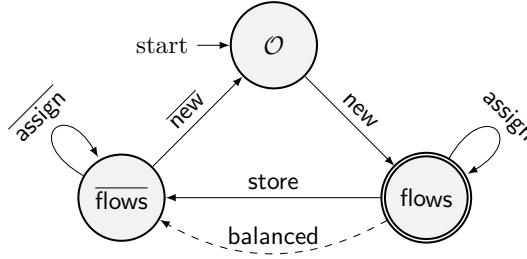

Figure 10 A DFA for accepting L_{D^r} .

4.1.3 P3Ctx

We follow [14] to develop a simple algorithm to verify **CS-C1–CS-C3** efficiently based on two properties that can be easily deduced from the DFA given in Figure 10 as stated below.

- Define $Q = \{\mathcal{O}, \text{flows}, \overline{\text{flows}}\}$ as the state set and $\delta : Q \times \Sigma \rightarrow Q$ as the transition function. For each PAG edge $n_1 \xrightarrow{\ell} n_2$ in G , the transition $\delta(q_1, \ell) = q_2$ leads to a one-step transition $(n_1, q_1) \rightarrow (n_2, q_2)$. The multiple-step transition \rightarrow^+ is the transitive closure of \rightarrow . The symmetry of flowsto and $\overline{\text{flowsto}}$ in L_{D^r} yields two straightforward properties of this DFA:
- **PROP-O.** Let O be an object created in a method M . Then $\langle \text{this}^M, \text{flows} \rangle \rightarrow^+ \langle O, \mathcal{O} \rangle \iff \langle O, \mathcal{O} \rangle \rightarrow^+ \langle \text{this}^M, \overline{\text{flows}} \rangle$ always holds.
 - **PROP-V.** Let v be a variable defined in a method M . Then $\langle \text{this}^M, \text{flows} \rangle \rightarrow^+ \langle v, q \rangle \iff \langle v, \overline{q} \rangle \rightarrow^+ \langle \text{this}^M, \overline{\text{flows}} \rangle$ always holds, where $q \in \{\text{flows}, \overline{\text{flows}}\}$ (since v is a variable).

To handle static callsites uniformly as virtual callsites, we assume that a static callsite is invoked on a dummy receiver object. Thus, in our PAG representation (Figure 6), passing arguments and receiving return values for a method must all flow through its “`this`” variable.

P3Ctx efficiently verify **CS-C1–CS-C3** as follows: For **CS-C1** (Equation (21)), where L_F is substituted with L_{D^r} , it is unnecessary to trace from an object along its flowsto paths. Instead, for each method, we start from its “`this`” variable, over-approximating that some object O can flow into it. For **CS-C2**, summary edges are utilized to confirm the balanced-parentheses property in L_C -paths. Finally, to ascertain **CS-C3**, we check for the existence of any $q \in Q$ such that:

$$\langle \text{this}^M, \text{flows} \rangle \rightarrow^+ \langle n, q \rangle \rightarrow^+ \langle \text{this}^M, \overline{\text{flows}} \rangle \quad (27)$$

where M is the containing method of n . This implies that n lies on an L_{D^r} -path collecting some values coming from outside M via `this`^M and pumping them out of M via `this`^M.

Let $R : Q \mapsto \wp(N)$ return the set of nodes in G reached at a state $q \in Q$. Then verifying **CS-C3**, i.e., checking Equation (27) involves determining if the following condition holds:

$$n \in R(\mathcal{O}) \quad \vee \quad n \in R(\text{flows}) \cap R(\overline{\text{flows}}) \quad (28)$$

Equation (27) is satisfied either when the first disjunct applies (due to **PROP-O**) or when the second disjunct applies (due to **PROP-V**).

Figure 11 outlines P3Ctx’s pre-analysis algorithm using three rules that streamline inter-procedural reachability in G . Here, $R^{-1} : N \mapsto \wp(Q)$ inversely maps nodes to their reachable states. The rules are: **[F-INIT]** for initializations, **[F-PROPA]** for iterative state reachability determination, and **[F-SUM]** for applying standard context-sensitive summaries [46] at callsites. This involves adding summary edges $n_1 \xrightarrow{\text{balanced}} n_2$ to encapsulate inter-procedural reachability, thereby streamlining reachability computations for method M .

$$\begin{array}{c}
 \frac{n_1 \xrightarrow{\hat{c}} \text{this}^M \in E}{\text{this}^M \in R(\text{flows}) \quad \text{flows} \in R^{-1}(\text{this}^M)} \quad [\text{F-INIT}] \\
 \frac{n_1 \xrightarrow{\ell} n_2 \in E \quad q_1 \in R^{-1}(n_1) \quad \delta(q_1, \ell) = q_2}{n_2 \in R(q_2) \quad q_2 \in R^{-1}(n_2)} \quad [\text{F-PROPA}] \\
 \frac{n_1 \xrightarrow{\hat{c}} \text{this}^M \in E \quad \text{this}^M \xrightarrow{\hat{c}} n_2 \in E \quad \overline{\text{flows}} \in R^{-1}(\text{this}^M)}{n_1 \xrightarrow{\text{balanced}} n_2 \in E} \quad [\text{F-SUM}]
 \end{array}$$

■ **Figure 11** Rules for conducting P3CTX over $G = (N, E)$.

► **Theorem 7.** *kCFA (performed in terms of the rules in Figure 1) produces exactly the same points-to information when performed with selective context-sensitivity under P3CTX.*

Proof. Follows from the facts that (1) Equation (21) provides necessary conditions for supporting selective context-sensitivity, (2) L_{DCR} provides a specification of kCFA with CFL-reachability for callgraph construction, (3) $L_{D^r C} \supseteq L_{DCR}$, and (4) [F-INIT] has weakened CS-C1 by starting from the `this` variable of every method instead of every object O . ◀

The worst-case time complexity of P3CTX in analyzing a program on $G = (N, E)$ is $O(|E| \times |Q|)$, which is linear to $|E|$ as $|Q|$ (the number of states in our DFA) is a constant.

4.2 Evaluation

We demonstrate that P3CTX significantly speeds up kCFA while maintaining precision. Compared to non-precision-preserving pre-analyses, SELECTX [33] and ZIPPER [29], P3CTX excels in achieving more efficient precision trade-offs in certain application scenarios.

4.2.1 Experimental Setup

We implemented *kCFA* (Figure 1) and P3CTX (Figure 11) in SOOT [59], using its context-insensitive pointer analysis, SPARK [26], for PAG construction. To compare P3CTX with SELECTX and ZIPPER, we used their existing implements from the SELECTX artifact [34]. Our evaluation follows pointer analysis standards [35, 33, 32, 42, 58, 14, 16], including using TAMIFLEX [4] for Java reflection, SOOT’s native code summaries, and context-insensitive analysis for special objects like strings and exceptions, distinguished per dynamic type.

We selected a set of 13 benchmarks from the DaCapo benchmark suite (latest version 6cf0380) [3] along with a large Java library (JRE1.8.0_31). We excluded `jython` because both *kCFA* and *P-kCFA* could not scale this benchmark due to its overly conservative reflection log [57]. Our artifact is publicly available at [19].

Our experiments were conducted on an Intel(R) Xeon(R) W-2245 3.90GHz machine with 512GB of RAM, operating under Ubuntu 20.04.3 LTS (Focal Fossa).

4.2.2 Results

Table 2 presents the results for *kCFA* and its three accelerated variants: *P-kCFA* (by P3CTX), *S-kCFA* (by SELECTX), and *Z-kCFA* (by ZIPPER), along with SPARK for comparison purposes, focusing on $k \in \{1, 2\}$. For $k \geq 3$, *kCFA* is unscalable for all 13 programs under a 12-hour budget and thus has never been considered in the literature [33, 42, 29, 30, 58, 50, 20, 57].

Table 2 Main analysis results. The analysis times for P - k CFA, S - k CFA, and Z - k CFA are given as $x(y)$, where x is the pointer analysis time and y is the pre-analysis time (in seconds). For all metrics, smaller is better.

4.2.2.1 Precision

Pointer analysis precision is gauged using four key metrics: (1) “#Call Edges”, indicating discovered call graph edges; (2) “#Fail Casts”, representing potential type cast failures; (3) “#Alias Pairs”, counting base variable pairs in stores and loads that may alias, excluding trivial must-aliases like direct assignments [10]; and (4) “Avg PTS”, the average number of objects pointed to by reachable local variables. Lower metric values signify higher precision.

For each metric M , M_{PTA} denotes the result obtained by PTA , where PTA denotes any pointer analysis in {SPARK, k CFA, P - k CFA, S - k CFA, Z - k CFA}. Let A - k CFA $\in \{P$ - k CFA, S - k CFA, Z - k CFA} be one of the three variants of k CFA such that A - k CFA is no less precise than SPARK but no more precise than k CFA. We define the precision loss of A - k CFA with respect to k CFA on metric M as:

$$\Delta_{A-k\text{CFA}}^M = \frac{(M_{\text{SPARK}} - M_{k\text{CFA}}) - (M_{\text{SPARK}} - M_{A-k\text{CFA}})}{M_{\text{SPARK}} - M_{k\text{CFA}}} = \frac{M_{A-k\text{CFA}} - M_{k\text{CFA}}}{M_{\text{SPARK}} - M_{k\text{CFA}}} \quad (29)$$

The precision gain from SPARK to k CFA is 100%. If A - k CFA matches k CFA in precision ($M_{A-k\text{CFA}} = M_{k\text{CFA}}$), then $\Delta_{A-k\text{CFA}}^M = 0\%$, indicating no precision loss in A - k CFA. Conversely, if A - k CFA reverts to SPARK’s precision ($M_{A-k\text{CFA}} = M_{\text{SPARK}}$), $\Delta_{A-k\text{CFA}}^M = 100\%$, reflecting a complete loss of k CFA’s precision advantage.

P - k CFA retains precision, matching k CFA across all metrics in 13 benchmarks, supported by Theorem 7 and Table 2. S - k CFA, leveraging L_{FC} for context-sensitivity, has small average precision losses of 0.8%, 1.2%, 0.1%, and 0.1% in “#Call Edges”, “#Fail Casts”, “#Alias Pairs”, and “Avg PTS”, respectively, at $k = 2$. However, for “#Call Edges”, S - 2 CFA incurs a 5% precision loss in both `tradebeans` and `tradesoap`. Conversely, Z - k CFA experiences higher average precision losses of 6.2%, 8.1%, 2.2%, and 2.0% for the same metrics at $k = 2$, attributed to ZIPPER’s use of pattern-based heuristics for context-sensitivity decisions.

To explore S - 2 CFA’s precision loss in `tradebeans` (Figure 12), it is noted that S - 2 CFA fails to identify the call in line 15 as monomorphic, unlike P - 2 CFA. When `put()` is invoked on a `TreeMap` object, a virtual call `compare()` occurs on the `comparator` object stored in the `TreeMap` object. With 2 CFA, `put()` is analyzed under contexts [L1] and [L2]. Under [L1], `cmp` links to `CMP1` and `k` to `I`, leading to `compare()` from line 10 to be invoked under [L3, L1]. Under [L2], `cmp` points to `CMP2` and `k` to `S1`, calling `compare()` from line 14 under [L3, L2], making `o1` point uniquely to `S1`. Thus, the virtual call in line 15 invokes only the `toString()` method defined in `java.lang.String`.

SELECTX, using L_{FC} , treats `cmp` and `k` in `put()` as context-insensitive, violating **CS-C3** in Equation (21). With S - 2 CFA, `o1` erroneously points to both `I` and `S1` under [L3, L2], leading to a polymorphic call in line 15. In contrast, P3CTX with L_{DCR} treats these as context-sensitive, adhering to **CS-C3**, resulting in `o1` pointing only to `S1` and ensuring a monomorphic call in line 15. This change prevents a 5% precision loss in “#Call Edges”, potentially enhancing critical software security analyses.

4.2.2.2 Efficiency

In Table 2, the efficiency of a pointer analysis is gauged by the time required in analyzing a program. This includes time for both the pointer analysis and the corresponding pre-analysis in each k CFA variant, denoted as A - k CFA ($A \in \{P, S, Z\}$). For $k = 1$ and $k = 2$, pre-analysis is done separately, causing slight differences in pre-analysis times for the same program. SPARK’s time is not included, as its results are shared by all three pre-analyses.

```

1 class TreeMap {
2     Comparator comparator;
3     TreeMap(Comparator cmp1) { this.comparator = cmp1; }
4     void put(Object k, Object v) {
5         Comparator cmp = this.comparator;
6         int i = cmp.compare(k, ...); // L3
7     }
8 // in java.lang.String
9 class CaseInsensitiveComparator implements Comparator {
10    int compare(String p1, String p2) { return 0; }
11 }
12 // in org.apache.geronimo.main
13 class StringComparator implements Comparator {
14    int compare(Object o1, Object o2) {
15        String s1 = o1.toString(); // #Call Edges?
16        return s1.compareTo(o2.toString());
17 }
18 void main() {
19     Comparator cmp1 = new CaseInsensitiveComparator(); // CMP1
20     Comparator cmp2 = new StringComparator(); // CMP2

28 }

```

Figure 12 An example abstracted from `tradebeans` and JDK8 to illustrate why SELECTX is not precision-preserving (by applying L_{FC} to determine precision-critical variables/objects in a program).

Table 2 reveals that P3CTX, SELECTX, and ZIPPER significantly boost k CFA for $k = 2$. Z-2CFA leads with $1.7\times$ to $41.0\times$ speedups, averaging $10.9\times$. S-2CFA ranges from $1.2\times$ to $17.6\times$, averaging $6.0\times$. P3CTX increases speeds from $1.2\times$ to $4.4\times$, averaging $3.2\times$. At $k = 1$, P3CTX performs best due to lower pre-analysis overhead and faster 1CFA. ZIPPER moderately improves 1CFA for most programs, but less effectively than P3CTX. SELECTX slows down 1CFA when including pre-analysis time. For P -1CFA, speedups range from $1.6\times$ to $3.5\times$, averaging $2.6\times$. Z-1CFA sees $0.3\times$ to $2.6\times$ speedups, averaging $1.5\times$. S-1CFA shows no gains, with $0.4\times$ to $0.8\times$ speedups, averaging $0.6\times$.

When assessing the precision and efficiency of P - k CFA, S - k CFA, and Z - k CFA, several key insights emerge. For tasks where precision is paramount, such as in software security analysis, P - k CFA emerges as the superior choice. It offers a speed advantage without compromising the precision inherent to k CFA. In contexts where the precision of 1CFA is needed, but with greater efficiency, P -1CFA is the standout option. It surpasses both S -1CFA and Z -1CFA in terms of speed while retaining the precision level of 1CFA. Finally, for applications requiring pointer analysis at the precision level of 2CFA, the recommendation depends on the user's priorities: Z -2CFA for those valuing efficiency above precision, S -2CFA for those who prioritize efficiency but can accept minor precision loss, and P -2CFA for those who deem precision crucial but also desire increased speed.

5 Related Work

In this section, we focus exclusively on prior work that is directly relevant to our study.

CFL-Reachability. CFL-reachability, introduced in program analysis for inter-procedural dataflow analysis [46, 44], has been applied in tackling various problems such as pointer analysis [54, 53, 64, 61, 62, 48, 63, 35, 32], information flow [37, 28, 36], and type inference [43, 41]. Traditionally, *kCFA*'s CFL-reachability formulation [53, 62, 48] relies on a separate call graph construction algorithm, either pre-applied or on-the-fly. This paper introduces L_{DCR} , a new CFL-reachability formulation for *kCFA*, integrating built-in call graph construction. An earlier attempt to address the same problem by Sridharan [52] is sound but less precise than L_{DCR} due to the lack of L_R . Without L_R , a context used for parameter passing at a virtual callsite can be incorrectly restored as a different context after finding the dispatched method and returning to the same callsite (as in Figure 9).

Another line of research on CFL-reachability focuses on its computational complexity. Generally, the all-pairs CFL-reachability problem can be resolved in $O(m^3n^3)$ time, where m is the CFL grammar size and n is the graph node count. Kodumal et al. [23] efficiently solved Dyck-CFL-reachability in $O(mn^3)$. Chaudhuri [7] later optimized the general CFL-reachability algorithm to subcubic time using the Four Russians' Trick [24]. Zhang et al. [63] demonstrated that bidirected Dyck-CFL reachability could be solved in $O(n + p \log p)$ (with p being the graph edge count), noting that reachability in a bidirected graph forms an equivalence relation. This complexity was further reduced to $O(p + n \cdot \alpha(n))$ in [6], where $\alpha(n)$ is the inverse Ackermann function. This paper introduces P3CTX, an L_{DCR} -enabled pre-analysis for accelerating *kCFA*, linear in terms of the number of PAG edges in the program's PAG and preserving precision.

A CFL-reachability-based formulation recently proposed for object-sensitive pointer analysis [35, 38, 39] naturally includes call graph construction, as it uses receiver objects as context elements. However, integrating call graph construction into callsite-sensitive analyses using the traditional CFL-reachability framework [53, 62, 48] is challenging, as detailed in Section 2. An earlier attempt [52] was sound but lacked precision, particularly in restoring contexts correctly after method dispatch and return at virtual callsites, as shown in Figure 9. L_{DCR} is the first known solution to effectively integrate call graph construction into CFL-reachability for callsite-sensitive analyses.

Selective Context-sensitivity. In the realm of pointer analysis acceleration, three primary approaches exist: pattern-based [51, 12, 29, 30], data-driven [21, 20], and CFL-reachability-guided [35, 33, 14, 13]. By exploiting CFL-reachability, EAGLE [35, 32], TURNER [14], CONCH [16, 18], and DEBLOATERX [13] represent recent efforts in accelerating object-sensitive pointer analysis [39]. SELECTX [33] marks the initial CFL-reachability-based effort to accelerate *kCFA*, but it lacks precision preservation due to its reliance on L_{FC} [53]. This paper introduces P3CTX, the first precision-preserving pre-analysis for *kCFA*, grounded in L_{DCR} .

6 Conclusion

We have introduced L_{DCR} , a new CFL-reachability formulation for supporting *k*-callsite-based context-sensitive pointer analysis (*kCFA*), featuring a unique built-in call graph construction to effectively handle dynamic dispatch. To demonstrate its utility, we have also introduced P3CTX, which is developed based on L_{DCR} , to enhance the performance of *kCFA* while preserving its precision. We hope that L_{DCR} can provide some new insights on understanding *kCFA* and its demand-driven forms [54, 53, 62], potentially inspiring novel algorithmic advancements. Future explorations include applying L_{DCR} to selective context sensitivity and extending its application to areas such as library-code summarization [48, 56, 8] and information flow analysis [28, 36].

Fearless Asynchronous Communications with Timed Multiparty Session Protocols

Ping Hou 

University of Oxford, UK

Nicolas Lagaillardie 

Imperial College London, UK

Nobuko Yoshida 

University of Oxford, UK

Abstract

Session types using *affinity* and *exception handling* mechanisms have been developed to ensure the communication safety of protocols implemented in concurrent and distributed programming languages. Nevertheless, current affine session types are inadequate for specifying real-world asynchronous protocols, as they are usually imposed by *time constraints* which enable *timeout exceptions* to prevent indefinite blocking while awaiting valid messages. This paper proposes the first formal integration of *affinity*, *time constraints*, *timeouts*, and *time-failure handling* based on multiparty session types for supporting reliability in asynchronous distributed systems. With this theory, we statically guarantee that asynchronous timed communication is deadlock-free, communication safe, while being *fearless* – never hindered by timeout errors or abrupt terminations.

To implement our theory, we introduce *MultiCrusty^T*, a RUST toolchain designed to facilitate the implementation of safe affine timed protocols. *MultiCrusty^T* leverages generic types and the `time` library to handle timed communications, integrated with optional types for affinity. We evaluate *MultiCrusty^T* by extending diverse examples from the literature to incorporate time and timeouts. We also showcase the *correctness by construction* of our approach by implementing various real-world use cases, including protocols from the Internet of Remote Things domain and real-time systems.

1 Introduction

Background. The growing prevalence of distributed programming has emphasised the significance of prioritising *reliability* in distributed systems. Dedicated research efforts focus on enhancing reliability through the study and modelling of failures. This research enables the design of more resilient distributed systems, capable of effectively handling failures and ensuring reliable operation.

A lightweight, type-based methodology, which ensures basic reliability – *safety* in distributed communication systems, is *session types* [16]. This type discipline is further advanced by *Multiparty Session Types* (MPST) [17, 18], which enable the specification and verification of communication protocols among multiple message-passing processes in concurrent and distributed systems. MPST ensure that protocols are designed to prevent common safety errors, i.e. deadlocks and communication mismatches during interactions among many participants [17, 18, 37]. By adhering to a specified MPST protocol, participants (a.k.a. end-point programs) can communicate reliably and efficiently. From a practical perspective, MPST have been implemented in various programming languages [5, 26, 28, 32, 40, 42], facilitating their applications and providing safety guarantees in real-world programs.

Nevertheless, tackling the challenges of unreliability and failures remains a significant issue for session types. Most session type systems operate under the assumption of flawless and reliable communication without failures. To address this limitation, recent works [31, 14, 15, 28] have developed *affine session types* by incorporating the *affinity* mechanism that explicitly accounts for and handles unreliability and failures within session type systems. Unlike linear types that must be used *exactly* once, affine types can be used *at most* once, enabling the safe dropping of subsequent types and the premature termination of a session in the presence of protocol execution errors.

In most real-life devices and platforms, communications are predominantly asynchronous: inner tasks and message transfers may take time. When dealing with such communications, it becomes crucial to incorporate *time constraints* and implement *timeout failure handling* for each operation. This is necessary to avoid potential blockages where a process might wait indefinitely for a message from a non-failed process. While various works, as explained later, address time conditions and timeouts in session types, it is surprising that none of the mentioned works on affine session types tackles timeout failures during protocol execution.

This Paper. We introduce a new framework, *affine timed multiparty session types* (ATMP), to address the challenges of timeouts, disconnections and other failures in asynchronous communications:

- (1) We propose ATMP, an extension of asynchronous MPST that incorporates time specifications, affinity, and mechanisms for handling exceptions, thus facilitating effective management of failures, with a particular focus on timeouts. Additionally, we demonstrate that properties from MPST, i.e. *type safety*, *protocol conformance*, and *deadlock-freedom*, are guaranteed for well-typed processes, even in the presence of timeouts and their corresponding handling mechanism;
- (2) We present *MultiCrusty^T*, our RUST toolchain designed for building asynchronous timed multiparty protocols under ATMP: *MultiCrusty^T* enables the implementation of protocols adhering to the properties of ATMP.

The primary focus of ATMP lies in effectively *handling* timeouts during process execution, in contrast to the approaches in [4, 3], which aim to completely *avoid* time failures. Bocchi et al. [4] introduce time conditions in MPST to ensure precise timing in communication protocols, while their subsequent work [3] extends *binary* timed session types to incorporate timeouts, allowing for more robust handling of time constraints. Yet, they adopt strict requirements to *prevent* timeouts. In [4], *feasibility* and *wait-freedom* are required in their protocol design. Feasibility requires precise time specifications for protocol termination, while wait-freedom prohibits overlapping time windows for senders and receivers in a protocol, which is not practical in real-world applications. Similarly, in [3], strong conditions including *progress* of an entire set of processes and *urgent receive* are imposed. The progress property is usually *undecidable*, and the urgent receive condition, which demands immediate message reception upon availability, is infeasible with asynchronous communication.

Recently, [30] proposes the inclusion of timeout as the unique failure notation in MPST, offering flexibility in handling failures. Time also plays a role in *synchronous* communication systems, where [22] develops *rate-based binary* session types, ensuring *synchronous* message exchanges at the same *rate*, i.e. within the same time window. However, in both [30] and [22], time constraints are not integrated into types and static type checking, resulting in the specifications lacking the ability to guide time behaviour. Additionally, the model used in [22] assumes that all communications and computations are non-time-consuming, i.e. with zero time cost, making it unfeasible in distributed systems.

By the efficient integration of time and failure handling mechanisms in our framework, none of those impractical requirements outlined in [4, 3] is necessary. In ATMP, when a process encounters a timeout error, a mechanism for handling time failures is triggered, notifying all participants about the timeout, leading to the termination of those participants and ultimately ending the session. Such an approach guarantees that participants consistently reach the *end of the protocol*, as the communication session is entirely dropped upon encountering a timeout error. As a result, every process can terminate successfully, reducing the risk of indefinite blockages, even with timeouts. Additionally, in our system, time constraints over local clocks are incorporated with types to effectively model asynchronous timed communication, addressing the limitations in [30, 22].

Except for [22], the aforementioned works on timed session types focus more on theory, lacking implementations. To bridge this gap on the practical side, we provide *MultiCrusty^T*, a RUST implementation of ATMP designed for secure timed communications. *MultiCrusty^T* makes use of affine timed meshed channels, a communication data structure that integrates time constraints and clock utilisation. Our toolchain relies on macros and native generic types to ensure that asynchronous protocols are inherently *correct by construction*. In particular, *MultiCrusty^T* performs compile-time verification to guarantee that, at any given point in the protocol, each isolated pair of participants comprises one sender and one receiver with corresponding time constraints. Additionally, we employ affine asynchronous primitives and native optional types to effectively handle *runtime* timeouts and errors.

To showcase the capabilities and expressiveness of our toolchain, we evaluate *MultiCrusty^T* through examples from the literature, and further case studies including a remote data protocol from an Internet of Remote Things (IoRT) network [7], a servo web protocol from a web engine [38], and protocols from real-time systems such as Android motion sensor [2], PineTime smartwatch [35], and keyless entry [41]. Our comparative analysis with a RUST implementation of affine MPST without time [28] reveals that *MultiCrusty^T* exhibits minimal overhead while providing significantly strengthened property checks.

Structure. § 2 offers a comprehensive overview of our theory and toolchain. § 3 provides a session π -calculus for ATMP that incorporates timeout, affinity, asynchrony, and failure handling mechanisms. § 4 introduces an extended theory of asynchronous multiparty session types with time annotations. Additionally, we present a typing system for ATMP session π -calculus, and demonstrate the properties of typed processes. § 5 delves into the design and usage of *MultiCrusty^T*, our RUST implementation of ATMP. § 6 showcases the compilation and execution benchmarks of *MultiCrusty^T*, based on selected case studies. § 7 concludes the paper by discussing related work, and offering conclusions and potential future work. Full proofs, auxiliary material, and more details of *MultiCrusty^T* can be found in the full version of the paper [19]. Our toolchain and evaluation examples are available in an [artifact](#).

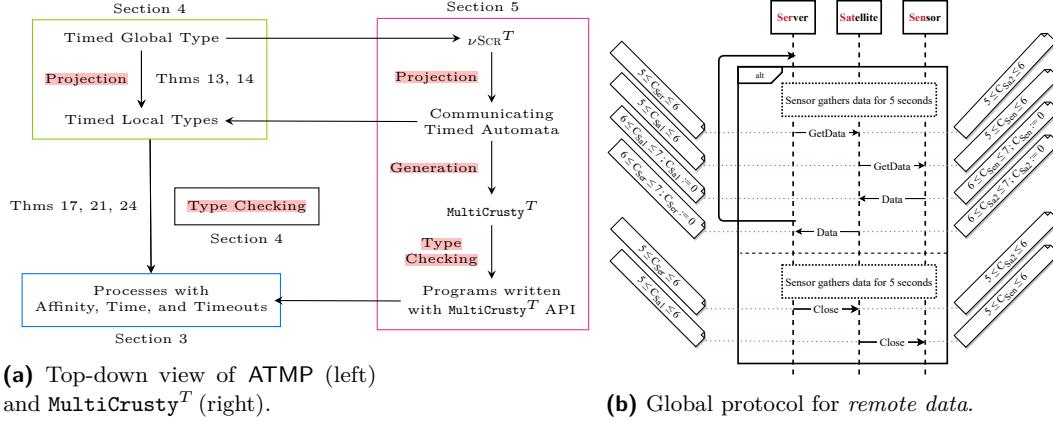

Figure 1 Overview of affine asynchronous communication with time.

2 Overview

In this section, we give an overview of affine timed multiparty session types (ATMP) and MultiCrusty^T, our toolchain for implementing affine timed asynchronous protocols. First, we share a real-world example inspiring our work on affine asynchronous timed communication.

Fig. 1b depicts our running example, *remote data*. This real-world scenario is sourced from a satellite-enabled Internet of Remote Things network [7], and describes data transmissions among a *Sensor* (*Sen*), a *Server* (*Ser*), and a *Satellite* (*Sat*): *Ser* aims to periodically retrieve data gathered by *Sen* via *Sat*. The protocol revolves around a loop initiated by *Ser*, which faces a decision: either retrieve data or end the protocol. In the former scenario, *Ser* requests data retrieval from *Sen* with a message labelled *GetData* via *Sat* within the time window of 5 and 6 time units, as indicated by clock constraints (i.e. $5 \leq C_{\text{Ser}} \leq 6$, where C_{Ser} is the clock associated with *Ser*). Upon receiving this request, *Sen* responds by sending the data with a message labelled *Data* to *Ser* through *Sat* within 6 and 7 time units, followed by clock resets denoted as reset predicates (i.e. $C_{\text{Ser}} := 0$, resetting the clock to 0). In the alternative branch, *Ser* sends a *Close* message to *Sat*, which is then forwarded to *Sen*, between 5 and 6 time units.

Our remote data protocol includes internal tasks that consume time, notably *Sen* requiring 5 time units to gather data before transmitting. In cases where our protocol lacks a specified timing strategy (i.e. no time requirements), and *Sen* cannot accomplish the data-gathering tasks, it results in indefinite blocking for *Sat* and *Ser* as they await the data. This could lead to undesirable outcomes, including partially processed data, data corruption, or incomplete transmission of processed data. Therefore, incorporating time constraints into communication protocols is imperative, as it better reflects real-world scenarios and ensures practical viability.

2.1 ATMP: Theory Overview

Our ATMP theory follows the *top-down* methodology [17, 18], enhancing asynchronous MPST with time features to facilitate timed global and local types. As shown in Fig. 1a (left), we specify multiparty protocols with time as *timed global types*. These timed global types are projected into *timed local types*, which are then used for type-checking processes with affine types, time, timeouts, and failure handling, written in a session calculus. As an example, we consider a simple communication scenario derived from remote data: the Satellite (*Sat*) communicates with the server (*Ser*) by sending a *Data* message (*Data*). Specifically, *Sat* needs to send the message between 6 and 7 time units and reset its clock afterwards, while *Ser* is expected to receive the message within the same time window and reset its clock accordingly.

Timed Types and Processes. This communication behaviour can be represented by the timed global type G :

$$\text{Sat} \rightarrow \text{Ser}: \{\text{Data}\{6 \leq C_{\text{Sat}} \leq 7, C_{\text{Sat}} := 0, 6 \leq C_{\text{Ser}} \leq 7, C_{\text{Ser}} := 0\}\}.end\}$$

where C_{Sat} and C_{Ser} denote the clocks of **Sat** and **Ser**, respectively. A global type represents a protocol specification involving multiple roles from a global standpoint.

Adhering to the MPST top-down approach, a timed global type is then *projected* onto timed local types, which describe communications from the perspective of individual roles. In our example, G is projected onto two timed local types, one for each role **Sat** and **Ser**:

$$T_{\text{Sat}} = \text{Ser} \oplus \text{Data}\{6 \leq C_{\text{Sat}} \leq 7, C_{\text{Sat}} := 0\}.end \quad T_{\text{Ser}} = \text{Sat} \& \text{Data}\{6 \leq C_{\text{Ser}} \leq 7, C_{\text{Ser}} := 0\}.end$$

Here T_{Sat} indicates that **Sat** sends (\oplus) the message **Data** to **Ser** between 6 and 7 time units and then immediately resets its clock C_{Sat} . Dually, T_{Ser} denotes **Ser** receiving ($\&$) the message from **Sat** within the same time frame and resetting its clock C_{Ser} .

In the final step of the top-down approach, we employ timed local types to conduct type-checking for processes, denoted as P_i , in the ATMP session calculus. Our session calculus extends the framework for *affine multiparty session types* (AMPST) [28] by incorporating processes that model time, timeouts, and asynchrony. In our example, T_{Sat} and T_{Ser} are used for the type-checking of $s[\text{Sat}]$ and $s[\text{Ser}]$, which respectively represent the channels (a.k.a. session endpoints) played by roles **Sat** and **Ser** in a multiparty session s , within the processes:

$$P_{\text{Sat}} = \text{delay}(C_1 = 6.5).s[\text{Sat}]^{0.4}[\text{Ser}] \oplus \text{Data.0} \quad P_{\text{Ser}} = \text{delay}(C_2 = 6).s[\text{Ser}]^{0.3}[\text{Sat}]\text{Data.0}$$

The Satellite process P_{Sat} waits for exactly 6.5 time units ($\text{delay}(C_1 = 6.5)$), then sends the message **Data** with a timeout of 0.4 time units ($s[\text{Sat}]^{0.4}[\text{Ser}] \oplus \text{Data}$), and becomes inactive (**0**). Meanwhile, the Server process P_{Ser} waits for 6 time units ($\text{delay}(C_2 = 6)$), then receives the message with a timeout of 0.3 time units ($s[\text{Ser}]^{0.3}[\text{Sat}]\text{Data}$), subsequently becoming inactive.

Solution to Stuck Processes Due to Time Failures. It appears that the parallel execution of P_{Sat} and P_{Ser} , $P_{\text{Sat}} \mid P_{\text{Ser}}$, cannot proceed further due to the disparity in timing requirements. Specifically, using the same session s , **Sat** sends the message **Data** to **Ser** between 6.5 and 6.9 time units, while **Ser** must receive it from **Sat** between 6 and 6.3 time units. This results in a stuck situation, as **Ser** cannot meet the required timing condition to receive the message.

Fortunately, in our system, timeout failures are allowed, which can be addressed by leveraging affine session types and their associated failure handling mechanisms. Back to our example, when $s[\text{Ser}]$ waits for 6 time units and cannot receive **Data** within 0.3 time units, a timeout failure is raised ($\text{timeout}[s[\text{Ser}]^{0.3}[\text{Sat}]\text{Data.0}]$). Furthermore, we apply our time-failure handling approach to manage this timeout failure, initiating the termination of the channel $s[\text{Ser}]$ and triggering the cancellation process of the session s ($s\#$). As a result, the process will successfully terminate by canceling (or killing) all usages of s within it.

Conversely, the system introduced in [4] enforces strict requirements, including *feasibility* and *wait-freedom*, on timed global types to prevent time-related failures in well-typed processes, thus preventing them from becoming blocked due to unsolvable timing constraints. Feasibility ensures the successful termination of each allowed partial execution, while wait-freedom guarantees that receivers do not have to wait if senders follow their time constraints. In our example, we start with a timed global type that is neither feasible nor wait-free, showcasing how our system effectively handles time failures and ensures successful process termination without imposing additional conditions on timed global types. In essence, reliance on feasibility and wait-freedom becomes unnecessary in our system, thanks to the inclusion of affinity and time-failure handling mechanisms.

2.2 MultiCrusty^T: Toolchain Overview

To augment the theory, we introduce the MultiCrusty^T library, a toolchain for implementing communication protocols in RUST. MultiCrusty^T specifies protocols where communication operations must adhere to specific time limits (*timed*), allowing for *asynchronous* message reception and runtime handling of certain failures (*affine*). This library relies on two fundamental types: `Send` and `Recv`, representing message sending and receiving, respectively. Additionally, it incorporates the `End` type, signifying termination to close the connection. Figs. 2a and 2b illustrate the `Send` and `Recv` types respectively, used for sending and receiving messages of any thread-safe type (represented as `T` in Line 1). After sending or receiving a message, the next operation or continuation (`S` in Line 8) is determined, which may entail sending another message, receiving another message, or terminating the connection.

Similar to ATMP, each communication operation in MultiCrusty^T is constrained by specific time boundaries to avoid infinite waiting. These time bounds are represented by the parameters in Lines 2–7 of Fig. 2a, addressing scenarios where a role may be required to send after a certain time unit or receive between two specific time units. Consider the final communication operation in the first branch of Fig. 1b from `Sat`'s perspective. To remain consistent with § 2.1, the communication is terminated here instead of looping back to the beginning of the protocol. In this operation, `Sat` sends a message labelled `Data` to `Ser` between time units 6 and 7, with respect to its inner clock '`b`', and then terminates after resetting its clock. This can be implemented as: `Send<Data, 'b', 6, true, 7, true, 'b', End>`.

To enable multiparty communication in MultiCrusty^T, we use the `MeshedChannels` type, inspired by [28]. This choice is necessary as `Send` and `Recv` types are primarily designed for *binary* (peer-to-peer) communication. Within `MeshedChannels`, each binary channel pairs the owner role with another, establishing a mesh of communication channels that encompasses all participants. Fig. 2c demonstrates an example of using `MeshedChannels` for `Sat` in our running example: `Sat` receives a `Data` message from `Sen` (Line 2) and forwards it to `Ser` (Line 4) before ending all communications, following the order specified by the stack in Line 6.

Creating these types manually in RUST can be challenging and error-prone, especially because they represent the local perspective of each role in the protocol. Therefore, as depicted in Fig. 1a (right), MultiCrusty^T employs a top-down methodology similar to ATMP to generate local viewpoints from a global protocol, while ensuring the *correctness* of the generated types *by construction*. To achieve this, we extend the syntax of ν SCR [42], a language for describing multiparty communication protocols, to include time constraints, resulting in ν SCR^T. A timed global protocol represented in ν SCR^T is then projected onto local types, which are used for generating RUST types in MultiCrusty^T.

3 Affine Timed Multiparty Session Calculus

In this section, we formalise an affine timed multiparty session π -calculus, where processes are capable of performing time actions, raising timeouts, and handling failures. We start with the formal definitions of time constraints used in the paper.

Clock Constraint, Valuation, and Reset. Our time model is based on the timed automata formalism [1, 27]. Let \mathbf{C} denote a finite set of *clocks*, ranging over C, C', C_1, \dots , that take non-negative real values in $\mathbb{R}_{\geq 0}$. Additionally, let t, t', t_1, \dots be *time constants* ranging over $\mathbb{R}_{\geq 0}$. A *clock constraint* δ over \mathbf{C} is defined as:

$$\delta ::= \text{true} \mid C > \mathfrak{b} \mid C = \mathfrak{b} \mid \neg\delta \mid \delta_1 \wedge \delta_2$$

where $C \in \mathbf{C}$ and \mathfrak{b} is a *constant time bound* ranging over non-negative rationals $\mathbb{Q}_{\geq 0}$. We define $\text{false}, <, \geq, \leq$ in the standard way. For simplicity and consistency with our implementation (§ 5), we assume each clock constraint contains a *single* clock. Extending a clock constraint with *multiple* clocks is straightforward.

A *clock valuation* $\mathbb{V} : \mathbf{C} \rightarrow \mathbb{R}_{\geq 0}$ assigns time to each clock in \mathbf{C} . We define $\mathbb{V} + t$ as the valuation that assigns to each $C \in \mathbf{C}$ the value $\mathbb{V}(C) + t$. The *initial* valuation that maps all clocks to 0 is denoted as \mathbb{V}^0 , and the valuation that assigns a value of t to all clocks is denoted as \mathbb{V}^t . $\mathbb{V} \models \delta$ indicates that the constraint δ is satisfied by the valuation \mathbb{V} . Additionally, we use $\sqcup_{i \in I} \mathbb{V}_i$ to represent the overriding union of the valuations \mathbb{V}_i for $i \in I$.

A *reset predicate* λ over \mathbf{C} is a subset of \mathbf{C} that defines the clocks to be reset. If $\lambda = \emptyset$, no reset is performed. Otherwise, the valuation for each clock $C \in \lambda$ is set to 0. For clarity, we represent a reset predicate as $C := 0$ when a single clock C needs to be reset. To denote the clock valuation identical to \mathbb{V} but with the values of clocks in λ to 0, we use $\mathbb{V}[\lambda \mapsto 0]$.

Syntax of Processes. Our session π -calculus for affine timed multiparty session types (ATMP) models timed processes interacting via affine meshed multiparty channels. It extends the calculus for affine multiparty session types (AMPST) [28] by incorporating asynchronous communication, time features, timeouts, and failure handling.¹

► **Definition 1 (Syntax).** Let $\mathbf{p}, \mathbf{q}, \mathbf{r}, \dots$ denote roles belonging to a (fixed) set \mathcal{R} ; s, s', \dots for sessions; x, y, \dots for variables; $\mathbf{m}, \mathbf{m}', \dots$ for message labels; and X, Y, \dots for process variables. The affine timed multiparty session π -calculus syntax is defined as follows:

$c, d ::= x \mid s[\mathbf{p}]$	(variable, channel with role \mathbf{p})
$P, Q ::= \mathbf{0} \mid P \parallel Q \mid (\nu s). P$	(inaction, parallel composition, restriction)
$c^n[\mathbf{q}] \oplus \mathbf{m} \langle d \rangle . P$	(timed selection towards role \mathbf{q})
$c^n[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i). P_i$	(timed branching from role \mathbf{q} with $I \neq \emptyset$)
$\text{def } D \text{ in } P \mid X(\bar{c})$	(process definition, process call)
$\text{delay}(\delta) . P \mid \text{delay}(t) . P$	(time-consuming delay, deterministic delay)
$\text{timeout}[P] \mid \text{try } P \text{ catch } Q$	(timeout failure, try-catch)
$\text{cancel}(c) . P \mid \text{cerr} \mid \underline{s}$	(cancel, communication error, kill)
$s[\mathbf{p}] \blacktriangleright \sigma$	(output message queue of role \mathbf{p} in session s)
$D ::= X(\bar{x}) = P$	(declaration of process variable X)
$\sigma ::= \mathbf{q}! \mathbf{m} \langle s[\mathbf{r}] \rangle \cdot \sigma \mid \epsilon$	(message queue, non-empty or empty)

¹ To simplify, our calculus exclusively emphasises communication. Standard extensions, e.g. integers, booleans, and conditionals, are routine and independent of our formulation.

Restriction, branching, and process definitions and declarations act as binders; $\text{fc}(P)$ is the set of free channels with roles in P , $\text{fv}(P)$ is the set of free variables in P , and $\Pi_{i \in I} P_i$ is the parallel composition of processes P_i . Extensions w.r.t. AMPST calculus are highlighted. Runtime processes, generated dynamically during program execution rather than explicitly written by users, are underlined.

Our calculus comprises:

Channels c, d , being either variables x or channels with roles (a.k.a. session endpoints) $s[\mathbf{p}]$.
Standard processes as in [37, 28], including inaction $\mathbf{0}$, parallel composition $P \mid Q$, session scope restriction $(\nu s) P$, process definition **def** D **in** P , process call $X\langle \tilde{c} \rangle$, and communication error **cerr**.

Time processes that follow the program time behaviour of Fig. 2c:

- **Timed selection** (or **timed internal choice**) $c^n[\mathbf{q}] \oplus \mathbf{m}(d).P$ indicates that a message \mathbf{m} with payload d is sent to role \mathbf{q} via endpoint c , whereas **timed branching** (or **timed external choice**) $c^n[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i).P_i$ waits to receive a message \mathbf{m}_i from role \mathbf{q} via endpoint c and then proceeds as P_i .

The parameter n in both timed selection and branching is a *timeout* that allows modelling different types of communication primitives: *blocking with a timeout* ($n \in \mathbb{R}_{>0}$), *blocking* ($n = \infty$), or *non-blocking* ($n = 0$). When $n \in \mathbb{R}_{\geq 0}$, the timed selection (or timed branching) process waits for up to n time units to send (or receive) a message. If the message cannot be sent (or received) within this time, the process moves into a *timeout state*, raising a *timeout failure*. If n is set to ∞ , the timed selection (or timed branching) process blocks until a message is successfully sent (or received).

In our system, we allow *send* processes to be time-consuming, enabling processes to wait before sending messages. Consider the remote data example shown in Fig. 1b. This practical scenario illustrates how a process might wait before sending a message, resulting in the possibility of send actions failing due to timeouts. It highlights the importance of timed selection, contrasting with systems like in [3] where send actions are instantaneous.

- **delay(δ)**. P represents a *time-consuming delay* action, such as method invocation or sleep. Here, δ is a clock constraint involving a *single* clock variable C , used to specify the interval for the delay. When executing **delay(δ)**. P , any time value t that satisfies the constraint δ can be consumed. Consequently, the *runtime deterministic delay* process **delay(t)**. P , arising during the execution of **delay(δ)**. P , is introduced. In **delay(t)**. P , t is a constant and a solution to δ , and P is executed after a precise delay of t time units.
- **timeout[P]** signifies that the process P has violated a time constraint, resulting in a *timeout failure*.

Failure-handling processes that adopt the AMPST approach [28]:

- **try** P **catch** Q consists of a **try** process P that is prepared to communicate with a parallel composed process, and a **catch** process Q , which becomes active in the event of a cancellation or timeout. For clarity, **try** $\mathbf{0}$ **catch** Q is not allowed within our calculus.
- **cancel(c)**. P performs the **cancellation** of other processes with channel c .
- $s \not\models \mathbf{kills}$ (terminates) all processes with session s , and is dynamically generated only at *runtime* from timeout failure or cancel processes.

Message queues: $s[\mathbf{p}] \blacktriangleright \sigma$ represents the *output message queue* of role \mathbf{p} in session s . It contains all the messages previously sent by \mathbf{p} . The queue σ can be a sequence of messages of the form $\mathbf{q}! \mathbf{m}(s[\mathbf{r}])$, where \mathbf{q} is the receiver, or ϵ , indicating an *empty* message queue. The set of *receivers in* σ , denoted as $\text{receivers}(\sigma)$, is defined in a standard way as:

$$\text{receivers}(\mathbf{q}! \mathbf{m}(s[\mathbf{r}]) \cdot \sigma') = \{\mathbf{q}\} \cup \text{receivers}(\sigma') \quad \text{receivers}(\epsilon) = \emptyset$$

[R-OUT]	$\mathbb{E} [s[\mathbf{q}]^n [\mathbf{p}] \oplus \mathbf{m} \langle s'[\mathbf{r}] \rangle . Q] \mid s[\mathbf{q}] \blacktriangleright \sigma \rightarrow Q \mid s[\mathbf{q}] \blacktriangleright \sigma \cdot \mathbf{p}! \mathbf{m} \langle s'[\mathbf{r}] \rangle \cdot \epsilon$	
[R-IN]	$\mathbb{E} [s[\mathbf{p}]^n [\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i] \mid s[\mathbf{q}] \blacktriangleright \mathbf{p}! \mathbf{m}_k \langle s'[\mathbf{r}] \rangle \cdot \sigma \rightarrow P_k \{ s'[\mathbf{r}] / x_k \} \mid s[\mathbf{q}] \blacktriangleright \sigma$	($k \in I$)
[R-ERR]	$\mathbb{E} [s[\mathbf{p}]^n [\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i] \mid s[\mathbf{q}] \blacktriangleright \mathbf{p}! \mathbf{m} \langle s'[\mathbf{r}] \rangle \cdot \sigma \rightarrow \mathbf{cerr}$	($\forall i \in I : \mathbf{m}_i \neq \mathbf{m}$)

Figure 3 Top: reduction rules for ATMP session π -calculus. Bottom: structural congruence rules for the ATMP π -calculus, where $\text{fpv}(D)$ is the set of free process variables in D , and $\text{dpv}(D)$ is the set of declared process variables in D . New rules are highlighted.

Operational Semantics. We present the operational semantics of our session π -calculus for modelling the behaviour of affine timed processes, including asynchronous communication, time progression, timeout activation, and failure handling.

► **Definition 2 (Semantics).** A **try-catch** context \mathbb{E} is defined as $\mathbb{E} ::= \mathbf{try} \mathbb{E} \mathbf{catch} P \mid []$, and a reduction context \mathbb{C} is defined as $\mathbb{C} ::= \mathbb{C} \mid P \mid (\nu s) \mathbb{C} \mid \mathbf{def} D \mathbf{in} \mathbb{C} \mid []$. The reductions \rightarrow , $\rightarrow\rightarrow$, and $\rightarrow\rightarrow\rightarrow$ are inductively defined in Fig. 3 (top), with respect to a structural congruence \equiv depicted in Fig. 3 (bottom). We write \rightarrow^* , $\rightarrow\rightarrow^*$, and $\rightarrow\rightarrow\rightarrow^*$ for their reflexive and transitive closures, respectively. $P \not\rightarrow$ (or $P \not\rightarrow\rightarrow$, $P \not\rightarrow\rightarrow\rightarrow$) means $\nexists P'$ such that $P \rightarrow P'$ (or $P \rightarrow\rightarrow P'$, $P \rightarrow\rightarrow\rightarrow P'$) is derivable. We say P has a communication error iff $\exists \mathbb{C}$ with $P = \mathbb{C}[\mathbf{cerr}]$.

We decompose the reduction rules in Fig. 3 into three relations: \rightarrow represents *instantaneous* reductions without time consumption, $\rightarrow\rightarrow$ handles time-consuming steps, and $\rightarrow\rightarrow\rightarrow$ is a general relation that can arise either from \rightarrow by [R-INS] or $\rightarrow\rightarrow$ by [R-TC]. Now let us explain the operational semantics rules for our session π -calculus.

Communication: Rules [R-OUT] and [R-IN] model asynchronous communication by queuing and dequeuing pending messages, respectively. Rule [R-ERR] is triggered by a message label mismatch, resulting in a fatal communication **error**.

Time: Rule [R-DET] specifies a deterministic delay of a specific duration t , where t is a solution to the clock constraint δ . Rule [R-TIME] incorporates a time-passing function $\Psi_t(P)$, depicted in Fig. 4, to represent time delays within a process. This *partial* function simulates a delay of time t that may occur at different parts of the process. It is *undefined* only if P is a time-consuming delay, i.e. $P = \mathbf{delay}(\delta) . P'$, or if the specified delay time t exceeds the

$$\begin{aligned}
 \Psi_t(\mathbf{0}) &= \mathbf{0} & \Psi_t(P_1 | P_2) &= \Psi_t(P_1) | \Psi_t(P_2) & \Psi_t((\nu s) P) &= (\nu s) \Psi_t(P) & \Psi_t(\text{timeout}[P]) &= \text{timeout}[P] \\
 \Psi_t(\mathbf{cerr}) &= \mathbf{cerr} & \Psi_t(\mathbf{def } D \mathbf{ in } P) &= \mathbf{def } D \mathbf{ in } \Psi_t(P) & \Psi_t(\mathbf{try } P \mathbf{ catch } Q) &= \mathbf{try } \Psi_t(P) \mathbf{ catch } \Psi_t(Q) \\
 \Psi_t(s[\mathbf{p}] \blacktriangleright \sigma) &= s[\mathbf{p}] \blacktriangleright \sigma & \Psi_t(\mathbf{delay}(\delta) . P) &= \mathbf{undefined} & \Psi_t(\mathbf{cancel}(c) . Q) &= \mathbf{cancel}(c) . \Psi_t(Q) \\
 \Psi_t(\mathbf{delay}(t') . P) &= \begin{cases} \mathbf{delay}(t' - t) . P & \text{if } t' \geq t \\ \mathbf{undefined} & \text{otherwise} \end{cases} & \Psi_t(c^\infty[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i) &= c^\infty[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i \\
 \Psi_t(c^{t'}[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P) &= \begin{cases} c^{t'-t}[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P & \text{if } t' \geq t \\ \mathbf{timeout}[c^{t'}[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P] & \text{otherwise} \end{cases} & \Psi_t(c^\infty[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P) &= c^\infty[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P \\
 \Psi_t(s \notin) &= s \notin & \Psi_t(c^{t'}[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i) &= \begin{cases} c^{t'-t}[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i & \text{if } t' \geq t \\ \mathbf{timeout}[c^{t'}[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i] & \text{otherwise} \end{cases}
 \end{aligned}$$

Figure 4 Time-passing function $\Psi_t(P)$.

duration of a runtime deterministic delay, i.e. $P = \mathbf{delay}(t') . P'$ with $t > t'$. The latter case arises because deterministic delays must always adhere to their specified durations, e.g. if a program is instructed to sleep for 5 time units, it must strictly follow this duration.

Notably, $\Psi_t(P)$ acts as the *only mechanism* for triggering a timeout failure $\text{timeout}[P]$, resulting from a timed selection or branching. Such a timeout failure occurs when $\Psi_t(P)$ is defined, and the specified delay t exceeds a *deadline* set within P .

Cancellation: Rules [C-IN] and [C-QUEUE] model the process cancellations. [C-IN] is triggered only when there are no messages in the queue that can be received from \mathbf{q} via the endpoint $s[\mathbf{p}]$. Cancellation of a timed selection is expected to eventually occur via [C-QUEUE]; therefore, there is no specific rule dedicated to it. Similarly, in our implementation, the timed selection is not directly cancelled either.

Rules [R-CAN] and [C-CAT], adapted from [28], state cancellations from other parties. [R-CAN] facilitates cancellation and generates a kill process, while [C-CAT] transitions to the **catch** process Q due to the termination of session s , where the **try** process P is communicating on s . Therefore, the set of *subjects* of process P , denoted as $\text{subjP}(P)$, is included in the side condition of [C-CAT] to ensure that P has a prefix at s , as defined below:

$$\begin{aligned}
 \text{subjP}(\mathbf{0}) &= \text{subjP}(\mathbf{cerr}) = \emptyset & \text{subjP}(P | Q) &= \text{subjP}(P) \cup \text{subjP}(Q) & \text{subjP}(s[\mathbf{p}] \blacktriangleright \sigma) &= \{s[\mathbf{p}]^Q\} \\
 \text{subjP}((\nu s) P) &= \text{subjP}(P) \setminus \{s[\mathbf{p}_i]\}_{i \in I} \cup \{s[\mathbf{p}_i]^Q\}_{i \in I} \\
 \text{subjP}(\mathbf{def } X(\widetilde{x}) = P \mathbf{ in } Q) &= \text{subjP}(Q) \cup \text{subjP}(P) \setminus \{\widetilde{x}\} \text{ with } \text{subjP}(X\langle \widetilde{c} \rangle) = \text{subjP}(P\{\widetilde{c}/\widetilde{x}\}) \\
 \text{subjP}(c^n[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle . P) &= \text{subjP}(c^n[\mathbf{q}] \sum_{i \in I} \mathbf{m}_i(x_i) . P_i) = \text{subjP}(\mathbf{cancel}(c) . P) = \{c\} \\
 \text{subjP}(\mathbf{delay}(\delta) . P) &= \text{subjP}(\mathbf{delay}(t) . P) = \text{subjP}(\mathbf{try } P \mathbf{ catch } Q) = \text{subjP}(\text{timeout}[P]) = \text{subjP}(P)
 \end{aligned}$$

Subjects of processes determine sessions that may need cancellation, a crucial aspect for handling failed or cancelled processes properly. In our definition, subjects not only denote the endpoints via which processes start interacting but also indicate whether they are used for message queue processes. Specifically, an endpoint $s[\mathbf{p}]$ annotated with Q signifies its use in a queue process. This additional annotation, and thus the distinction it implies, is pivotal in formulating the typing rule for the **try-catch** process, as discussed later in § 4.4, where we rely on subjects to exclude queue processes within any **try** construct.

Timeout Handling: Rules [R-FAIL] and [R-FAILCAT] address time failures. In the event of a timeout, a killing process is generated. Moreover, in [R-FAILCAT], the **catch** process Q is triggered. To identify the session requiring termination, the set of subjects of the failure process $\text{timeout}[P]$ is considered in both rules as a side condition. Note that a timeout arises exclusively from timed selection or branching. Therefore, the subject set of $\text{timeout}[P]$ must contain a *single* endpoint devoid of Q , indicating the generation of only one killing process.

Standard: Rules [R-X], [R-CTX], and [R-≡] are standard [37, 28]. [R-X] expands process definitions when invoked; [R-CTX] and [R-≡] allow processes to reduce under reduction contexts

and through structural congruence, respectively. Rule $[R \equiv T]$ introduces a timed variant of $[R \equiv]$, enabling time-consuming reductions via structural congruence.

Congruence: As shown in Fig. 3 (bottom), we introduce additional congruence rules related to queues, delays, and process killings, alongside standard rules from [37]. Specifically, two rules are proposed for queues: the first addresses the *garbage* collection of queues that are not referenced by any process, while the second rearranges messages with different receivers. The rule for delays states that adding a delay of zero time units has no effect on the process execution. The rule regarding process killings eliminates duplicate kills.

► **Example 3.** Consider the processes: $P_1 = s[\text{Sat}]^{0.4}[\text{Ser}] \oplus \text{Data.0}$, $P_2 = s[\text{Ser}]^{0.3}[\text{Sat}]\text{Data.0}$, and $P_3 = s[\text{Sat}] \blacktriangleright \epsilon$. Rule $[C\text{-CAT}]$ can be applied to $\text{try } P_1 \text{ catch } Q \mid s \not\in$, as $\text{subjP}(P_1) = \{s[\text{Sat}]\}$ satisfies its side condition. However, neither $\text{timeout}[P_1 \mid P_2]$ nor $\text{timeout}[P_3]$ can generate the killing process $s \not\in$, as $\text{subjP}(P_1 \mid P_2) = \{s[\text{Sat}], s[\text{Ser}]\}$, whereas $\text{subjP}(P_3) = \{s[\text{Sat}]^0\}$.

► **Example 4.** Processes Q_{Sen} , Q_{Sat} , and Q_{Ser} interact on a session s :

$$\begin{aligned} Q_{\text{Sen}} &= \text{delay}(C_{\text{Sen}} = 6.5) \cdot Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \text{ where } Q'_{\text{Sen}} = \text{try } s[\text{Sen}]^{0.3}[\text{Sat}] \oplus \text{Data catch cancel}(s[\text{Sen}]) \\ Q_{\text{Sat}} &= \text{delay}(C_{\text{Sat}} = 6) \cdot Q'_{\text{Sat}} \mid s[\text{Sat}] \blacktriangleright \epsilon \text{ where } Q'_{\text{Sat}} = s[\text{Sat}]^{0.2}[\text{Sen}] \sum \left\{ \begin{array}{l} \text{Data.} s[\text{Sat}]^{0.3}[\text{Ser}] \oplus \text{Data} \\ \text{fail.} s[\text{Sat}]^{0.4}[\text{Ser}] \oplus \text{fatal} \end{array} \right\} \\ Q_{\text{Ser}} &= \text{delay}(C_{\text{Ser}} = 6) \cdot Q'_{\text{Ser}} \mid s[\text{Ser}] \blacktriangleright \epsilon \text{ where } Q'_{\text{Ser}} = s[\text{Ser}]^{0.8}[\text{Sat}] \sum \{\text{Data, fatal}\} \end{aligned}$$

Process Q_{Sen} delays for exactly 6.5 time units before executing process Q'_{Sen} . Here, Q'_{Sen} attempts to use $s[\text{Sen}]$ to send **Data** to **Sat** within 0.3 time units. If the attempt fails, the cancellation of $s[\text{Sen}]$ is triggered. Process Q_{Sat} waits for precisely 6 time units before using $s[\text{Sat}]$ to receive either **Data** or **fail** from **Sen** within 0.2 time units; subsequently, in the first case, it uses $s[\text{Sat}]$ to send **Data** to **Ser** within 0.3 time units, while in the latter, it uses $s[\text{Sat}]$ to send **fail** to **Ser** within 0.4 time units. Similarly, process Q_{Ser} waits 6 time units before using $s[\text{Ser}]$ to receive either **Data** or **fatal** from **Sat** within 0.8 time units.

In Q_{Sen} , $s[\text{Sen}]$ can only start sending **Data** to **Sat** after 6.5 time units, whereas in Q_{Sat} , $s[\text{Sat}]$ must receive the message from **Sen** within 0.2 time units after a 6-time unit delay. Consequently, $s[\text{Sat}]$ fails to receive the message from **Sen** within the specified interval, resulting in a timeout failure, i.e.

$$\begin{aligned} Q_{\text{Sen}} \mid Q_{\text{Sat}} \mid Q_{\text{Ser}} &\rightsquigarrow \text{delay}(6.5) \cdot Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \mid \text{delay}(6) \cdot Q'_{\text{Sat}} \mid s[\text{Sat}] \blacktriangleright \epsilon \mid \text{delay}(6) \cdot Q'_{\text{Ser}} \mid s[\text{Ser}] \blacktriangleright \epsilon \\ &\rightarrow \Psi_{6.5}(\text{delay}(6.5) \cdot Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \mid \text{delay}(6) \cdot Q'_{\text{Sat}} \mid s[\text{Sat}] \blacktriangleright \epsilon \mid \text{delay}(6) \cdot Q'_{\text{Ser}} \mid s[\text{Ser}] \blacktriangleright \epsilon) \\ &\equiv Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \mid \text{timeout}[Q'_{\text{Sat}}] \mid s[\text{Sat}] \blacktriangleright \epsilon \mid \Psi_{0.5}(Q'_{\text{Ser}}) \mid s[\text{Ser}] \blacktriangleright \epsilon \end{aligned}$$

Therefore, the kill process $s \not\in$ is generated from $\text{timeout}[Q'_{\text{Sat}}]$, successfully terminating the process $Q_{\text{Sen}} \mid Q_{\text{Sat}} \mid Q_{\text{Ser}}$ by the following reductions:

$$\begin{aligned} &Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \mid \text{timeout}[Q'_{\text{Sat}}] \mid s[\text{Sat}] \blacktriangleright \epsilon \mid \Psi_{0.5}(Q'_{\text{Ser}}) \mid s[\text{Ser}] \blacktriangleright \epsilon \\ &\rightsquigarrow Q'_{\text{Sen}} \mid s[\text{Sen}] \blacktriangleright \epsilon \mid s \not\in \mid s[\text{Sat}] \blacktriangleright \epsilon \mid \Psi_{0.5}(Q'_{\text{Ser}}) \mid s[\text{Ser}] \blacktriangleright \epsilon \\ &\rightsquigarrow \text{cancel}(s[\text{Sen}]) \mid s[\text{Sen}] \blacktriangleright \epsilon \mid s \not\in \mid s[\text{Sat}] \blacktriangleright \epsilon \mid 0 \mid s[\text{Ser}] \blacktriangleright \epsilon \\ &\rightsquigarrow s \not\in \mid 0 \mid s[\text{Sen}] \blacktriangleright \epsilon \mid s \not\in \mid s[\text{Sat}] \blacktriangleright \epsilon \mid 0 \mid s[\text{Ser}] \blacktriangleright \epsilon \equiv 0 \mid s \not\in \end{aligned}$$

4 Affine Timed Multiparty Session Type System

In this section, we introduce our affine timed multiparty session type system. We begin by exploring the types used in ATMP, as well as subtyping and projection, in § 4.1. We furnish a Labelled Transition System (LTS) semantics for typing environments (collections of timed local types and queue types) in § 4.2, and timed global types in § 4.3, illustrating their relationship with Thms. 13 and 14. Furthermore, we present a type system for our ATMP session π -calculus in § 4.4. Finally, we show the main properties of the type system: *subject reduction* (Thm. 17), *session fidelity* (Thm. 21), and *deadlock-freedom* (Thm. 24), in § 4.5.

$S ::= (\delta, \textcolor{blue}{T})$	sort
$G ::= \textcolor{red}{p} \rightarrow \textcolor{brown}{q}; \{\textcolor{brown}{m}_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}$	transmission
$\textcolor{brown}{p} \rightsquigarrow \textcolor{brown}{q}; j \{\textcolor{brown}{m}_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I} \quad (j \in I)$	transmission en route
$\mu t.G \quad \quad \mathbf{t} \quad \quad \mathbf{end}$	recursion, type variable, termination
$T ::= \textcolor{blue}{p} \& \{\textcolor{brown}{m}_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I} \quad \quad \textcolor{blue}{p} \oplus \{\textcolor{brown}{m}_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I}$	external choice, internal choice
$\mu t.T \quad \quad \mathbf{t} \quad \quad \mathbf{end}$	recursion, type variable, termination
$\mathcal{M} ::= \textcolor{blue}{p}! \textcolor{brown}{m}(S) \cdot \mathcal{M} \quad \quad \emptyset$	queue types

■ **Figure 5** Syntax of timed global types, timed local types, and queue types.

4.1 Timed Multiparty Session Types

Affine session frameworks keep the original system’s type-level syntax intact, requiring no changes. To introduce affine timed asynchronous multiparty session types, we simply need to augment global and local types with clock constraints and resets introduced in §3 to derive *timed global and local types*. The syntax of types used in this paper is presented in Fig. 5. As usual, all types are required to be closed and have guarded recursion variables.

Sorts. Sorts are ranged over S, S', S_i, \dots , and facilitate the delegation of the remaining behaviour $\textcolor{blue}{T}$ to the receiver, who can execute it under any clock assignment satisfying δ .

Timed Global Types. Timed global types are ranged over G, G', G_i, \dots , and describe an *overview* of the behaviour for all roles ($\textcolor{red}{p}, \textcolor{brown}{q}, \textcolor{brown}{s}, \textcolor{brown}{t}, \dots$) belonging to a (fixed) set \mathcal{R} . The set of roles in a timed global type G is denoted as $\text{roles}(G)$, while the set of its free variables as $\text{fv}(G)$.

A transmission $\textcolor{red}{p} \rightarrow \textcolor{brown}{q}; \{\textcolor{brown}{m}_i(\textcolor{blue}{S}_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}$ represents a message sent from role $\textcolor{red}{p}$ to role $\textcolor{brown}{q}$, with labels $\textcolor{brown}{m}_i$, payload types $\textcolor{blue}{S}_i$ (which are sorts), and continuations G_i , where i is taken from an index set I , and $\textcolor{brown}{m}_i$ taken from a fixed set of all labels \mathcal{M} . Each branch is associated with a *time assertion* consisting of four components: δ_{O_i} and λ_{O_i} for the output (sending) action, and δ_{I_i} and λ_{I_i} for the input (receiving) action. These components specify the clock constraint and reset predicate for the respective actions. A message can be sent (or received) at any time satisfying the guard δ_{O_i} (or δ_{I_i}), and the clocks in λ_{O_i} (or λ_{I_i}) are reset upon sending (or receiving). In addition to the standard requirements for global types as in [11], we impose a condition from [4], stating that sets of clocks “owned” by different roles, i.e. those that can be read and reset, must be pairwise disjoint. Furthermore, the clock constraint and reset predicate of an output or input action performed by a role are defined only over the clocks owned by that role.

A transmission en route $\textcolor{red}{p} \rightsquigarrow \textcolor{brown}{q}; j \{\textcolor{brown}{m}_i(\textcolor{blue}{S}_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I} \quad (j \in I)$ is a *runtime* construct to represent a message $\textcolor{brown}{m}_j$ sent by $\textcolor{red}{p}$, and yet to be received by $\textcolor{brown}{q}$. Recursion $\mu t.G$ and termination \mathbf{end} (omitted where unambiguous) are standard [11]. Note that contractive requirements [34, §21.8], i.e. ensuring that each recursion variable \mathbf{t} is bound within a $\mu t \dots$ and is guarded, are applied in recursive types.

Timed Local Types. Timed local types (or *timed session types*) are ranged over $\textcolor{blue}{T}, \textcolor{blue}{U}, \textcolor{blue}{T}', \textcolor{blue}{U}'$, $\textcolor{blue}{T}_i, \textcolor{blue}{U}_i, \dots$, and describe the behaviour of a *single* role. An *internal choice (selection)* $\textcolor{blue}{p} \oplus \{\textcolor{brown}{m}_i(\textcolor{blue}{S}_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I}$ (or *external choice (branching)* $\textcolor{blue}{p} \& \{\textcolor{brown}{m}_i(\textcolor{blue}{S}_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I}$) states that the *current* role is to *send to* (or *receive from*) the role $\textcolor{red}{p}$ when δ_i is satisfied, followed by resetting the clocks in λ_i . *Recursive* and *termination* types are defined similarly to timed global types. The requirements for the index set, labels, clock constraints, and reset predicates in timed local types mirror those in timed global types.

Queue Types. Queue Types are ranged over $\mathcal{M}, \mathcal{M}', \mathcal{M}_i, \dots$, and represent (possibly empty) sequences of *message types* $p!m(S)$ having receiver p , label m , and payload type S (omitted when $S=(\delta, \text{end})$). As interactions in our formalisation are asynchronous, queue types are used to capture the states in which messages are in transit. We adopt the notation receivers(\cdot) from §3 to denote the set of *receivers* in \mathcal{M} as receivers(\mathcal{M}) as well, with a similar definition.

Subtyping. We introduce a subtyping relation \leqslant on timed local types in Def. 5, based on the standard behaviour-preserving subtyping [37]. This relation indicates that a smaller type entails fewer external choices but more internal choices.

► **Definition 5** (Subtyping). *The subtyping relation \leqslant is coinductively defined:*

$$\begin{array}{c} \frac{\forall i \in I \quad S'_i \leqslant S_i \quad \delta_i = \delta'_i \quad \lambda_i = \lambda'_i \quad T_i \leqslant T'_i}{p \oplus \{m_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I \cup J} \leqslant p \oplus \{m_i(S'_i)\{\delta'_i, \lambda'_i\}.T'_i\}_{i \in I}} \text{ [SUB-}\oplus\text{]} \\ \frac{\forall i \in I \quad S_i \leqslant S'_i \quad \delta_i = \delta'_i \quad \lambda_i = \lambda'_i \quad T_i \leqslant T'_i}{p \& \{m_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I} \leqslant p \& \{m_i(S'_i)\{\delta'_i, \lambda'_i\}.T'_i\}_{i \in I \cup J}} \text{ [SUB-}\&\text{]} \quad \frac{}{\text{end} \leqslant \text{end}} \text{ [SUB-end]} \\ \frac{T \leqslant T'}{\langle \delta, T \rangle \leqslant \langle \delta, T' \rangle} \text{ [SUB-S]} \quad \frac{T \{\mu t.T/t\} \leqslant T'}{\mu t.T \leqslant T'} \text{ [SUB-}\mu\text{L]} \quad \frac{T \leqslant T' \{\mu t.T'/t\}}{T \leqslant \mu t.T'} \text{ [SUB-}\mu\text{R]} \end{array}$$

Projection. Projection of a timed global type G onto a role p yields a timed local type. Our definition of projection in Def. 6 is mostly standard [37], with the addition of projecting time assertions onto the sender and receiver, respectively.

► **Definition 6** (Projection). *The projection of a timed global type G onto a role p , written as $G \upharpoonright p$, is:*

$$\begin{aligned} (q \rightarrow r : \{m_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}) \upharpoonright p &= \begin{cases} r \oplus \{m_i(S_i)\{\delta_{O_i}, \lambda_{O_i}\}.(G_i \upharpoonright p)\}_{i \in I} & \text{if } p = q \\ q \& \{m_i(S_i)\{\delta_{I_i}, \lambda_{I_i}\}.(G_i \upharpoonright p)\}_{i \in I} & \text{if } p = r \\ \prod_{i \in I} G_i \upharpoonright p & \text{otherwise} \end{cases} \\ (q \rightsquigarrow r : j \{m_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}) \upharpoonright p &= \begin{cases} G_j \upharpoonright p & \text{if } p = q \\ q \& \{m_i(S_i)\{\delta_{I_i}, \lambda_{I_i}\}.(G_i \upharpoonright p)\}_{i \in I} & \text{if } p = r \\ \prod_{i \in I} G_i \upharpoonright p & \text{otherwise} \end{cases} \\ (\mu t.G) \upharpoonright p &= \begin{cases} \mu t.(G \upharpoonright p) & \text{if } p \in \text{roles}(G) \text{ or } \text{fv}(\mu t.G) \neq \emptyset \\ \text{end} & \text{otherwise} \end{cases} \quad \begin{cases} t \upharpoonright p = t & \\ \text{end} \upharpoonright p = \text{end} & \end{cases} \end{aligned}$$

where \prod is the merge operator for timed session types:

$$\begin{aligned} p \& \{m_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I} \sqcap p \& \{m_j(S'_j)\{\delta'_j, \lambda'_j\}.T'_j\}_{j \in J} &= \\ p \& \{m_k(S_k)\{\delta_k, \lambda_k\}.(T_k \sqcap T'_k)\}_{k \in I \cap J} \& p \& \{m_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I \setminus J} \& p \& \{m_j(S'_j)\{\delta'_j, \lambda'_j\}.T'_j\}_{j \in J \setminus I} \\ p \oplus \{m_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I} \sqcap p \oplus \{m_i(S_i)\{\delta_i, \lambda_i\}.T'_i\}_{i \in I} &= p \oplus \{m_i(S_i)\{\delta_i, \lambda_i\}.(T_i \sqcap T'_i)\}_{i \in I} \\ \mu t.T \sqcap \mu t.U &= \mu t.(T \sqcap U) \quad t \sqcap t = t \quad \text{end} \sqcap \text{end} = \text{end} \end{aligned}$$

► **Example 7.** Take the timed global type G , and timed local types T_{Sat} and T_{Ser} from §2.1. Consider a timed global type G_{data} , derived from remote data (Fig. 1b) as well, representing data transmission from **Sen** to **Ser** via **Sat**:

$$G_{\text{data}} = \text{Sen} \rightarrow \text{Sat} : \{\text{Data}\{6 \leq C_{\text{Sen}} \leq 7, C_{\text{Sen}} := 0, 6 \leq C_{\text{Sat}} \leq 7, \emptyset\}.G\}$$

which can be projected onto roles **Sen**, **Sat**, and **Ser**, respectively, as:

$$\begin{aligned} G_{\text{data}} \upharpoonright \text{Sen} &= \text{Sat} \oplus \text{Data}\{6 \leq C_{\text{Sen}} \leq 7, C_{\text{Sen}} := 0\}.end \quad G_{\text{data}} \upharpoonright \text{Ser} = G \upharpoonright \text{Ser} = T_{\text{Ser}} \\ G_{\text{data}} \upharpoonright \text{Sat} &= \text{Sen} \& \text{Data}\{6 \leq C_{\text{Sat}} \leq 7, \emptyset\}.G \upharpoonright \text{Sat} = \text{Sen} \& \text{Data}\{6 \leq C_{\text{Sat}} \leq 7, \emptyset\}.T_{\text{Sat}} \end{aligned}$$

$$\begin{array}{c}
\text{Congruence (top)} \\
\frac{\text{p} \neq \text{q}}{(\mathbb{V}, T) \equiv (\mathbb{V}, T)} \quad \frac{\text{p}!m_1(S_1) \cdot \text{q}!m_2(S_2) \cdot \mathcal{M} \equiv \text{q}!m_2(S_2) \cdot \text{p}!m_1(S_1) \cdot \mathcal{M}}{\mathcal{M} \equiv \mathcal{M}' \quad (\mathbb{V}, T) \equiv (\mathbb{V}, T')} \\
\frac{\mathcal{M} \equiv \mathcal{M}'}{\mathcal{M}; (\mathbb{V}, T) \equiv \mathcal{M}'; (\mathbb{V}, T')} \\
\text{Subtyping (bottom)} \\
\frac{\text{p}!m(S) \cdot \mathcal{O} \cdot \mathcal{M} \equiv \mathcal{O} \cdot \text{p}!m(S) \cdot \mathcal{M}}{\mathcal{O} \leqslant \mathcal{O}} \quad \frac{\text{S}' \leqslant S \quad \mathcal{M} \leqslant \mathcal{M}'}{\text{q}!m(S) \cdot \mathcal{M} \leqslant \text{q}!m(S') \cdot \mathcal{M}'} \quad \frac{T \leqslant T'}{(\mathbb{V}, T) \leqslant (\mathbb{V}, T')} \quad \frac{\mathcal{M} \leqslant \mathcal{M}'}{\mathcal{M}; (\mathbb{V}, T) \leqslant \mathcal{M}'; (\mathbb{V}, T')}
\end{array}$$

Figure 6 Congruence (top) and subtyping (bottom) rules for timed-session/queue types.

4.2 Typing Environments

To reflect the behaviour of timed global types (§ 4.3), present a typing system for our session π -calculus (§ 4.4), and introduce type-level properties (§ 4.5), we formalise *typing environments* in Def. 8, followed by their Labelled Transition System (LTS) semantics in Def. 9.

► **Definition 8** (Typing Environments). *The typing environments Θ and Γ are defined as:*

$$\Theta ::= \emptyset \mid \Theta, X:(\mathbb{V}_1, T_1), \dots, (\mathbb{V}_n, T_n) \quad \Gamma ::= \emptyset \mid \Gamma, x:(\mathbb{V}, T) \mid \Gamma, s[p]:\tau$$

where τ is a timed-session/queue type: $\tau ::= (\mathbb{V}, T) \mid \mathcal{M} \mid \mathcal{M}; (\mathbb{V}, T)$, i.e. either a timed session type, a queue type, or a combination.

The environment composition Γ_1, Γ_2 is defined iff $\forall c \in \text{dom}(\Gamma_1) \cap \text{dom}(\Gamma_2) : \Gamma_i(c) = \mathcal{M}$ and $\Gamma_j(c) = (\mathbb{V}, T)$ with $i, j \in \{1, 2\}$, and for all such c , we posit $(\Gamma_1, \Gamma_2)(c) = \mathcal{M}; (\mathbb{V}, T)$.

We write $\text{dom}(\Gamma) = \{s\}$ iff for any $c \in \text{dom}(\Gamma)$, there is p such that $c = s[p]$ (i.e. Γ only contains session s). We write $s \notin \Gamma$ iff $\forall p : s[p] \notin \text{dom}(\Gamma)$ (i.e. session s does not occur in Γ). We write Γ_s iff $\text{dom}(\Gamma_s) = \{s\}$, $\text{dom}(\Gamma_s) \subseteq \text{dom}(\Gamma)$, and $\forall s[p] \in \text{dom}(\Gamma) : \Gamma(s[p]) = \Gamma_s(s[p])$ (i.e. restriction of Γ to session s). We denote updates as $\Gamma[c \mapsto \tau] : \Gamma[c \mapsto \tau](c) = \tau$ and $\Gamma[c \mapsto \tau](c') = \Gamma(c')$ (where $c \neq c'$).

Congruence and subtyping are imposed on typing environments: $\Gamma \equiv \Gamma'$ (resp. $\Gamma \leqslant \Gamma'$) iff $\text{dom}(\Gamma) = \text{dom}(\Gamma')$ and $\forall c \in \text{dom}(\Gamma) : \Gamma(c) \equiv \Gamma'(c)$ (resp. $\Gamma(c) \leqslant \Gamma'(c)$), incorporating additional congruence and subtyping rules for time-session/queue types, as depicted in Fig. 6.

In Def. 8, the typing environment Θ maps process variables to n -tuples of timed session types, while Γ maps variables to timed session types, and channels with roles to timed-session/queue types. Note that in our typing environments, timed session types are annotated with clock valuations, denoted as (\mathbb{V}, T) . This enables us to capture timing information within the type system, facilitating the tracking of the (virtual) time at which the next action can be validated during the execution of a process.

The congruence relation \equiv for timed-session/queue types is inductively defined as in Fig. 6 (top), reordering queued messages with different receivers. Subtyping for timed-session/queue types extends Def. 5 with rules in Fig. 6 (bottom): particularly, rule [SUB- \mathcal{M}] states that a sequence of queued message types is a subtype of another if messages in the same position have identical receivers and labels, and their payload sorts are related by subtyping.

► **Definition 9** (Typing Environment Reduction). *Let α be a transition label of the form $s:p!q:m$, $s:p,q:m$, or t . The typing environment transition $\xrightarrow{\alpha}$ is inductively defined by the rules in Fig. 7 (top). We write $\Gamma \xrightarrow{\alpha}$ iff $\Gamma \xrightarrow{\alpha} \Gamma'$ for some Γ' . We define two reductions $\Gamma \xrightarrow{s} \Gamma'$ (where s is a session) and $\Gamma \xrightarrow{} \Gamma'$ as follows:*

- $\Gamma \xrightarrow{s} \Gamma'$ holds iff $\Gamma \xrightarrow{\alpha} \Gamma'$ with $\alpha \in \{s:p!q:m, s:p,q:m, t \mid p, q \in \mathcal{R}\}$ (where \mathcal{R} is the set of all roles). We write $\Gamma \xrightarrow{} \Gamma$ iff $\Gamma \xrightarrow{s} \Gamma'$ for some Γ' , and $\xrightarrow{*}$ as the reflexive and transitive closure of \xrightarrow{s} ;
- $\Gamma \xrightarrow{} \Gamma'$ holds iff $\Gamma \xrightarrow{s} \Gamma'$ for some s . We write $\Gamma \xrightarrow{} \Gamma$ iff $\Gamma \xrightarrow{} \Gamma'$ for some Γ' , and $\xrightarrow{*}$ as the reflexive and transitive closure of $\xrightarrow{}$.

$$\begin{array}{c}
\frac{\Gamma, s[\mathbf{p}]:(\mathbb{V}, T\{\mu t.T/\mathbf{t}\}) \xrightarrow{\alpha} \Gamma'}{\Gamma, s[\mathbf{p}]:(\mathbb{V}, \mu t.T) \xrightarrow{\alpha} \Gamma'} \text{ [Γ-μ]} \quad \frac{\Gamma \xrightarrow{\alpha} \Gamma' \quad \alpha \neq t}{\Gamma, x:(\mathbb{V}, T) \xrightarrow{\alpha} \Gamma', x:(\mathbb{V}, T)} \text{ [Γ-,x]} \quad \frac{\Gamma \xrightarrow{\alpha} \Gamma' \quad \alpha \neq t}{\Gamma, s[\mathbf{p}]:\tau \xrightarrow{\alpha} \Gamma', s[\mathbf{p}]:\tau} \text{ [Γ-,τ]} \\
\frac{k \in I \quad \mathbb{V} \models \delta_k}{s[\mathbf{p}]:\mathcal{M}; (\mathbb{V}, \mathbf{q} \oplus \{\mathbf{m}_i(S_i)\{\delta_i, \lambda_i\}.T_i\}_{i \in I}) \xrightarrow{s:\mathbf{p}!\mathbf{q}:\mathbf{m}_k} s[\mathbf{p}]:\mathcal{M} \cdot \mathbf{q}!\mathbf{m}_k(S_k) \cdot \emptyset; (\mathbb{V}[\lambda_k \mapsto 0], T_k)} \text{ [Γ-⊕]} \\

\frac{c:(\mathbb{V}, T) \xrightarrow{t} c:(\mathbb{V} + t, T) \text{ [Γ-Ts]} \quad s[\mathbf{p}]:\mathcal{M} \xrightarrow{t} s[\mathbf{p}]:\mathcal{M} \text{ [Γ-TQ]} \quad s[\mathbf{p}]:\mathcal{M}; (\mathbb{V}, T) \xrightarrow{t} s[\mathbf{p}]:\mathcal{M}; (\mathbb{V} + t, T) \text{ [Γ-Tc]}}{\frac{\Gamma_1 \xrightarrow{t} \Gamma'_1 \quad \Gamma_2 \xrightarrow{t} \Gamma'_2}{\Gamma_1, \Gamma_2 \xrightarrow{t} \Gamma'_1, \Gamma'_2} \text{ [Γ-,T]} \quad \frac{\Gamma \equiv \Gamma_1 \quad \Gamma_1 \xrightarrow{\alpha} \Gamma'_1 \quad \Gamma'_1 \equiv \Gamma'}{\Gamma \xrightarrow{\alpha} \Gamma'} \text{ [Γ-STRUCT]}} \\
\hline
\frac{\langle \mathbb{V}; G \rangle \xrightarrow{t} \langle \mathbb{V} + t; G \rangle \text{ [GR-T]} \quad \frac{\langle \mathbb{V}; G\{\mu t.G/\mathbf{t}\} \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G' \rangle \quad \langle \mathbb{V}; \mu t.G \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G' \rangle}{j \in I \quad \mathbb{V} \models \delta_{O,j} \quad \mathbb{V}' = \mathbb{V}[\lambda_{O,j} \mapsto 0]} \text{ [GR-μ]} \quad \frac{j \in I \quad \mathbb{V} \models \delta_{I,j} \quad \mathbb{V}' = \mathbb{V}[\lambda_{I,j} \mapsto 0]}{\langle \mathbb{V}; \mathbf{p} \rightarrow \mathbf{q}: \{\mathbf{m}_i(S_i)\{\mathcal{A}_i\}.G'_i\}_{i \in I} \xrightarrow{s:\mathbf{p}!\mathbf{q}:\mathbf{m}_j} \langle \mathbb{V}'; \mathbf{p} \rightsquigarrow \mathbf{q}: j \{\mathbf{m}_i(S_i)\{\mathcal{A}_i\}.G'_i\}_{i \in I} \rangle} \text{ [GR-⊕]} \\
\frac{\langle \mathbb{V}; \mathbf{p} \rightsquigarrow \mathbf{q}: j \{\mathbf{m}_i(S_i)\{\mathcal{A}_i\}.G'_i\}_{i \in I} \xrightarrow{s:\mathbf{q},\mathbf{p}:\mathbf{m}_j} \langle \mathbb{V}'; G'_j \rangle}{\forall i \in I : \langle \mathbb{V}; G'_i \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G''_i \rangle \quad \mathbf{p}, \mathbf{q} \notin \text{subject}(\alpha) \quad \alpha \neq t} \text{ [GR-CTX-I]} \\
\frac{\forall i \in I : \langle \mathbb{V}; G'_i \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G''_i \rangle \quad \mathbf{q} \notin \text{subject}(\alpha) \quad \alpha \neq t}{\langle \mathbb{V}; \mathbf{p} \rightsquigarrow \mathbf{q}: j \{\mathbf{m}_i(S_i)\{\mathcal{A}_i\}.G'_i\}_{i \in I} \xrightarrow{\alpha} \langle \mathbb{V}'; \mathbf{p} \rightsquigarrow \mathbf{q}: j \{\mathbf{m}_i(S_i)\{\mathcal{A}_i\}.G''_i\}_{i \in I} \rangle} \text{ [GR-CTX-II]}
\end{array}$$

Figure 7 Top: typing environment semantics. Bottom: timed global type semantics, where $\mathcal{A}_i = \delta_{O,i}, \lambda_{O,i}, \delta_{I,i}, \lambda_{I,i}$.

The label $s:\mathbf{p}!\mathbf{q}:\mathbf{m}$ indicates that \mathbf{p} sends the message \mathbf{m} to \mathbf{q} on session s , while $s:\mathbf{p},\mathbf{q}:\mathbf{m}$ denotes the reception of \mathbf{m} from \mathbf{q} by \mathbf{p} on s . Additionally, the label t ($\in \mathbb{R}_{\geq 0}$) represents a time action modelling the passage of time.

The (highlighted) main modifications in the reduction rules for typing environments, compared to standard rules, concern time. Rule $[\Gamma-\oplus]$ states that an entry can perform an output transition by appending a message at the respective queue within the time specified by the output clock constraint. Dually, rule $[\Gamma-&]$ allows an entry to execute an input transition, consuming a message from the corresponding queue within the specified input clock constraint, provided that the payloads are compatible through subtyping. Note that in both rules, the associated clock valuation of the reduced entry must be updated according to the reset.

Rules $[\Gamma-,x]$ and $[\Gamma-,τ]$ pertain to *untimed* reductions, i.e. $\alpha \neq t$, within a larger environment. Rule $[\Gamma-Ts]$ models time passing on an entry of timed session type by incrementing the associated clock valuation, while rule $[\Gamma-TQ]$ specifies that an entry of queue type is not affected with respect to time progression. Thus, rule $[\Gamma-Tc]$ captures the corresponding time behaviour for a timed-session/queue type entry. Additionally, rule $[\Gamma-,T]$ ensures that time elapses uniformly across compatibly composed environments. Other rules are standard: $[\Gamma-μ]$ is for recursion, and $[\Gamma-STRUCT]$ ensures that reductions are closed under congruence.

The reduction $\Gamma \xrightarrow{s} \Gamma'$ indicates that the typing environment Γ can advance on session s , involving any roles, while $\Gamma \rightarrow \Gamma'$ signifies Γ progressing on any session. This distinction helps in illustrating properties of typed processes discussed in § 4.5.

4.3 Relating Timed Global Types and Typing Environments

One of our main results is establishing an operational relationship between the semantics of timed global types and typing environments, ensuring the *correctness* of processes typed by environments that reflect timed global types. To accomplish this, we begin by assigning LTS semantics to timed global types.

Similar to that of typing environments, we define the LTS semantics for timed global types G over tuples of the form $\langle \mathbb{V}; G \rangle$, where \mathbb{V} is a clock valuation. Additionally, we specify the subject of an action α as its responsible principal: $\text{subject}(s:p!q:m) = \text{subject}(s:p,q:m) = \{p\}$, and $\text{subject}(t) = \emptyset$.

► **Definition 10** (Timed Global Type Reduction). *The timed global type transition $\xrightarrow{\alpha}$ is inductively defined by the rules in Fig. 7 (bottom). We denote $\langle \mathbb{V}; G \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G' \rangle$ if there exists α such that $\langle \mathbb{V}; G \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G' \rangle$, $\langle \mathbb{V}; G \rangle \rightarrow$ if there exists $\langle \mathbb{V}'; G' \rangle$ such that $\langle \mathbb{V}; G \rangle \rightarrow \langle \mathbb{V}'; G' \rangle$, and \rightarrow^* as the transitive and reflexive closure of \rightarrow .*

In Fig. 7 (bottom), the (highlighted) changes from the standard global type reduction rules [11] focus on time. Rule [GR-T] accounts for the passage of time by incrementing the clock valuation. Rules [GR-⊕] and [GR-&] model the sending and receiving of messages within specified clock constraints, respectively. Both rules also require the adjustment of the clock valuation using the reset predicate. Rule [GR-μ] handles recursion. Finally, rules [GR-CTX-i] and [GR-CTX-ii] allow reductions of (intermediate) global types causally independent of their prefixes. Note that the execution of any timed global type transition always starts with an initial clock valuation \mathbb{V}^0 , i.e. all clocks in \mathbb{V} are set to 0.

We are now ready to establish a *new* relationship, *association*, between timed global types and typing environments. This association, which is more general than projection (Def. 6) by incorporating subtyping \leqslant (Def. 5), plays a crucial role in formulating the typing rules (§ 4.4) and demonstrating the properties of typed processes (§ 4.5).

► **Definition 11** (Association). *A typing environment Γ is associated with a timed global type $\langle \mathbb{V}; G \rangle$ for a multiparty session s , written $\langle \mathbb{V}; G \rangle \sqsubseteq_s \Gamma$, iff Γ can be split into three (possibly empty) sub-environments $\Gamma = \Gamma_G, \Gamma_\Delta, \Gamma_{\text{end}}$ where:*

1. Γ_G is associated with $\langle \mathbb{V}; G \rangle$ for s , provided as:

- (i) $\text{dom}(\Gamma_G) = \{s[p] \mid p \in \text{roles}(G)\}$;
- (ii) $\forall s[p] \in \text{dom}(\Gamma_G) : \Gamma_G(s[p]) = (\mathbb{V}_p, T_p)$;
- (iii) $\forall p \in \text{roles}(G) : G \upharpoonright p \leqslant T_p$; and
- (iv) $\mathbb{V} = \sqcup_{p \in \text{roles}(G)} \mathbb{V}_p$ (recall that \sqcup is an overriding union).

2. Γ_Δ is associated with G for s , given as follows:

- (i) $\text{dom}(\Gamma_\Delta) = \{s[p] \mid p \in \text{roles}(G)\}$;
- (ii) $\forall s[p] \in \text{dom}(\Gamma_\Delta) : \Gamma_\Delta(s[p]) = \mathcal{M}_p$;
- (iii) if $G = \text{end}$ or $G = \mu t.G'$, then $\forall s[p] \in \text{dom}(\Gamma_\Delta) : \Gamma_\Delta(s[p]) = \emptyset$;
- (iv) if $G = p \rightarrow q : \{m_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}$, then
 - (a1) $q \notin \text{receivers}(\Gamma_\Delta(s[p]))$, and
 - (a2) $\forall i \in I : \Gamma_\Delta$ is associated with G_i for s ;
- (v) if $G = p \rightsquigarrow q ; j : \{m_i(S_i)\{\delta_{O_i}, \lambda_{O_i}, \delta_{I_i}, \lambda_{I_i}\}.G_i\}_{i \in I}$, then
 - (b1) $\Gamma_\Delta(s[p]) = q!m_j(S'_j) \cdot \mathcal{M}$ with $S'_j \leqslant S_j$, and
 - (b2) $\Gamma_\Delta[s[p] \mapsto \mathcal{M}]$ is associated with G_j for s .

3. $\forall s[p] \in \text{dom}(\Gamma_{\text{end}}) : \Gamma_{\text{end}}(s[p]) = \emptyset; (\mathbb{V}_p, \text{end})$.

The association $\cdot \sqsubseteq \cdot$ is a binary relation over timed global types $\langle \mathbb{V}; G \rangle$ and typing environments Γ , parameterised by multiparty sessions s . There are three requirements for the association:

- (1) The typing environment Γ must include two entries for each role of the global type G in s : one of timed session type and another of queue type;
- (2) The timed session type entries in Γ reflect $\langle \mathbb{V}; G \rangle$ by ensuring that:
 - a. they align with the projections of G via subtyping, and
 - b. their clock valuations match \mathbb{V} ;
- (3) The queue type entries in Γ correspond to the transmissions en route in G .

Note that Γ_{end} is specifically used to associate typing environments and **end**-types $\langle \mathbb{V}; \text{end} \rangle$, as in this case, both Γ_G and Γ_Δ are empty.

► **Example 12.** Consider the timed global type $\langle \{C_{\text{Sen}} = 0, C_{\text{Sat}} = 0, C_{\text{Ser}} = 0\}; G_{\text{data}} \rangle$, where G_{data} is from Ex. 7, and a typing environment $\Gamma_{\text{data}} = \Gamma_{G_{\text{data}}}, \Gamma_{\Delta_{\text{data}}}$, where:

$$\begin{aligned}\Gamma_{G_{\text{data}}} &= s[\text{Sen}]:(\{C_{\text{Sen}} = 0\}, \text{Sat} \oplus \text{Data}\{6 \leq C_{\text{Sen}} \leq 7, C_{\text{Sen}} := 0\}), \\ s[\text{Sat}] &:(\{C_{\text{Sat}} = 0\}, \text{Sen} \& \left\{ \begin{array}{l} \text{Data}\{6 \leq C_{\text{Sat}} \leq 7, \emptyset\}. \text{Ser} \oplus \text{Data}\{6 \leq C_{\text{Sat}} \leq 7, C_{\text{Sat}} := 0\} \\ \text{fail}\{6 \leq C_{\text{Sat}} \leq 7, \emptyset\}. \text{Ser} \oplus \text{fatal}\{6 \leq C_{\text{Sat}} \leq 7, C_{\text{Sat}} := 0\} \end{array} \right\}), \\ s[\text{Ser}] &:(\{C_{\text{Ser}} = 0\}, \text{Sat} \& \left\{ \begin{array}{l} \text{Data}\{6 \leq C_{\text{Ser}} \leq 7, C_{\text{Ser}} := 0\} \\ \text{fatal}\{6 \leq C_{\text{Ser}} \leq 7, C_{\text{Ser}} := 0\} \end{array} \right\}) \\ \Gamma_{\Delta_{\text{data}}} &= s[\text{Sen}]:\emptyset, s[\text{Sat}]:\emptyset, s[\text{Ser}]:\emptyset\end{aligned}$$

Γ_{data} is associated with $\langle \{C_{\text{Sen}} = 0, C_{\text{Sat}} = 0, C_{\text{Ser}} = 0\}; G_{\text{data}} \rangle$ for s , which can be formally verified by ensuring that Γ_{data} satisfies all conditions outlined in Def. 11.

We establish the operational correspondence between a timed global type and its associated typing environment, our main result for timed multiparty session types, through two theorems: Thm. 13 demonstrates that every possible reduction of a typing environment is mirrored by a corresponding action in reductions of the associated timed global type, while Thm. 14 indicates that the reducibility of a timed global type is equivalent to its associated environment.

► **Theorem 13 (Completeness of Association).** *Given associated timed global type $\langle \mathbb{V}; G \rangle$ and typing environment $\Gamma: \langle \mathbb{V}; G \rangle \sqsubseteq_s \Gamma$. If $\Gamma \xrightarrow{\alpha} \Gamma'$, then there exists $\langle \mathbb{V}'; G' \rangle$ such that $\langle \mathbb{V}; G \rangle \xrightarrow{\alpha} \langle \mathbb{V}'; G' \rangle$ and $\langle \mathbb{V}'; G' \rangle \sqsubseteq_s \Gamma'$.*

► **Theorem 14 (Soundness of Association).** *Given associated timed global type $\langle \mathbb{V}; G \rangle$ and typing environment $\Gamma: \langle \mathbb{V}; G \rangle \sqsubseteq_s \Gamma$. If $\langle \mathbb{V}; G \rangle \rightarrow$, then there exists $\alpha', \mathbb{V}', \langle \mathbb{V}''; G'' \rangle, \Gamma',$ and Γ'' , such that $\langle \mathbb{V}'; G \rangle \sqsubseteq_s \Gamma', \langle \mathbb{V}'; G \rangle \xrightarrow{\alpha'} \langle \mathbb{V}''; G'' \rangle, \Gamma' \xrightarrow{\alpha'} \Gamma'',$ and $\langle \mathbb{V}''; G'' \rangle \sqsubseteq_s \Gamma''$.*

► **Remark 15.** We formulate a soundness theorem that does not mirror the completeness theorem, differing from prior work such as [11]. This choice stems from our reliance on subtyping (Def. 5), notably $[\text{SUB-}\oplus]$. In our framework, a timed local type in the typing environment might offer fewer selection branches compared to the corresponding projected timed local type. Consequently, certain sending actions with their associated clock valuations may remain uninhabited within the timed global type. Consider, e.g. a timed global type:

$$\langle \mathbb{V}_r; G_r \rangle = \langle \{C_p = 3, C_q = 3\}; p \rightarrow q: \left\{ \begin{array}{l} m_1\{0 \leq C_p \leq 1, \emptyset, 1 \leq C_q \leq 2, \emptyset\}. \text{end} \\ m_2\{2 \leq C_p \leq 4, \emptyset, 5 \leq C_q \leq 6, \emptyset\}. \text{end} \end{array} \right\} \rangle$$

An associated typing environment Γ_r may have:

$$\Gamma_r(s[p]) = (\{C_p = 3\}, q \oplus m_1\{0 \leq C_p \leq 1, \emptyset\}. \text{end}); \emptyset \geq (\{C_p = 3\}, q \oplus \left\{ \begin{array}{l} m_1\{0 \leq C_p \leq 1, \emptyset\}. \text{end} \\ m_2\{2 \leq C_p \leq 4, \emptyset\}. \text{end} \end{array} \right\}); \emptyset$$

While the timed global type $\langle \mathbb{V}_r; G_r \rangle$ might transition through $s:p!q:m_2$, the associated environment Γ_r cannot. Nevertheless, our soundness theorem *adequately* guarantees communication safety (communication matches) via association.

$$\begin{array}{c}
 \frac{\Theta(X) = (\mathbb{V}_1, T_1), \dots, (\mathbb{V}_n, T_n)}{\Theta \vdash X:(\mathbb{V}_1, T_1), \dots, (\mathbb{V}_n, T_n)} \text{ [T-X]} \quad \frac{\forall i \in 1..n \quad c_i:(\mathbb{V}_i, T_i) \vdash c_i:(\mathbb{V}'_i, \mathbf{end})}{\text{end}(c_1:(\mathbb{V}_1, T_1), \dots, c_n:(\mathbb{V}_n, T_n))} \text{ [T-end]} \\

 \end{array}$$

Figure 8 ATMP typing rules.

4.4 Affine Timed Multiparty Session Typing System

We now present a typing system for ATMP, which relies on *typing judgments* of the form:

$$\Theta \cdot \Gamma \vdash P \quad (\text{with } \Theta \text{ omitted when empty})$$

This judgement indicates that the process P adheres to the usage of its variables and channels as specified in Γ (Def. 8), guided by the process types in Θ (Def. 8). Our typing system is defined inductively by the typing rules shown in Fig. 8, with channels annotated for convenience, especially those bound by process definitions and restrictions.

The innovations (highlighted) in Fig. 8 primarily focus on typing processes with time, timeout failures, message queues, and using association (Def. 11) to enforce session restrictions. **Standard** from [37]: Rule [T-X] retrieves process variables. Rule [T-SUB] applies subtyping within a singleton typing environment $c:(\mathbb{V}, T)$. Rule [T-end] introduces a predicate $\text{end}(\cdot)$ for typing environments, signifying the termination of all endpoints. This predicate is used in [T-0] to type an inactive process $\mathbf{0}$. Rules [T-def] and [T-X-CALL] deal with recursive processes declarations and calls, respectively. Rule [T-|] partitions the typing environment into two, each dedicated to typing one sub-process.

Session Restriction: Rule [T- ν -G] depends on a typing environment associated with a timed global type in a given session s to validate session restrictions.

Delay: Rule [T- δ] ensures the typedness of time-consuming delay $\mathbf{delay}(\delta) . P$ by checking every deterministic delay $\mathbf{delay}(t) . P$ with t as a possible solution to δ . Rule [T-t] types a deterministic delay $\mathbf{delay}(t) . P$ by adjusting the clock valuations in the environment used to type P . Here, $\Gamma + t$ denotes the typing environment obtained from Γ by increasing the associated clock valuation in each entry by t .

Timed Branching and Selection: Rules [T-&] and [T-⊕] are for timed branching and selection, respectively. We elaborate on [T-&], as [T-⊕] is its dual. The first premise in [T-&] specifies a time interval $[\mathbb{V}, \mathbb{V} + n]$ within which the message must be received, in accordance with each δ_i . The last premise requires that each continuation process be well-typed against the continuation of the type in all possible typing environments where the time falls between $[\mathbb{V}, \mathbb{V} + n]$. Here, the clock valuation \mathbb{V} is reset based on each λ_i . The remaining premises stipulate that the clock valuation \mathbb{V}'_i of each delegated receiving session must satisfy δ'_i , and that c is typed.

Try-Catch, Cancellation, and Kill: Rules [T-TRY], [T-CANCEL], and [T-KILL] pertain to try-catch, cancellation, and kill processes, respectively, analogous to the corresponding rules in [28]. [T-CANCEL] is responsible for generating a kill process at its declared session. [T-KILL] types a kill process arising during reductions: it involves broadcasting the cancellation of $s[p]$ to all processes that belong to s . [T-TRY] handles a **try-catch** process **try** P **catch** Q by ensuring that the **try** process P and the **catch** process Q maintain consistent session typing. Additionally, P cannot be a queue or parallel composition, as indicated by $\text{subjP}(P) = \{c\}$.

Timeout Failure: Rule [T-FAILED] indicates that a process raising timeout failure can be typed by *any* typing environment.

Queue: Rules [T-ε] and [T-σ] concern the typing of queues. [T-ε] types an empty queue under an ended typing environment, while [T-σ] types a non-empty queue by inserting a message type into Γ . This insertion may either prepend the message to an existing queue type in Γ or add a queue-typed entry to Γ if not present.

► **Example 16.** Take the typing environment Γ_{data} from Ex. 12, along with the processes Q_{Sen} , Q_{Sat} , Q_{Ser} from Ex. 4. Verifying the typing of $Q_{\text{Sen}} | Q_{\text{Sat}} | Q_{\text{Ser}}$ by Γ_{data} is easy. Moreover, since Γ_{data} is associated with a timed global type $\langle \{C_{\text{Sen}} = 0, C_{\text{Sat}} = 0, C_{\text{Ser}} = 0\}; G_{\text{data}} \rangle$ for session s (as demonstrated in Ex. 12), i.e. $\langle \{C_{\text{Sen}} = 0, C_{\text{Sat}} = 0, C_{\text{Ser}} = 0\}; G_{\text{data}} \rangle \sqsubseteq_s \Gamma_{\text{data}}$, following [T-ν-G], $Q_{\text{Sen}} | Q_{\text{Sat}} | Q_{\text{Ser}}$ is closed under Γ_{data} , i.e. $\vdash (\nu s : \Gamma_{\text{data}}) Q_{\text{Sen}} | Q_{\text{Sat}} | Q_{\text{Ser}}$.

4.5 Typed Process Properties

We demonstrate that processes typed by the ATMP typing system exhibit the desirable properties: *subject reduction* (Thm. 17), *session fidelity* (Thm. 21), and *deadlock-freedom* (Thm. 24).

Subject Reduction. Subject reduction ensures the preservation of well-typedness of processes during reductions. Specifically, it states that if a well-typed process P reduces to P' , this reduction is reflected in the typing environment Γ used to type P . Notably, in our subject reduction theorem, P is constructed from a timed global type, i.e. typed by an environment associated with a timed global type, and this construction approach persists as an invariant property throughout reductions. Furthermore, the theorem does not require P to contain only a single session; instead, it includes all restricted sessions in P , ensuring that reductions on these sessions uphold their respective restrictions. This enforcement is facilitated by rule [T-ν-G] in Fig. 8.

► **Theorem 17** (Subject Reduction). *Assume $\Theta \cdot \Gamma \vdash P$ where $\forall s \in \Gamma : \exists \langle \mathbb{V}; G \rangle : \langle \mathbb{V}; G \rangle \sqsubseteq_s \Gamma_s$. If $P \rightarrow P'$, then $\exists \Gamma'$ such that $\Gamma \xrightarrow{*} \Gamma'$, $\Theta \cdot \Gamma' \vdash P'$, and $\forall s \in \Gamma' : \exists \langle \mathbb{V}'; G' \rangle : \langle \mathbb{V}'; G' \rangle \sqsubseteq_s \Gamma'_s$.*

► **Corollary 18** (Type Safety). *Assume $\emptyset \cdot \emptyset \vdash P$. If $P \xrightarrow{*} P'$, then P' has no communication error.*

► **Example 19.** Take the typed process $Q_{\text{Sen}} | Q_{\text{Sat}} | Q_{\text{Ser}}$ and the typing environment Γ_{data} from Exs. 4, 12, and 16. After a reduction using [R-DET], $Q_{\text{Sen}} | Q_{\text{Sat}} | Q_{\text{Ser}}$ transitions to $\text{delay}(6.5) \cdot Q'_{\text{Sen}} | s[\text{Sen}] \blacktriangleright \epsilon | \text{delay}(6) \cdot Q'_{\text{Sat}} | s[\text{Sat}] \blacktriangleright \epsilon | \text{delay}(6) \cdot Q'_{\text{Ser}} | s[\text{Ser}] \blacktriangleright \epsilon = Q_2$, which

remains typable by Γ_{data} ($\Gamma_{\text{data}} \rightarrow^* \Gamma_{\text{data}}$). Then, applying [R-TIME], Q_2 evolves to $\Psi_{6.5}(Q_2)$, typed as $\Gamma_{\text{data}} + 6.5$, derived from $\Gamma_{\text{data}} \xrightarrow{6.5} \Gamma_{\text{data}} + 6.5$. Further reduction through [R-FAIL] leads $\Psi_{6.5}(Q_2)$ to $Q'_{\text{Sen}} | s[\text{Sen}] \blacktriangleright \epsilon | s[\text{Sat}] \blacktriangleright \epsilon | \Psi_{0.5}(Q'_{\text{Ser}}) | s[\text{Ser}] \blacktriangleright \epsilon = Q_3$, typable by $\Gamma_{\text{data}} + 6.5$. Later, via [C-CAT], Q_3 reduces to $\text{cancel}(s[\text{Sen}]) | s[\text{Sen}] \blacktriangleright \epsilon | s[\text{Sat}] \blacktriangleright \epsilon | \Psi_{0.5}(Q'_{\text{Ser}}) | s[\text{Ser}] \blacktriangleright \epsilon$, which can be typed by Γ''_{data} , obtained from $\Gamma_{\text{data}} + 6.5 \xrightarrow{s:\text{Sen}!\text{Sat}:Data} . \xrightarrow{s:\text{Sat},\text{Sen}:Data} \Gamma''_{\text{data}}$.

Session Fidelity. Session fidelity states the converse implication of subject reduction: if a process P is typed by Γ and Γ can reduce, then P can simulate at least one of the reductions performed by Γ – although not necessarily all such reductions, as Γ over-approximates the behavior of P . Consequently, we can infer P 's behaviour from that of Γ . However, this result does not hold for certain well-typed processes, such as those that get trapped in recursion loops like $\text{def } X(\dots) = X \text{ in } X$, or deadlock due to interactions across multiple sessions [8]. To address this, similarly to [37] and most session type works, we establish session fidelity specifically for processes featuring guarded recursion and implementing a single multiparty session as a parallel composition of one sub-process per role. The formalisation of session fidelity is provided in Thm. 21, building upon the concepts introduced in Def. 20.

► **Definition 20** (From [37]). Assume $\emptyset \cdot \Gamma \vdash P$. We say that P :

1. has guarded definitions if and only if in each process definition in P of the form $\text{def } X(x_1:(\mathbb{V}_1, T_1), \dots, x_n:(\mathbb{V}_n, T_n)) = Q \text{ in } P'$, for all $i \in 1 \dots n$, $T_i \not\leq \text{end}$ implies that a call $Y(\dots, x_i, \dots)$ can only occur in Q as a subterm of $x_i^n[\mathbf{q}] \sum_{j \in \mathbf{m}} (y_j).P_j$ or $x_i^n[\mathbf{q}] \oplus \mathbf{m}\langle d \rangle.P''$ (i.e. after using x_i for input or output);
2. only plays role p in s , by Γ , if and only if
 - (i) P has guarded definitions;
 - (ii) $\text{fv}(P) = \emptyset$;
 - (iii) $\Gamma = \Gamma_0, s[p]:\tau$ with $\tau \not\leq (\mathbb{V}, \text{end})$ and $\text{end}(\Gamma_0)$;
 - (iv) in all subterms $(\nu s':\Gamma') P'$ of P , we have $\Gamma' \leq s'[p']:\emptyset; (\mathbb{V}', \text{end})$ or $\Gamma' \leq s'[p']:(\mathbb{V}', \text{end})$ (for some p', \mathbb{V}').

We say “ P only plays role p in s ” if and only if $\exists \Gamma : \emptyset \cdot \Gamma \vdash P$, and item 2 holds.

In Def. 20, item 1 describes guarded recursion for processes, while item 2 specifies a process limited to playing exactly *one* role within *one* session, preventing an ensemble of such processes from deadlocking by waiting for each other on multiple sessions.

We proceed to present our session fidelity result, taking kill processes into account. We denote $Q \not\leq$ to indicate that Q consists only of a parallel composition of kill processes. Similar to subject reduction (Thm. 17), our session fidelity relies on a typing environment associated with a timed global type for a specific session s to type the process, ensuring the fulfilment of single-session requirements (Def. 20) and maintaining invariance during reductions.

► **Theorem 21** (Session Fidelity). Assume $\emptyset \cdot \Gamma \vdash P$, with $\langle \mathbb{V}; G \rangle \sqsubseteq_s \Gamma$, $P \equiv \Pi_{p \in I} P_p \mid Q \not\leq$, and $\Gamma = \bigcup_{p \in I} \Gamma_p \cup \Gamma_0$, such that $\emptyset \cdot \Gamma_0 \vdash Q \not\leq$, and for each P_p :

- (1) $\emptyset \cdot \Gamma_p \vdash P_p$, and
 - (2) either $P_p \equiv \mathbf{0}$, or P_p only plays role p in s , by Γ_p .
- Then, $\Gamma \rightarrow_s$ implies $\exists \Gamma', \langle \mathbb{V}'; G' \rangle, P'$ such that $\Gamma \rightarrow_s \Gamma'$, $P \rightarrow^* P'$, and $\emptyset \cdot \Gamma' \vdash P'$, with $\langle \mathbb{V}'; G' \rangle \sqsubseteq_s \Gamma'$, $P' \equiv \Pi_{p \in I} P'_p \mid Q' \not\leq$, and $\Gamma' = \bigcup_{p \in I} \Gamma'_p \cup \Gamma'_0$ such that $\emptyset \cdot \Gamma'_0 \vdash Q' \not\leq$, and for each P'_p :
- (1) $\emptyset \cdot \Gamma'_p \vdash P'_p$, and
 - (2) either $P'_p \equiv \mathbf{0}$, or P'_p only plays role p in s , by Γ'_p .

► **Example 22.** Consider the processes Q_{Sen} , Q_{Sat} , Q_{Ser} from Ex. 4, the process Q_3 from Ex. 19, and the typing environment Γ_{data} from Ex. 12. Q_{Sen} , Q_{Sat} , and Q_{Ser} only play roles Sen , Sat , and Ser , respectively, in s , which can be easily verified. As demonstrated

in Ex. 19, Q_3 is typed by $\Gamma_{\text{data}} + 6.5$, satisfying all prerequisites specified in Thm. 21. Consequently, given $\Gamma_{\text{data}} + 6.5 \xrightarrow{s:\text{Sen!Sat:Data}} \Gamma'_{\text{data}}$, there exists Q_4 , resulting from $Q_3 \rightarrow Q_4$ via [R-OUT], such that Γ'_{data} can type Q_4 , with Γ'_{data} and Q_4 fulfilling the single session requirements of session fidelity.

Deadlock-Freedom. Deadlock-freedom ensures that a process can always either progress via reduction or terminate properly. In our system, where time can be infinitely reduced and session killings may occur during reductions, deadlock-freedom implies that if a process cannot undergo any further instantaneous (communication) reductions, and if any subsequent time reduction leaves it unchanged, then it contains only inactive or kill sub-processes. This desirable runtime property is guaranteed by processes constructed from timed global types. We formalise the property in Def. 23, and conclude, in Thm. 24, that a typed ensemble of processes interacting on a single session, restricted by a typing environment Γ associated with a timed global type $\langle \mathbb{V}^0; G \rangle$, is deadlock-free.

► **Definition 23** (Deadlock-Free Process). P is deadlock-free if and only if $P \rightarrow^* P' \not\rightarrow$ and $\forall t \geq 0 : \Psi_t(P') = P'$ (recall that $\Psi_t(\cdot)$ is a time-passing function defined in Fig. 4) implies $P' \equiv \mathbf{0} \mid \prod_{i \in I} s_i \not\downarrow$.

► **Theorem 24** (Deadlock-Freedom). Assume $\emptyset \cdot \emptyset \vdash P$, where $P \equiv (\nu s : \Gamma) \prod_{p \in \text{roles}(G)} P_p$, $\langle \mathbb{V}^0; G \rangle \sqsubseteq_s \Gamma$, and each P_p is either $\mathbf{0}$ (up to \equiv), or only plays p in s . Then, P is deadlock-free.

► **Example 25.** Given the processes Q_{Sen} , Q_{Sat} , and Q_{Ser} from Ex. 4, along with the typing environment Γ_{data} from Ex. 12, $(\nu s : \Gamma_{\text{data}}) Q_{\text{Sen}} \mid Q_{\text{Sat}} \mid Q_{\text{Ser}}$ is deadlock-free.

5 Design and Implementation of MultiCrusty^T

In this section, we present our toolchain, MultiCrusty^T, a RUST implementation of ATMP. MultiCrusty^T is designed with two main goals: correctly cascading failure notifications, and effectively handling time constraints. To achieve the first goal, we use RUST’s native $\text{?}-\text{operator}$ along with optional types, inspired by [28]. For the second objective, we begin by discussing the key challenges encountered during implementation.

Challenge 1: Representation of Time Constraints. To handle asynchronous timed communications using ATMP, we define a time window (δ in ATMP) and a corresponding behaviour for each operation. Addressing this constraint involves two subtasks: creating and using clocks in RUST, and representing all clock constraints as shown in § 3. RUST allows the creation of virtual clocks that rely on the CPU’s clock and provide nanosecond-level accuracy. Additionally, it is crucial to ensure that different behaviours can involve blocking or non-blocking communications, pre- or post-specific time tags, or adherence to specified time bounds.

Challenge 2: Enforcement of Time Constraints. To effectively enforce time windows, implementing reliable and accurate clocks and using them correctly is imperative. This requires addressing all cases related to time constraints properly: clocks may be considered unreliable if they skip ticks, do not strictly increase, or if the API for clock comparison does not yield results quickly enough. Enforcing time constraints in MultiCrusty^T involves using two libraries: the `crossbeam_channel` RUST library [9] for *asynchronous* messaging, and the RUST standard library `time` [39] for handling and comparing virtual clocks.

5.1 Time Bounds in MultiCrusty^T

Implementing Time Bounds. To demonstrate the integration of time bounds in MultiCrusty^T, we consider the final interaction between **Sen** and **Sat** in Fig. 1b, specifically from **Sat**'s perspective: **Sat** sends a **Close** message between time units 5 and 6 (both inclusive), following clock $C_{\text{Sat}2}$, which is not reset afterward.

In MultiCrusty^T, we define the **Send** type for message transmission, incorporating various parameters to specify requirements as `Send<[parameter1], [parameter2], ...>`. Assuming the (payload) type **Close** is defined, sending it using the **Send** type initiates with `Send<Close, ...>`. If $C_{\text{Sat}2}$ is denoted as '**b**', the clock '**b**' is employed for time constraints, expressed as `Send<Close, 'b', ...>`. Time bounds parameters in the **Send** type follow the clock declaration. In this case, both bounds are integers within the time window, resulting in the **Send** type being parameterised as `Send<Close, 'b', 0, true, 1, false, ...>`. Notably, bounds are integers due to the limitations of RUST's generic type parameters. To ensure that the clock '**b**' is not reset after triggering the **send** operation, we represent this with a whitespace char value in the **Send** type: `Send<Close, 'b', 0, true, 1, false, ' ', ...>`. The last parameter, known as the *continuation*, specifies the operation following the sending of the integer. In this case, closing the connection is achieved with an **End** type. The complete sending operation is denoted as `Send<Close, 'b', 0, true, 1, false, ' ', End>`.

Similarly, the **Recv** type is instantiated as `Recv<Close, 'b', 0, true, 1, false, ' ', End>`. The inherent mirroring of **Send** and **Recv** reflects their dual compatibility. Figs. 2a and 2b provide an analysis of the functioning of **Send** and **Recv**, detailing their parameters and features. Generic type parameters preceded by **const** within **Send** and **Recv** types also serve as values, representing general type categories supported by RUST. This type-value duality facilitates easy verification during compilation, ensuring compatibility between communicating parties.

Enforcing Time Bounds. It is crucial to rely on dependable clocks and APIs to enforce time constraints. RUST's standard library provides the time module [39], enabling developers to manage clocks and measure durations between events. This library, utilising the OS API, offers two clock types: **Instant** (monotonic but non-steady) and **SystemTime** (steady but non-monotonic). In MultiCrusty^T, the **Instant** type serves for both correctly prioritising event order and implementing virtual clocks. Virtual clocks are maintained through a dictionary (**HashMap** in RUST). Table 1 details the primitives provided by MultiCrusty^T for sending and receiving payloads, implementing branching, or closing connections. All primitives, except for **close**, require a specific **HashMap** of clocks to enforce time constraints.

Verifying Time Bounds. Our **send** and **recv** primitives use a series of conditions to ensure the integrity of a time window. The verification process adopts a *divide-and-conquer* strategy, validating the left-hand side time constraint for each clock before assessing the right-hand side constraint. The corresponding operation, whether sending or receiving a payload, is executed only after satisfying these conditions. This approach guarantees the effective enforcement of time constraints without requiring complex solver mechanisms.

5.2 Remote Data Implementation

Implementation of Server. Fig. 9 explores our MultiCrusty^T implementation of **Ser** in the remote data protocol (Fig. 1b). Specifically, the left side of Fig. 9 delves into the **MeshedChannels** type, representing the behaviour of **Ser** in the first branch and encapsulating various elements. In MultiCrusty^T, the **MeshedChannels** type incorporates $n + 1$ parameters,

■ **Table 1** Primitives available in MultiCrusty^T.

<code>let s = s.send(p, clocks)?;</code>	If allowed by the time constraint compared to the given clock in <code>clocks</code> , sends a payload <code>p</code> on a channel <code>s</code> and assigns the continuation of the session (a new meshed channel) to a new variable <code>s</code> .
<code>let (p, s) = s.recv(clocks)?;</code>	If allowed by the time constraint compared to the given clock in <code>clocks</code> , receives a payload <code>p</code> on channel <code>s</code> and assigns the continuation of the session to a new variable <code>s</code> .
<code>s.close()</code>	Closes the channel <code>s</code> and returns a unit type.
<code>offer!(s, clocks, { enum_i :: variant_k(e) => {...} }_{k ∈ K} }</code>	If allowed by the time constraint compared to the given clock in <code>clocks</code> , role <code>i</code> receives a choice as a message label on channel <code>s</code> , and, depending on the label value which should match one of the variants <code>variant_k</code> of <code>enum_i :: ...</code> , runs the related block of code.
<code>choose_X!(s, clocks, { enum_i :: variant_k(e) }_{i ∈ I})</code>	For role <code>X</code> , if allowed by the time constraint compared to the given clock in <code>clocks</code> , sends the chosen label, corresponding to <code>variant_k</code> to all other roles.

```

1  type EndpointSerData = MeshedChannels<
2    Send<GetData, 'a', 5, true, 5, true, ' ', ,
3      Recv<Data, 'a', 6, true, 7, true, 'a', End
4      >>,
5    End,
6    RoleSat<RoleSat<RoleBroadcast>>,
7    fn endpoint_data_ser(
8      s: EndpointSerData,
9      clocks: &mut HashMap<char, Instant>,
10     ) -> Result<(), Error> { [...] }
11    let s = s.send(GetData {}, clocks)?;
12    let (_data, s) = s.recv(clocks)?; [...]
6    NameSer>;

```

■ **Figure 9** Types (left) and primitives (right) for `Ser`.

where n is the count of roles in the protocol. These parameters include the role's name, $n - 1$ binary channels for interacting with other roles, and a stack dictating the sequence of binary channel usage. All types relevant to `Ser` are depicted in Fig. 9 (left).

The alias `EndpointSerData`, as indicated in Line 1, represents the `MeshedChannels` type. Binary types, defined in Lines 2–4, facilitate communication between `Ser`, `Sat`, and `Sen`. When initiating communication with `Sat`, `Ser` sends a `GetData` message in Line 2, receives a `Data` response, and ends communication on this binary channel. These operations use the clock '`a`' and adhere to time windows between 5 and 6 seconds for the first operation and between 6 and 7 seconds for the second. Clock '`a`' is reset only within the second operation. The order of operations is outlined in Line 5, where `Ser` interacts twice with `Sat` using `RoleSat` before initiating a choice with `RoleBroadcast`. Line 6 designates `Ser` as the owner of the `MeshedChannels` type. The behaviour of all roles in each branch can be specified similarly.

The right side of Fig. 9 illustrates the usage of `EndpointSerData` as an input type in the RUST function `endpoint_data_ser`. The function's output type, `Result<(), Error>`, indicates the utilization of affinity in RUST. In Line 11, variable '`s`', of type `EndpointSerData`, attempts to send a contentless message `GetData`. The `send` function can return either a value resembling `EndpointSerData` or an `Error`. If the clock's time does not adhere to the time constraint displayed in Line 2 with respect to the clock '`a`' from the set of clocks `clocks`, an `Error` is raised. Similarly, in Line 12, `Ser` attempts to receive a message using the same set of clocks. Both `send` and `recv` functions verify compliance with time constraints by comparing the relevant clock provided in the type for the time window and resetting the clock if necessary.

Error Handling. The error handling capabilities of MultiCrusty^T cover various potential errors that may arise during protocol implementation and execution. These errors include the misuse of generated types and timeouts, showcasing the flexibility of our implementation

```

1  global protocol RemoteData(role Sen, role Sat, role Ser){
2    rec Loop {
3      choice at Ser {
4        GetData() from Ser to Sat within [5;6] using a and resetting ();
5        GetData() from Sat to Sen within [5;6] using b and resetting ();
6        Data() from Sen to Sat within [6;7] using b and resetting (b);
7        Data() from Sat to Ser within [6;7] using a and resetting (a);
8        continue Loop
9    } or {
10      Close() from Ser to Sat within [5;6] using a and resetting ();
11      Close() from Sat to Sen within [5;6] using b and resetting (); } } }
```

Figure 10 Remote data protocol in νSCR^T .

in verifying communication protocols. For instance, if Lines 11 and 12 in Fig. 9 are swapped, the program will fail to compile because it expects a `send` primitive in Line 11, as indicated by the type of '`s`'. Another compile-time error occurs when a payload with the wrong type is sent. For example, attempting to send a `Data` message instead of a `GetData` in Line 11 will result in a compilation error. `MultiCrustyT` can also identify errors at runtime. If the content of the function `endpoint_data_ser`, spanning in Lines 10–12, is replaced with a single `Ok()`, the code will compile successfully. However, during runtime, the other roles will encounter failures as they consider `Ser` to have failed.

Timeouts are handled dynamically within `MultiCrustyT`. If a time-consuming task with a 10-second delay is introduced between Lines 11 and 12, `Ser` will enter a sleep state for the same duration. Consequently, the `recv` operation in Line 12 will encounter a time constraint violation, resulting in the failure and termination of `Ser`. Furthermore, the absence of clock '`a`' in the set of clocks, where it is required for a specific primitive, will trigger a runtime error, as the evaluation of time constraints depends on the availability of the necessary clocks.

Timed Protocol Specification. To specify timed multiparty protocols, we extend νSCR [42], a multiparty protocol description language, with time features, resulting in νSCR^T . Additional keywords such as `within`, `using`, and `and resetting` are incorporated in νSCR to support the specification of time windows, clocks, and resets, respectively. In Fig. 10, we illustrate the νSCR^T protocol for remote data, showcasing the application of these enhancements. νSCR^T ensures the accuracy of timed multiparty protocols by verifying interactions, validating time constraints, handling clock increments, and performing standard MPST protocol checks.

6 Evaluation: Expressiveness, Case Studies and Benchmarks

We evaluate our toolchain `MultiCrustyT` from two perspectives: *expressivity* and *feasibility*. In terms of expressivity, we implement protocols from the session type literature [20, 33, 13, 24, 21, 36], as well as newly introduced protocols derived from real-world applications [7, 38, 2, 35, 41]. Regarding feasibility, we compare our system to `MultiCrusty` [28], an untimed implementation of affine synchronous MPST, demonstrating that our tool introduces negligible compile-time and runtime overhead in all cases, as expected.

6.1 Performance: `MultiCrustyT` vs. `MultiCrusty`

When comparing `MultiCrustyT` with `MultiCrusty`, we evaluate their performance on two standard benchmark protocols: the *ring* protocol, which involves sequentially passing a message through roles, and the *mesh* protocol, where each participant sends a message to every other. Both protocols underwent 100 iterations within a time window of 0 to 10 seconds. Fig. 11 (top) displays benchmark results for roles ranging from 2 to 8.

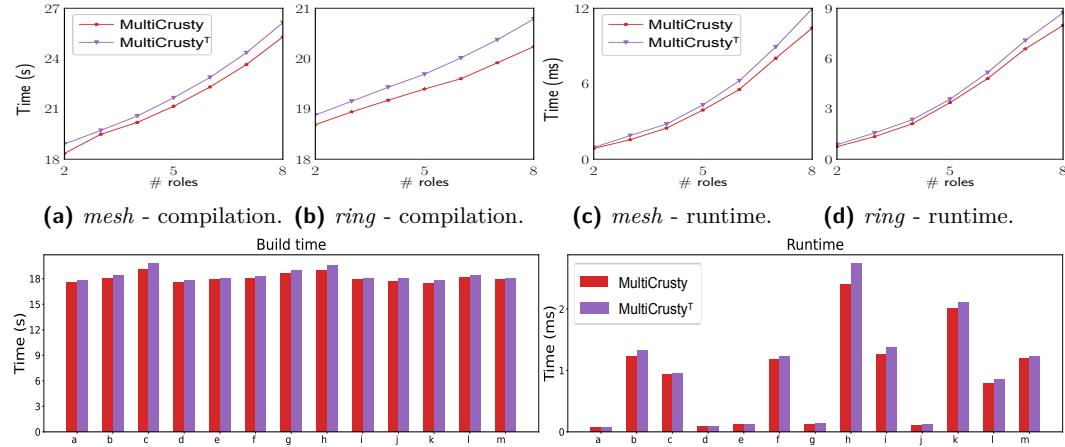

Figure 11 Top: microbenchmark results for mesh and ring protocols. Bottom: benchmark results for Calculator [20] (a), Online wallet [33] (b), SMTP [36] (c), Simple voting [20] (d), Three buyers [24] (e), Travel agency [21] (f), OAuth [33] (g), HTTP [13] (h), Remote data [7] (i), Servo [38] (j), Gravity sensor [2] (k), PineTime heart rate [35] (l), and Proximity based car key [41] (m).

In the *ring* protocol, compile-time benchmarks (Fig. 11b) indicate that *MultiCrusty^T* experiences a marginal slowdown of less than 2% with 2 roles, but achieves approximately 5% faster compilation time with 8 roles. Regarding runtime benchmarks (Fig. 11d), *MultiCrusty* demonstrates a 15% speed advantage with 2 roles, which decreases to 5% with 8 roles. The overhead remains consistent, with a difference of less than 0.5 ms at 6, 7, and 8 roles.

In the *mesh* protocol, where all roles send and receive messages (compile-time benchmarks in Fig. 11a and runtime benchmarks in Fig. 11c), *MultiCrusty^T* compiles slightly slower (less than 1% at 2 roles, 4% at 8 roles) and runs slower as well (less than 1% at 2 roles, 15% at 8 roles). Compile times for *MultiCrusty^T* range from 18.9 s to 26 s, with running times ranging between 0.9 ms and 11.9 ms. The performance gap widens exponentially with the increasing number of enforced time constraints. In summary, as the number of roles increases, *MultiCrusty^T* demonstrates a growing overhead, mainly attributed to the incorporation of additional time constraint checks.

6.2 Expressivity and Feasibility with Case Studies

We implement a variety of protocols to showcase the expressivity, feasibility, and capabilities of *MultiCrusty^T*, conducting benchmarking using both *MultiCrusty^T* and *MultiCrusty*. The `send` and `recv` operations in both libraries are ordered, directed, and involve the same set of participants. Additionally, when implemented with *MultiCrusty^T*, these operations are enriched with time constraints and reset predicates. The benchmark results for the selected case studies, including those from prior research and five additional protocols sourced from industrial use cases [7, 38, 2, 35, 41], are presented in the bottom part of Fig. 11. To ensure a fair comparison between *MultiCrusty^T* (purple) and *MultiCrusty* (red), time constraints are enforced for all examples without introducing any additional sleep or timeouts.

Note that rate-based protocols ((k), (l), (m) in Fig. 11 (bottom)) from real-time systems [2, 35, 41] are implemented in *MultiCrusty^T*, showcasing its expressivity in real-time applications. These implementations feature the establishment of consistent time constraints and a shared clock for operations with identical rates. For example, in the Car Key protocol [41], where the car periodically sends a wake-up message to probe the presence of the key, all interactions

between two wake-up signals must occur within a period of e.g. 100 ms. Consequently, when implementing this protocol with MultiCrusty^T , all time constraints are governed by a single clock ranging from 0 to 100 ms, with the clock resetting at the end of each loop.

The feasibility of our tool, MultiCrusty^T , is demonstrated in Fig. 11 (bottom). The results indicate that MultiCrusty^T incurs minimal compile-time overhead, averaging approximately 1.75%. Moreover, the runtime for each protocol remains within milliseconds, ensuring negligible impact. Notably, in the HTTP protocol, the runtime comparison percentage with MultiCrusty is 87.60%, primarily due to the integration of 126 time constraints within it. The relevant implementation metrics, including multiple participants (MP), branching, recursion (Rec), and time constraints, are illustrated in Table 2.

■ **Table 2** Metrics for protocols implemented in MultiCrusty^T .

Protocol	Generated Types	Implemented Lines of Code	MP	Branching	Rec	Time Constraints
Calculator [20]	52	51	✗	✓	✓	11

7 Related Work and Conclusion

Time in Session Types. Bocchi et al. [4] propose a timed extension of MPST to model real-time choreographic interactions, while Bocchi et al. [3] extend *binary* session types with time constraints, introducing a subtyping relation and a blocking receive primitive with timeout in their calculus. In contrast to their strategies to avoid time-related failures, as discussed in §1 and 2, ATMP focuses on actively managing failures as they occur, offering a distinct approach to handling timed communication.

Iraci et al. [22] extend *synchronous binary* session types with a periodic recursion primitive to model rate-based processes. To align their design with real-time systems, they encode time into a periodic construct, synchronised with a global clock. With *rate compatibility*, a relation that facilitates communication between processes with different periods by synthesising and verifying a common superperiod type, their approach ensures that well-typed processes remain free from rate errors during any specific period. On the contrary, ATMP integrates time constraints directly into communication through local clocks, resulting in distinct time behaviour. Intriguingly, our method of time encoding can adapt to theirs, while the opposite is not feasible. Consequently, not all the timed protocols in our paper, e.g. Fig. 1b, can be accurately represented in their system. Moreover, due to its *binary* and *synchronous* features, their theory does not directly model and ensure the properties of real distributed systems.

Le Brun et al. [30] develop a theory of multiparty session types that accounts for different failure scenarios, including message losses, delays, reordering, as well as link failures and network partitioning. Unlike ATMP, their approach does not integrate time specifications or address failures specifically related to time. Instead, they use *timeout* as a generic message label (\odot) for failure branches, which triggers the failure detection mechanism. Except for [22], all the mentioned works on session types with time are purely theoretical.

Affinity, Exceptions and Error-Handling in Session Types. Mostrous and Vasconcelos [31] propose affine binary session types with explicit cancellation, which Fowler et al. [14] extend to define Exceptional GV for binary asynchronous communication. Exceptions can be nested and handled over multiple communication actions, and their implementation is an extension of the research language LINKS. Harvey et al. [15] incorporate MPST with explicit connection actions to facilitate multiparty distributed communication, and develop a code generator based on the actor-like research language ENSEMBLE to implement their approach. The work in [31] remains theoretical, and both [31, 14] are limited to binary and linear logic-based session types. Additionally, none of these works considers time specifications or addresses the handling of time-related exceptions in their systems, which are key aspects of our work.

Session Types in Rust. MultiCrusty, extensively compared to MultiCrusty^T, is a RUST implementation based on affine MPST by Lagaillardie et al. [28]. Their approach relies on *synchronous* communication, rendering time and timeout exceptions unnecessary.

Cutner et al. [10] introduce Rumpsteak, a RUST implementation based on the `tokio` RUST library, which uses a different design for asynchronous multiparty communications compared to MultiCrusty^T, relying on the `crossbeam_channel` RUST library. The main goal of [10] is to compare the performance of Rumpsteak, mainly designed to analyse asynchronous message reordering, to existing tools such as the *k-MC* tool developed in [29]. Unlike MultiCrusty^T, Rumpsteak lacks formalisation, or handling of timed communications and failures.

Typestate is a RUST library implemented by Duarte and Ravara [12], focused on helping developers to write safer APIs using typestates and their macros `#[typestate]`, `#[automaton]` and `#[state]`. MultiCrusty^T and Typestate are fundamentally different, with Typestate creating a state machine for checking possible errors in APIs and not handling affine or timed communications. Ferrite, a RUST implementation introduced by Chen et al. [6], is limited to binary session types and forces the use of linear channels. The modelling of Ferrite is based on the shared binary session type calculus SILL_s.

Jespersen et al. [23] and Kokke [25] propose RUST implementations of binary session types for synchronous communication protocols. [22] extends the framework from [23] to encode the *rate compatibility* relation as a RUST trait and check whether two types are rate compatible. Their approach is demonstrated with examples from rate-based systems, including [2, 35, 41]. Motivated by these applications, we formalise and implement the respective timed protocols in MultiCrusty^T, showcasing the expressivity and feasibility of our system in real-time scenarios.

Conclusion and Future Work. To address time constraints and timeout exceptions in asynchronous communication, we propose *affine timed multiparty session types* (ATMP) along with the toolchain MultiCrusty^T, an implementation of ATMP in RUST. Thanks to the incorporation of affinity and failure handling mechanisms, our approach renders impractical conditions such as *wait-freedom* and *urgent receive* obsolete while ensuring communication safety, protocol conformance, and deadlock-freedom, even in the presence of (timeout) failures. Compared to a synchronous toolchain without time, MultiCrusty^T exhibits negligible overhead in various complex examples including those from real-time systems, while enabling the verification of time constraints under asynchronous communication. As future work, we plan to explore automatic recovery from errors and timeouts instead of simply terminating processes, which will involve extending the analysis of communication causality to timed global types and incorporating reversibility mechanisms into our system.

Abstract

Improving compilation time in optimizing compilers is challenging due to their large number of interconnected components. This includes compiler optimizations, compiler tiers, heuristics, and profiling information. Despite this complexity, research in compilation-time optimization is often guided by analyzing metrics of entire program runs, such as the total compilation time and overall memory footprint. This coarse-grained perspective hides relevant information, such as source program functions for which the compiler allocates a lot of memory or compiler optimizations with a high impact on the total compilation time. This leaves high-level metrics as the only reference point for driving optimization design. Consequently, compilation-time regressions in one program function that are obscured by improvements in other functions stay undetected, while the impacts of compiler changes on untouched parts of the compiler are mainly unknown. Furthermore, developers overlook long-standing compiler defects because their high-level metrics do not change over time.

To address these limitations, we propose ICON, a new data-driven approach to compilation-time optimization that breaks up high-level metrics into individual source program functions, compiler optimizations, or even into individual instructions in the compiler source code. Our methodology enables an iterative in-depth compilation-time analysis, focusing on outliers to identify optimization opportunities. We show that outliers, both in terms of time spent in a particular compiler optimization, and in terms of individual compilations that take substantially longer, can reveal potential problems in the compiler implementation. We applied our approach to GraalVM and extracted data for multiple of its language runtimes. We analyzed the resulting data, present the first detailed look into the distribution of compilation time in the GraalVM compiler, a state-of-the-art multi-language compiler, and identified defects that led to regressions in overall compilation time or the compilation time of specific languages. We furthermore designed two optimizations based on the identified outliers that improve compilation time between 2.25% and 9.45%. We believe that our approach can guide compiler developers in finding usually overlooked optimization potential and defects, and focus future research efforts in making compilers more efficient.

(a) Results of a hypothetical benchmark measuring total compilation time over the course of several commits. Lower is better.

(b) Results split into individual function compilation times over the course of several commits. Lower is better.

1 Introduction

Improving compilation time in optimizing compilers is challenging due to their large number of interconnected components. Multiple interacting compiler optimizations [24], several compiler tiers, various heuristics, and different profiling information make it challenging to identify the impact of compiler source code changes on the total compilation time of a program. Compilation time should be minimal, especially in modern cloud applications based on serverless functions or microservice architectures that are executed on demand and started frequently [42, 34]. The compilation time for these services is even more relevant for runtimes using just-in-time compilation, where the compilation time directly impacts the startup time of a service [46]. In these runtimes, savings in compilation time are not limited to a single compilation upfront but are reapplied every time an application is started and recompiled. Ahead-of-time-compiled runtimes should also strive for minimal compilation time such as in continuous integration and continuous delivery infrastructures, where compilations take up a large portion of the resource utilization as part of build steps [3].

Despite the high complexity of optimizing compilers and a high demand for fast compilation, research in this field often relies on metrics reflecting entire program runs, such as total compilation time or overall memory footprint, to guide compilation-time optimization. Using fine-grained metrics, such as the time spent compiling individual program functions or the time spent in specific compiler optimizations, could reveal outliers in compilation time that lead to defects and optimization opportunities in the compiler.

To illustrate this problem, consider the hypothetical implementation of a new compiler phase p that introduces an optimization to a compiler. To evaluate the compilation-time impact of p , the conventional approach of analyzing the total compilation time of several benchmarks and comparing it with previous records seems appropriate. As shown in Figure 1a, which illustrates the total compilation time of a hypothetical benchmark over the course of several commits, p , implemented in 9f1, leads to a compilation-time decrease, leaving the impression of a positive compilation-time impact. While this impression seems correct overall, it hides valuable information which is only unveiled by analyzing the compilation time of individual benchmark functions. As shown in Figure 1b, p improves the compilation time of nearly all functions in the benchmark but also results in an outlier with a significant increase in compilation time, the `fft` function. This outlier points towards a defect in p that only occurs under certain conditions, which seem to be present in the `fft` function, and requires further investigation. Consequently, relying solely on metrics of entire program runs to evaluate compilation-time performance can obscure newly-introduced or long-standing defects in compiler implementations.

Therefore, our contribution is to describe a new approach to compiler optimization focusing on outliers to identify defects:

- We describe *Iterative Compilation-time optimization through Outlier-driven Narrowing* (ICON), a novel data-driven approach to compilation-time optimization that splits compilation metrics into individual functions, compiler optimizations, or even into individual instructions in the compiler source code to identify potential problems in compiler implementations by focusing on the outliers in extracted data (Section 3). The approach combines a fine-grained metrics extraction based on iterative narrowing with an outlier-focused approach to finding potential optimization opportunities.
- We present the first detailed look into the distribution of compilation time in the GraalVM compiler, a state-of-the-art multi-language compiler (Section 4). We base our data on the evaluation of 94 benchmarks from the “Are We Fast Yet?”¹ [27], JetStream 2², “Computer Language Benchmark Game,”³ [27] and several internal benchmark suites, analyzing compilation-time metrics for five runtimes, including Python and JavaScript.
- To demonstrate the effectiveness of the ICON approach, we conducted an outlier analysis on the GraalVM compilation-time metrics, identifying one language-agnostic and three language-specific outliers in compilation time (Section 4.5). Through the iterative application of our approach, we narrowed the scopes of the outliers in the compiler and discovered four defects in the GraalVM compiler that were responsible for sub-optimal compilation time in compiler optimizations.
- We sketch the design of two optimizations that target two of the defects identified by our outlier analysis and improve compilation time between 2.25% in Python and 9.45% in Java (Section 5).

2 The Environment of Our Study

We describe ICON as a general methodology to optimize the compilation time of compilers and apply it to a specific runtime environment to emphasize its applicability. We thus begin our technical content by describing GraalVM, the runtime we worked with.

2.1 GraalVM

GraalVM [45] is a state-of-the-art high-performance Java Virtual Machine (JVM) [26] that includes a dynamic optimizing compiler called *GraalVM compiler*. GraalVM provides native support for JVM languages, is implemented in Java [17], and supports just-in-time (JIT) and ahead-of-time (AOT) compilation through the *JVM* [45] and *Native-Image* [42] deployments. The JVM deployment starts programs in the Java interpreter and just-in-time compiles frequently executed methods with the GraalVM compiler, while the Native-Image deployment compiles Java code ahead of time into a native executable, skipping interpretation and compilation of Java code at run time.

In addition to JVM languages, GraalVM supports the execution of guest languages by defining interpreters written with the *Truffle framework* [21]. Truffle is an abstraction layer in GraalVM that provides a domain-specific language API based on Java annotations. It allows to define interpreters and uses *partial evaluation* [44, 15, 9, 28] to transform these interpreters into an intermediate representation that can be further optimized by the GraalVM compiler.

¹ <https://github.com/smarr/are-we-fast-yet>

² <https://browserbench.org/JetStream/in-depth.html>

³ <https://benchmarksgame-team.pages.debian.net/benchmarksgame/index.html>

Partial evaluation must be performed at run time in both GraalVM deployments since it requires the input programs of guest language interpreters, which are not known ahead of time. Therefore, in the context of the Truffle framework, both GraalVM deployments support JIT compilation of partially-evaluated guest language interpreters. Consequently, in the Native-Image deployment of a guest language, the interpreter and runtime are AOT compiled, while the user code written in that guest language is still JIT compiled.

Through Truffle and partial evaluation, GraalVM provides official support for seven language runtimes with competitive performance [36, 37] for popular languages such as Python⁴, JavaScript⁵, C/C++ and others via LLVM bitcode⁶ [33], WebAssembly⁷, R⁸, Ruby⁹, and a meta-circular Java runtime called Espresso¹⁰. Apart from implementing different language specifications, these runtimes primarily differ in their internal data structures and interpreter implementations, including abstract-syntax-tree (AST) interpreters, bytecode interpreters, and hybrid approaches that combine aspects of AST and bytecode interpreters.

Our paper focuses on guest language runtimes using Truffle and partial evaluation in the Native-Image deployment of GraalVM. Therefore, the rest of this paper will refer to the Native-Image deployment when talking about GraalVM, the GraalVM compiler, or the Truffle language runtimes.

2.2 GraalVM Compiler

The *GraalVM compiler* [45] is a dynamic optimizing compiler used by GraalVM to compile multiple languages to highly optimized machine code. It contains numerous optimizations that apply platform-specific and platform-independent optimizations [13] and extensively uses *speculative optimizations* [11] based on *assumptions* [38]. If one of the assumptions no longer holds, the GraalVM compiler invalidates the generated machine code and transfers the execution back to the interpreter [38] through *deoptimization* [19].

In the context of guest language interpreters written with Truffle, GraalVM uses the GraalVM compiler as a just-in-time compiler to partially evaluate and compile guest language functions at run time [44]. For this purpose, the GraalVM compiler uses two different configurations called compiler tiers¹¹ [18]. Tier 1 focuses on compilation time and applies fewer short-running optimizations. Tier 2 focuses on optimal machine code and applies all optimizations available in the GraalVM compiler.

The GraalVM compiler’s architecture consists of a *front end*, performing platform-independent compiler optimizations on a high-level intermediate representation (IR) called *GraalIR* [11, 10], and a *back end*, performing register allocation and code generation on a low-level IR called *LIR* [13, 41, 23]. The front end further consists of a *high tier*, *mid tier*, and *low tier*, performing optimizations on different abstraction levels. When compiling guest language functions, the *truffle tier*, performing partial evaluation, precedes the front end.

```

1 TimerKey timer = DebugContext.timer("Timer");
2 CounterKey counter = DebugContext.counter("Counter");
3
4 void run(Graph graph) {
5     DebugContext debug = graph.getDebugContext();
6     try (DebugContext.Scope scope = debug.scope("Phase")) {
7         DebugCloseable t = timer.start(debug) {
8             ...
9             counter.increment(debug);
10            ...
11        }
12    }

```

2.3 GraalVM Compiler Debug Interface

The *GraalVM compiler debug interface*¹² in the GraalVM compiler enables logging, IR dumping, and the extraction of compilation-time metrics, such as the execution time of the compiler front end, the number of allocated bytes in the compiler mid tier, or the number of generated `mov` instructions during register allocation. The debug interface provides *timers*, for tracking execution time, *memory usage trackers*, for tracking memory usage (i.e., the number of allocated bytes), and *counters*, to keep track of arbitrary counts. This allows developers to get different metric values for parts of the compiler. Developers assign unique names to these metric values and define their measurement scopes with one or several *keys*. Keys allow combining measurements of several compiler regions into one metric value and are combined based on their name. For example, if a compiler performs parts of the same transformation in two different compiler locations and we want to measure the total time of this transformation, we can use two keys with the same name to combine both scopes into the same metric value. A *debug context* stores instances of each metric value. Debug contexts exist once per compilation, and the compiler passes them through all phases. This design enables a per-compilation extraction of metric values.

The debug interface provides *scopes* to enable the logical grouping of keys. Scopes have names and can be nested into one another. The debug context contains helper methods to open scopes while the closing is performed automatically with *try-with-resource* statements, as shown in line 6 of Listing 1. Scopes, timer keys, and memory usage trackers use this automatic closing mechanism, while counter keys need to be manually incremented by the developer, as shown in line 9.

Listing 1 provides an example for the use of the debug interface. When a developer creates a timer key with the help of the `DebugContext` class, as shown in line 1, the call to `timer()` allocates a new key object (`TimerKey`) and links it to a metric value based on the provided name. When the runtime starts the timer in line 7, the key object forwards the name of its metric value to the debug context, which initializes the timer value. After the runtime exits the `try` block in line 11, the timer stops and updates its value in the debug context. At the end of the compilation, the compiler extracts the metric values of all debug contexts and exports them to the console or a file.

¹²<https://github.com/oracle/graal/blob/master/compiler/docs/Debugging.md>

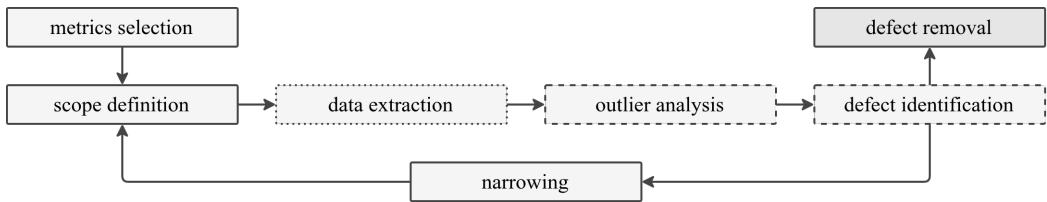

Figure 2 Abstract representation of ICON, consisting of three main phases represented by different border styles.

The GraalVM compiler provides a `Timers` option alongside counterparts for memory usage and counters to enable the extraction of specific metrics. Developers pass these options to the compiler at program startup, which enable metric values based on their name or the name of an enclosing scope. If a key is disabled, the compiler does not extract data for the associated metric value.

3 ICON: Iterative Compilation-Time Optimization Through Outlier-Driven Narrowing

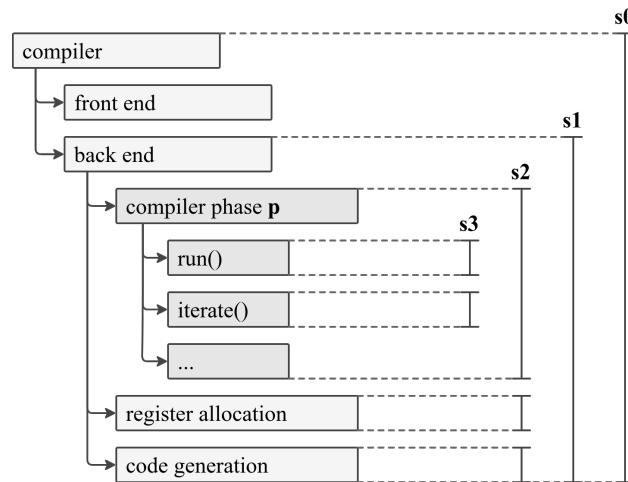

We propose ICON, a new data-driven approach to compilation-time optimization, a methodology focusing on outliers to identify potential problems in compiler implementations. The key idea of ICON is to split up high-level metrics, such as total compilation time or overall memory footprint, into individual *extraction scopes*, such as compiler optimizations, compilations of individual functions, or even into individual instruction in the compiler source code. ICON tries to find defect locations by iteratively narrowing extraction scopes until developers can identify the source of a problem. An outlier analysis after every iteration drives the narrowing process and identifies which extraction scopes to refine. Figure 2 shows an abstract depiction of ICON.

ICON consists of three steps, including the *metric and benchmark selection step* (solid border), the *data extraction step* (dotted border), and the *outlier analysis and defect identification step* (dashed border). To explain the methodology process depicted in Figure 2, consider the hypothetical implementation of a compiler phase p in the compiler back end of an existing compiler. Figure 3 shows a fragment of the resulting compiler architecture.

For the performance evaluation of p , the initial step of ICON is to pick representative benchmarks and metrics, such as compilation time or allocated memory, and to select an initial set of extraction scopes for the first iteration. In our example, the entire compilation pipeline represents a good starting point, as shown by scope s_0 in Figure 3. After applying the compiler code changes and enabling the relevant timers and counters, the next step is to extract a data set based on the selected extraction scopes with the help of the benchmarks. An outlier analysis follows the data extraction to identify outlier compilations via statistical analyses. This outlier analysis results either in a concrete source code location responsible for the outliers or at least in a direction to narrow the selected extraction scopes.

If the outlier analysis points in a new direction for the next iteration, the next step is to select a new set of extraction scopes that narrow the existing ones and to repeat the extraction and analysis process. In our example, a meaningful narrowing is extracting data for the compiler back end, as shown by scope s_1 in Figure 3.

If the data set of the next iteration contains evidence for the previous outliers, the process continues by refining the extraction scopes. Otherwise, the process continues at the previous iteration by narrowing the existing extraction scopes differently. Consequently, since we

■ **Figure 3** Fragment of a compiler pipeline structure after introducing a new compiler phase p.

assume that the narrowing in our example succeeded, the process continues with extraction scopes **s2** searching for outliers in individual compiler phases, including **p**, and scopes **s3**, searching for outliers in individual compiler functions in **p**.

Extraction scopes can theoretically be narrowed down to individual instructions in the compiler source code. The process ends when developers have a clear enough view about the defect locations responsible for the outliers or cannot find any outliers in the data.

While the outlier analysis is essential to ICON, we do not specify a concrete outlier-detection algorithm. Instead, methodology adopters can define concrete algorithms based on the requirements and properties of their compilers. We describe the approach we used for outlier detection in GraalVM in Section 4.4.

Although we focus on a manual inspection and outlier analysis in this paper, an automatic outlier detection and narrowing process could enhance our approach. This automation would aid in integrating our methodology into existing testing and benchmark infrastructures. However, defining such an automated process is outside the scope of our paper.

In the following, we present a detailed definition of *extraction scopes* and describe the necessary changes in GraalVM to support ICON.

3.1 Extraction Scopes

Extraction scopes define the granularity of the data extraction as tuples consisting of a *temporal* and a *spatial* component. The temporal component defines how to split or aggregate the entire execution time of the compiler into individual metric values. Examples are:

- *per execution*. This results in one metric value for the entire run time of the compiler. An example is the extraction of compilation time to compare against historical data.
- *per iteration*. This requires that the program under test executes several iterations and results in one metric value for every iteration. An example is the extraction of compilation time for every benchmark iteration to check their consistency over time.
- *per compilation unit*. This represents the usual approach to metric extraction and results in one metric value for each compilation unit. The metric values depend on the compiler's definition of compilation units (e.g., every function, every module, etc.).
- *per compiler tier*. This is a refinement of *per compilation unit* and results in one metric value per compiler tier. An example is the compilation-time extraction of a compiler phase for every compiler tier to compare the time spent in each compiler tier.

The spatial component defines how to split or aggregate the compilation pipeline (i.e., the compiler source code) into individual metric values. Examples are:

- *per pipeline*. This results in one metric value for the entire compiler pipeline. An example is the extraction of the maximum memory consumption of the compiler when running a benchmark to check that it does not exceed a predefined threshold.
- *per compiler phase*. This results in one metric value for each selected phase in the compiler pipeline. An example is the extraction of compilation time per compiler phase to find optimization potential.
- *per function*. This results in one metric value for each selected function in the compiler source code. An example is the memory-consumption extraction of all functions in a phase that allocates too much memory to find the exact allocation location.
- *per instruction*. This results in one metric value for each selected source code instruction. An example is the extraction of memory allocation for selected source code lines in the compiler.

The temporal and spatial components depend on the compiler architecture and might be linked based on the compiler’s design.

3.2 Implementation in GraalVM

GraalVM was already well fitted to support our methodology. However, in terms of data extraction, some critical parts were missing to support a fine-grained metric value extraction.

The initial implementation of the GraalVM compiler debug interface, as explained in Section 2.3, focuses primarily on the extraction of metric values on a per-name basis. Metrics are extracted for every compiler phase in the GraalVM compiler, so the metric values are associated with the names of the compiler phases. This represents a limitation, since multiple executions of the same compiler phase, which is common in the GraalVM compiler, are merged into a single metric value. An example is the *canonicalizer phase*, which transforms guest language constructs into a canonical form and is executed many times throughout a compilation. Even though these phase executions should be treated independently, the initial debug interface implementation merges their metric values.

To remove this limitation, we extended the existing concept of scopes in the GraalVM compiler debug interface to *aggregate*, *unique*, and *singleton* scopes. Aggregate scopes are similar to the existing scope implementation. As their name suggests, they combine the values produced by several scope executions into a single metric value. Unique scopes on the other hand separate the values of individual scope executions into separate metric values by assigning them a unique name. Singleton scopes ignore the nesting of previous scopes and produce a single metric value, regardless of the scopes they are nested in.

Consider the example in Listing 2. Since the timer key `a_t` in line 5 is part of an aggregate scope, all its executions will contribute to the same metric value `A.Timer`, even though the loop is executed three times. The code in line 12 however, will result in three individual metric values `U_1.Timer`, `U_2.Timer`, and `U_3.Timer`, since the timer key `u_t` is inside a unique scope. Although timer keys `s_t` in lines 7 and 14 are nested in the different outer scopes `A` and `U`, all their executions contribute to the same metric value `S.Timer`, since their nearest nesting scope is a singleton scope.

As a result of using these new scope types, it is possible to extract metric values independently for multiple executions of the same compiler phase. This allows a more precise analysis of the time spent in individual compiler phases and supports the fine-grained metric value extraction required for ICON.

Listing 2 Definition of aggregate, unique, and singleton scopes inside a loop.

```

1 void run (Graph graph) {
2     DebugContext debug = graph.getDebugContext();
3     for (int i = 0; i < 3; i++) {
4         try (DebugContext.Scope a = debug.aggregateScope("A");
5              TimerKey a_t = a.timer("Timer").start(debug)) {
6             try (DebugContext.Scope s = debug.singletonScope("S");
7                  TimerKey s_t = s.timer("Timer").start(debug)) {
8                 ...
9             }
10        }
11        try (DebugContext.Scope u = debug.uniqueScope("U");
12             TimerKey u_t = u.timer("Timer").start(debug)) {
13            try (DebugContext.Scope s = debug.singletonScope("S");
14                 TimerKey s_t = s.timer("Timer").start(debug)) {
15                 ...
16             }
17        }
18        ...

```

4 GraalVM Compilation-Time Evaluation

Based on ICON introduced in Section 3, we extracted compiler metrics for the GraalVM compiler. While our approach primarily focuses on finding defects in compiler implementations, its implementation in GraalVM also enables a detailed view of the distribution of compiler metrics across different compiler phases in the GraalVM compiler. We extracted compilation time and memory usage for all compiler phases based on a large set of benchmarks. In the context of this paper, we will focus on the evaluation of compilation time. The extracted data contains metric values for five partial-evaluation-based language runtimes on GraalVM and allows us to present the first detailed look into the distribution of compilation time across compilation phases in GraalVM. This distribution represents a good starting point for our evaluation and drives the narrowing required for the outlier analysis in Section 4.5.

We start this section by introducing the set of language runtimes we chose to get a representative data set of compilation-time metrics, then proceed by describing the used benchmarks and setup. We conclude by explaining the data extraction process, presenting our results, and performing an outlier analysis on the data.

4.1 Languages

We chose a set of five language runtimes based on the Truffle framework to get a representative data set of the compilation-time distribution in partial-evaluation-based languages compiled by the GraalVM compiler. The runtimes differ in their interpreter implementation and the type system of their implemented languages. Both impact the compilation-time distribution in the GraalVM compiler. Based on the available interpreter implementations and type systems, we chose GraalJS¹³, GraalPy¹⁴, Espresso¹⁵, GraalWasm¹⁶, and the GraalVM LLVM Runtime¹⁷, as further described in Table 1.

¹³ <https://github.com/oracle/graaljs>

¹⁴ <https://github.com/oracle/graalpython>

¹⁵ <https://github.com/oracle/graal/tree/master/espresso>

¹⁶ <https://github.com/oracle/graal/tree/master/wasm>

¹⁷ <https://github.com/oracle/graal/tree/sulong> [33]

 **Table 1** GraalVM language runtimes used for the extraction of compilation-time data.

Runtime	Language	Type system	Interpreter
GRAALJS	JavaScript	dynamic, weak typing	AST interpreter
GRAALPY	Python	dynamic, strong typing	bytecode interpreter
ESPRESSO	Java	static, strong typing	bytecode interpreter
GRAALWASM	WebAssembly	static, strong typing	bytecode interpreter
GRAALVM LLVM RUNTIME	LLVM bitcode	static, strong typing	hybrid interpreter (combines aspects of AST and bytecode interpreters)

4.2 Benchmarks and Setup

We used a set of 94 benchmarks from the “Are We Fast Yet?”¹⁸ [27], JetStream 2¹⁹, “Computer Language Benchmark Game,”²⁰ and several internal benchmark suites for our evaluation. The benchmarks represent real-world computing tasks and are already used internally by different GraalVM language teams to evaluate peak performance, interpreter speed, and memory usage of their language runtimes.

We used “Are We Fast Yet?” for evaluating Espresso, the Java runtime implemented in Truffle. It contains 14 benchmarks focusing on several computing areas, such as JSON string parsing, the computation of the Mandelbrot set, and physics simulations [27].

We used JetStream 2 for evaluating GraalJS and executed 15 of the 64 available benchmarks. These focus on cryptography, physics simulations, or PDF processing. Most excluded benchmarks require browser-specific functionality unavailable in standalone JavaScript engines or WebAssembly support. Since we measured our WebAssembly runtime separately, we did not want to pollute GraalJS results with WebAssembly compilations.

We used the “Computer Language Benchmark Game” [27] benchmarks in combination with other open source benchmarks (*bzip2*²¹, *gzip*²², *stockfish*²³, *oggenc*²⁴) to evaluate GraalPy, the Python runtime, and the GraalVM LLVM runtime. Based on the language runtime, we selected a subset of the available benchmarks used by the respective GraalVM language teams²⁵. Consequently, we used 34 benchmarks for evaluating GraalPy, and 18 for the GraalVM LLVM runtime. The benchmarks include compression algorithms, chess simulations, physics simulations, and scheduling tasks. We compiled the GraalVM-LLVM-runtime benchmarks with a custom LLVM toolchain²⁶ based on the *Clang*²⁷ compiler 16.0.1.

For evaluating GraalWasm, we used an internal benchmark suite consisting of 13 benchmarks. These include the DIGITRON benchmark, an AST interpreter for arithmetic expressions, the FFT [4] benchmark, computing the Fast Fourier transform, and the PHONG [31]

²⁶ <https://github.com/oracle/graal/blob/master/sulong/docs/contributor/TOOLCHAIN.md>

²⁷ <https://clang.llvm.org/>

benchmark, computing a shading model for a 3D scene. All of them are written in C and compiled with the *WASI SDK*²⁸ version 21.0 based on the *Clang* compiler version 17.0.0. The benchmark source code is publicly available as part of the GraalWasm repository²⁹.

We executed all benchmarks on the Community Edition (CE) and the Enterprise Edition (EE) of GraalVM. We conducted the execution on an Intel Core i7-8750H with six cores at a fixed CPU frequency of 2.30 GHz and turbo boost disabled. The system has 32GB of main memory and runs Fedora Linux 38 (Workstation Edition).

We compiled all runtimes with *LabsJDK CE 21*³⁰ (`labsjdk-ce-21-jvmci-23.1-b22`). The GraalVM compiler performs individual compilations in separate threads with a separate memory space. We used sufficient iterations to ensure that the GraalVM compiler compiled all relevant functions in each benchmark and ran each benchmark 6 times in separate processes. We used geometric means across all 6 runs to account for measurement inaccuracies due to garbage collection and non-deterministic optimization phases. The resulting numbers represent the evaluation of the Native-Image deployment of GraalVM CE and EE.

4.3 Data Extraction

We surrounded the `run` method, the entry point of each compiler phase, of all compiler phases in the GraalVM compiler with a unique scope, as introduced in Section 3.2, to extract compilation-time data. This implementation allows us to get an individual metric value per phase execution. We put *method inlining* and the *graph decoding* performed during partial evaluation into aggregate scopes since we are not interested in inlining and decoding metrics of individual functions but in their overall impact.

For our evaluation, we extracted the compilation time of every extraction scope in microseconds and computed the compilation time relative to the total compilation time. This normalization is necessary to account for the skewness of the raw data caused by the overrepresentation of short-running compilations in the data set. We extracted metric values for all compilations in our benchmarks and used the compilations of those source program functions that appeared in at least 3 of the 6 benchmark runs to compute the total compilation time for our evaluation. This preselection is necessary to avoid polluting the data with one-time compilations that might represent outliers due to garbage collection pauses or other non-deterministic influences happening exactly during this one compilation.

4.4 Evaluation

We start our evaluation with a high-level overview of the compilation-time distribution in GraalVM. The selected extraction scopes reflect the GraalVM compiler architecture and consist of *partial evaluation*, *compilation*, and *code installation*. We further divide the compilation into a *front end* and *back end*, and the front end into *high tier*, *mid tier*, and *low tier*. We chose the selected granularity to keep the resulting plots clear and readable. In the context of our plots, we define *total compilation time* as the sum of partial evaluation, compilation, and code installation.

²⁸ <https://github.com/WebAssembly/wasi-sdk>

²⁹ <https://github.com/oracle/graal/tree/master/wasm/src/org.graalvm.wasm.benchcases/src/bench>

³⁰ <https://github.com/graalvm/labs-openjdk-21>

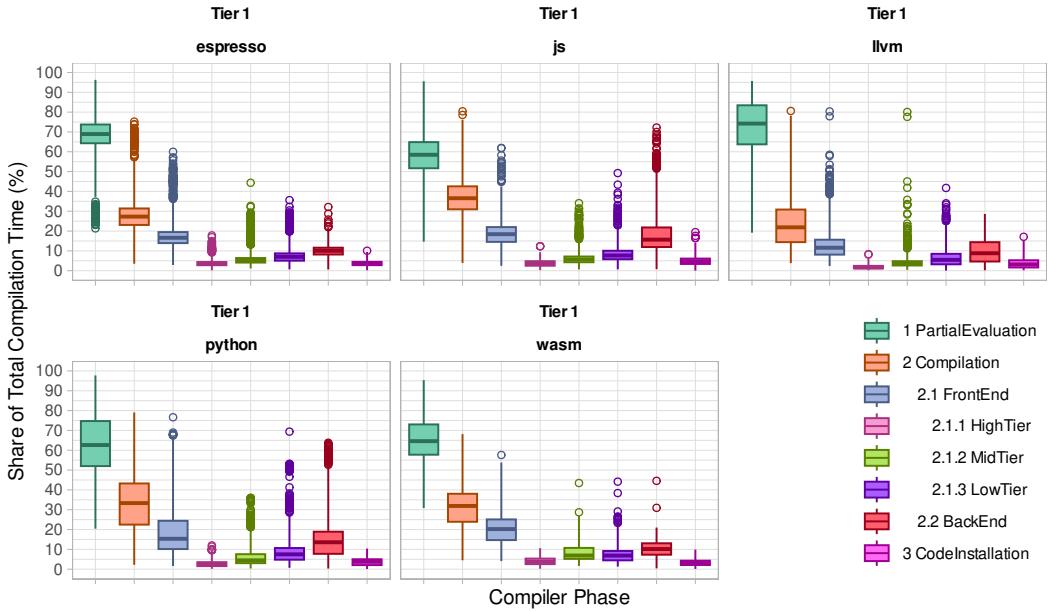

Figure 4 Compilation-time distribution of Tier-1 compilations in GraalVM CE and EE. Compiler phases are from left to right based on their index.

We show the results of the first extraction step in Figure 4, showing the compilation-time distribution of Tier-1 compilations in GraalVM CE and EE. Since their configuration is identical in Tier 1, we combined both editions into a single plot. Figure 5 shows GraalVM-CE Tier-2 compilations, and Figure 6 shows GraalVM-EE Tier 2. The plots show the selected extraction scopes from left to right based on their execution point in the compilations.

Figure 4 shows that partial evaluation has the highest impact on the total compilation time in Tier-1 compilations, with a median between 58.5% and 72.7%. It is also apparent that the median front-end time, in the range of 11.60% to 20.20%, is higher than the back-end time, 8.81% to 15.70%, while the average low-tier time, 5.46% to 7.49%, is higher than the high-tier, 1.66% to 3.79%, and mid-tier times, 3.41% to 6.90%.

Figure 5 shows that the difference in average time between front end and back end is larger in Tier-2 compilations, 7.88%pt (percentage points) to 15.10%pt, than in Tier 1, 1.70%pt to 10.05%pt. This observation seems reasonable since the back-end compiler phases are nearly identical in Tier-1 and Tier-2 compilations, whereas the GraalVM compiler applies additional, longer-running optimization phases in the front end of Tier 2. We verified this conclusion based on absolute numbers to make sure the back-end time stays consistent while the front-end time increases. The only exception is WebAssembly, where the difference between front end and back end is larger in Tier 1 (10.05%pt) than in Tier-2 CE (7.83%pt).

The difference between Tier-1 and Tier-2 front-end and back-end times becomes even more apparent in Figure 6, since Tier-2 EE, with differences in the range of 22.36%pt to 29.11%pt, has additional optimization phases compared to Tier-2 CE. Furthermore, compilation takes an equal amount of time or longer than partial evaluation in Python, with 48.71% and 49.19%, and JavaScript, 50.27% and 46.33%. This can again be explained by the increase in front-end time.

We try to identify possible outliers that require further investigation based on the extracted data. We define *outliers* based on the *interquartile range method* [16] and focus on *extreme* outliers that are more than 3 interquartile ranges (IQR) away from the first (Q1) and third quantile (Q3). We represent outliers in the plots by circles above and below the boxplots.

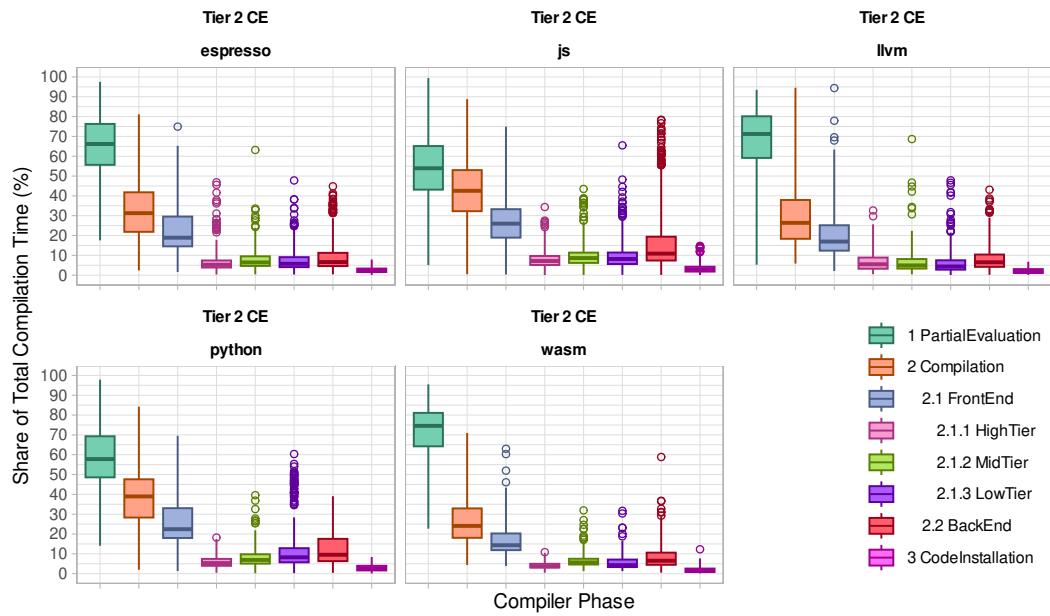

Figure 5 Compilation-time distribution of Tier-2 compilations in GraalVM CE. Compiler phases are from left to right based on their index.

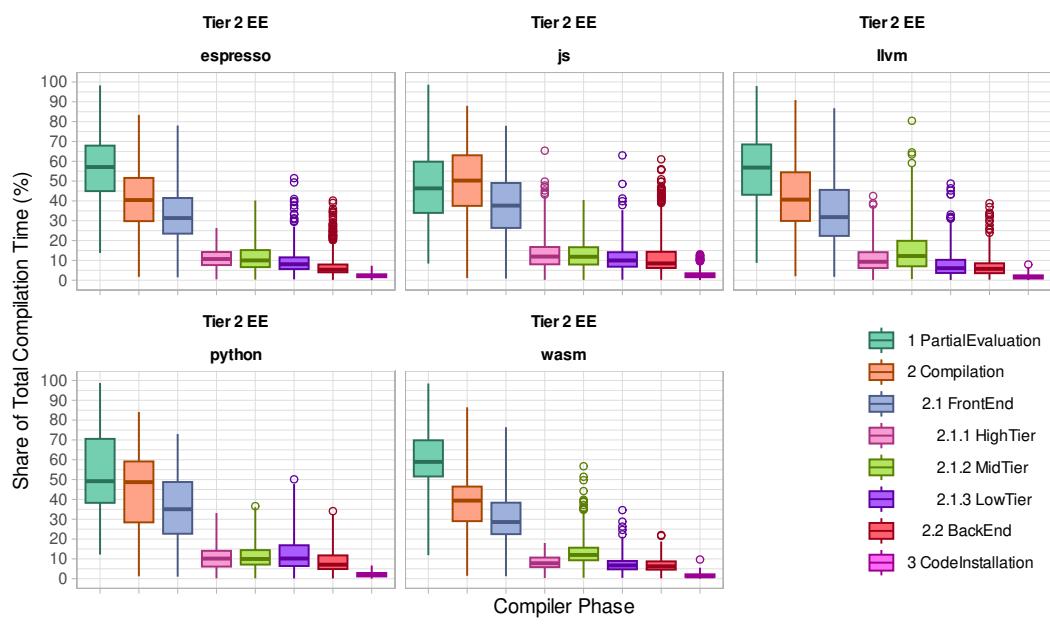

Figure 6 Compilation-time distribution of Tier-2 compilations in GraalVM EE. Compiler phases are from left to right based on their index.

All three data sets contain many outliers within individual extraction scopes. For example, Espresso and JavaScript contain a lot of outliers in all extraction scopes of Tier-1 compilations, while the GraalVM LLVM runtime shows significant outliers in the mid tier. In Tier-2 compilations, JavaScript presents significant outliers in the back end, while Python contains several outliers in the low tier of CE compilations. The GraalVM-LLVM-runtime outliers found in the mid tier of Tier-1 compilations are also found in Tier 2.

Analyzing all outliers in all data sets would be possible. However, we will focus on the most significant outliers to identify defects and optimizations with a high impact potential. To select the relevant outliers, we prioritize them based on their distance from Q_1 or Q_3 in terms of multiples of the IQR and look into extraction scopes with a high outlier density.

Consequently, we will analyze the outliers in the mid tier of GraalVM-LLVM-runtime compilations. Especially the outliers in Tier-1 compilations have a distance of more than $30IQR$ from Q_3 . The outliers are consistent throughout all editions and compiler tiers and are responsible for up to 80% of the total compilation time in Tier 1 and Tier-2 EE.

Furthermore, we will analyze the back end of JavaScript compilations. This extraction scope shows a high outlier density throughout all editions and compiler tiers. The same applies to the low tier of Python Tier 1 and Tier-2 CE compilations.

Although it is hard to quantify partial evaluation as an outlier, it is apparent from a visual analysis of the plots in Figures 4 to 6 that partial evaluation takes up a significant part of the total compilation time in all compiler editions and tiers. Therefore, in addition to our outlier analyses, we show the applicability of our methodology for finding optimizations in existing compiler phases by analyzing partial evaluation in all guest language runtimes.

4.5 Outlier Analysis

We perform an outlier analysis based on the possible defects identified during the evaluation of the GraalVM compilation time in Section 4.4. We verify the defects and identify their source code locations. In addition, we show that our approach can find optimization locations in compilers by focusing on long-running extraction scopes.

4.5.1 Mid Tier in the GraalVM LLVM Runtime

We first analyzed the outliers in the GraalVM-LLVM-runtime mid tier and identified the benchmark functions responsible for the outliers to find a possible defect in the compilations. The outliers were two functions in the *bzip2* and *oggenc* benchmarks that did not show any suspicious characteristics in the C source code. Next, we refined our extraction scopes from a top-level view of the mid tier to individual compiler phases. Figure 7 shows the result of the narrowed extraction scopes of Tier-1 compilations. The figure shows that the *frame-state-assignment phase* has a lot of outliers and the previously identified functions indeed spend nearly all of their mid-tier time in the frame-state-assignment phase of Tier-1 compilations. We also verified that the frame-state-assignment phase is the defect source in Tier-2 compilations (omitted from the paper).

Frame states are a mapping from machine state (i.e., registers and native stack frames) to interpreter state (i.e., JVM stack frames) and are required by GraalVM during deoptimizations to regenerate the interpreter state of a program [11, 12]. During partial evaluation, the GraalVM compiler generates a *frame-state* node for every operation that changes the local state of a method (local variables, operand stack values, and locked objects) and attaches it to the node in the GraalIR graph that causes this change. Subsequent compiler optimization phases might also introduce new nodes, and therefore new frame states. When entering

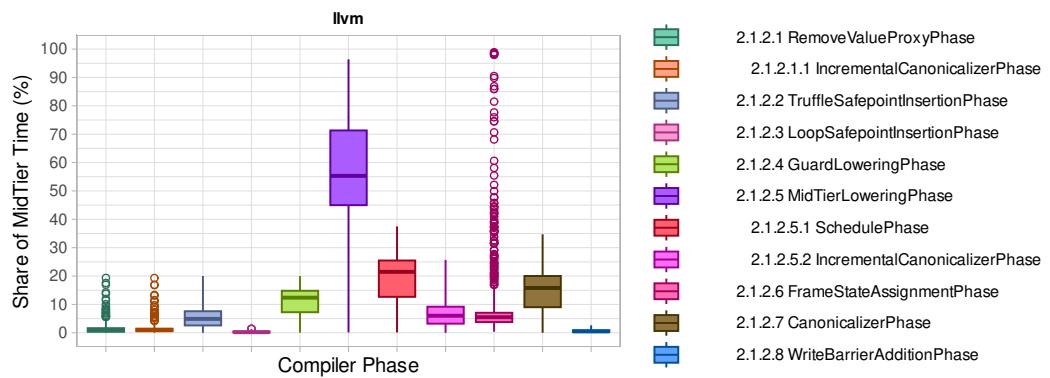

Figure 7 Compilation-time distribution of the mid tier in Tier-1 compilations. Compiler phases are from left to right based on their index.

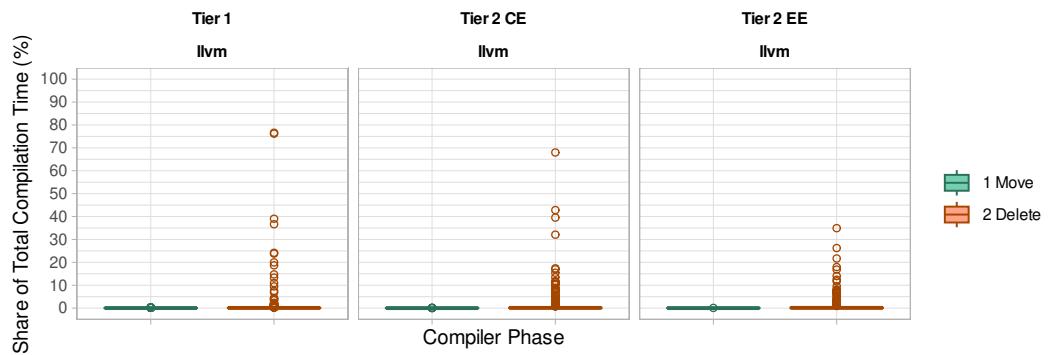

Figure 8 Compilation-time distribution of the two frame-state-assignment phase parts Move and Delete. Compiler phases are from left to right based on their index.

the frame-state-assignment phase, the graph is stable and no more nodes that may cause deoptimizations can be introduced in later compiler phases. Since the frame states are only required by deoptimizations, the frame-state-assignment phase moves the frame states from their originating nodes to deoptimization nodes at deoptimization points in the graph and removes unused frame states.

To further narrow the defect location, we introduced individual timers for the two source code method calls (*Move* and *Delete*) in the `run` method of the frame-state-assignment phase. The *Move* method moves existing frame-state nodes, while the *Delete* method deletes unused frame-state nodes. Figure 8 shows the result of this last narrowing step. The values of these last extraction scopes are relative to the total compilation time. The figure shows that the deletion of unused frame-state nodes is responsible for the outliers and should be optimized, as described in Section 5.1.

4.5.2 Back End in JavaScript

We analyzed the outliers in the JavaScript back end and identified that all functions responsible for the outliers are part of the *typescript* benchmark, which compiles a large TypeScript application to JavaScript. The benchmark uses the identified functions to walk the AST of the TypeScript application. The functions themselves are small and call each other recursively. As a result of these recursive calls, the GraalVM compiler can perform a lot of inlining.

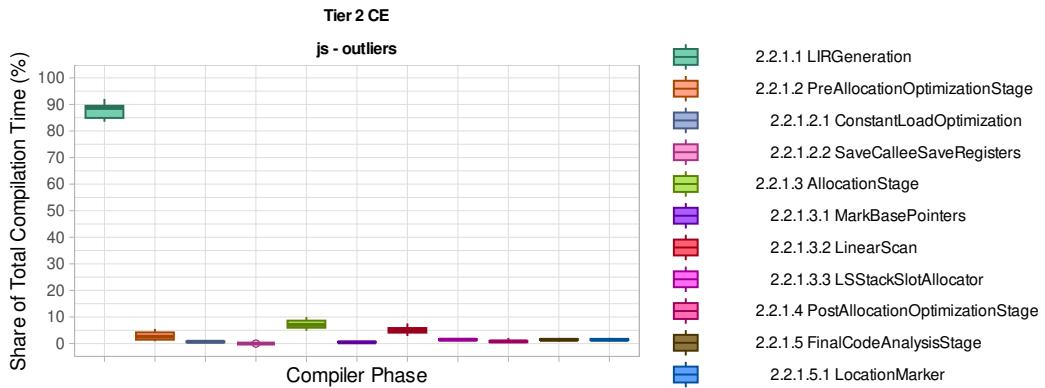

Figure 9 Compilation-time distribution of the back end in Tier-2 CE compilations. Compiler phases are from left to right based on their index.

We narrowed the extraction scopes to individual compiler phases in the back end and found that the identified functions on average spend 87% of their Tier-2 CE back-end time in *LIR generation*, as shown in Figure 9. Tier-1 (60%) and Tier-2 EE (82%) compilations produced similar numbers. The LIR-generation phase transforms high-level GraalIR nodes into low-level LIR nodes by iterating over the GraalIR graph and transforming each node.

We found out that the outlier functions spend most of their time transforming nodes that generate a *LIR frame state* during LIR generation. The LIR frame states represent garbage collection and deoptimization information and the GraalVM compiler computes them based on the frame-state nodes in the GraalIR graph by iterating over all values in the frame state and all its parent frame states and transforming the GraalIR representation of the frame-state values into LIR representations. A frame state has a parent frame state if its method was inlined into another method. The parent frame state represents the frame state of the method into which this method was inlined. We confirmed that the outlier functions had a lot of frame states as a result of inlining and, through a last narrowing step, confirmed that the identified outliers spend most of their time generating LIR frame states.

Optimizing this pattern would require significant changes in the compiler architecture which was not in the scope of this paper. We reported our findings to the GraalVM compiler team for further investigation.

4.5.3 Low Tier in Python

We analyzed the outliers in the Python low tier and found out that all outliers are instances of the same function in all benchmarks, the *time* function in the Python *time* module³¹. This function is built into GraalPy and returns the current time in seconds. The benchmarks use this function to measure execution time.

We narrowed the extraction scopes to individual compiler phases in the low tier and found that the identified functions spend more than 95% of the low-tier time in the *low-tier-lowering phase*. Lowering transforms nodes on a higher abstraction level to node structures on a lower abstraction level. For example, a *load-field* node, accessing a field on an object, is lowered to a *read* node, reading a value from an address in memory.

³¹ <https://docs.python.org/3/library/time.html#time.time>

We also extracted the node count for the graph of the *time* function and found that it is a small graph with only 157 nodes. We narrowed the extraction scopes to the lowering of individual node types and found that four individual nodes were responsible for the time spent in lowering. These were two *exception-object* nodes, one *truffle-safepoint* node, and one *new-instance* node. The commonality between these nodes is that they are all lowered with the help of *snippets* [35]. The GraalVM compiler creates these snippets the first time they are used and caches them based on their compilation unit. This implies an initial overhead that is, in most cases, amortized by several usages of the cached snippets. However, since the graphs for the *time* functions only contain one or two of the snippet-lowered nodes, this results in a significant run-time overhead during the low-tier-lowering phase.

Optimizing this process would again require significant changes to the implementation of snippets and the lowering process itself, which is out of the scope of this paper. We reported our findings to the GraalVM compiler and GraalPy teams for further investigation.

4.5.4 Partial Evaluation

The partial-evaluation time of compilations is a long-standing problem in the GraalVM compiler and, as our evaluation shows, is responsible for up to 73% of the total compilation time. Therefore, finding an optimization opportunity in partial evaluation would improve a large portion of the overall compilation time in GraalVM guest language interpreters.

We narrowed the extraction scopes to sub-phases of partial evaluation to find possible optimizations to partial evaluation. The sub-phases include *decode-graph*, *cleanup-graph*, two *post-partial-evaluation suites*, *decode-inline-graph*, and the *inline post-partial-evaluation suite*, apart from several other optimization phases and sub-phases. Figure 10 shows the result of the narrowed extracted scopes. The plots only show the sub-phases with the highest compilation-time impact to improve readability.

Figure 10 shows that *graph decoding* (*DecodeGraph*, *DecodeInlinedGraph*) has the highest impact on compilation time spent in partial evaluation. Graph decoding iterates over a graph representation of the program IR, processing one node after the other. During the decoding, the GraalVM compiler applies several optimizations based on the type of each node. *Load-field* nodes for example, can be constant folded, while *invoke-with-exception* nodes, representing function calls, can be inlined. Partial evaluation performs graph decoding on the main partial-evaluation function (*DecodeGraph*), the function for which Truffle requests partial evaluation, and all functions inlined during partial evaluation (*DecodeInlinedGraph*). In Tier-2 compilations, graph decoding of inlined functions dominates the partial-evaluation time due to aggressive inlining policies, while in Tier 1, inlining is restricted.

We extracted the time spent processing specific node types during graph decoding by adding singleton scopes for all node types, as described in Section 3.2. Examples of node types are *load-field* nodes that load the field of an object, *if* nodes that represent an if statement, and *loop-begin* nodes representing a loop header. Figure 11 shows the result of the individual node types. The plots only show the node types with the highest impact on compilation time to improve readability.

Figure 11 shows that *invoke-with-exception* nodes dominate the graph-decoding process. Since *invoke-with-exception* nodes perform function inlining, it is expected that these nodes take up most of the total graph-decoding time. During inlining, *invoke-with-exception* nodes have to recursively decode the callee function and attach the resulting graph to the graph that is currently decoded. This process is already heavily optimized and most of its time is spent in the recursive decoding. Therefore, we did not further consider *invoke-with-exception* nodes for finding optimization potential. We instead focused on *load-field* nodes. We optimized the constant-folding performed for *load-field* nodes to improve the graph-decoding performance, as described in Section 5.2.

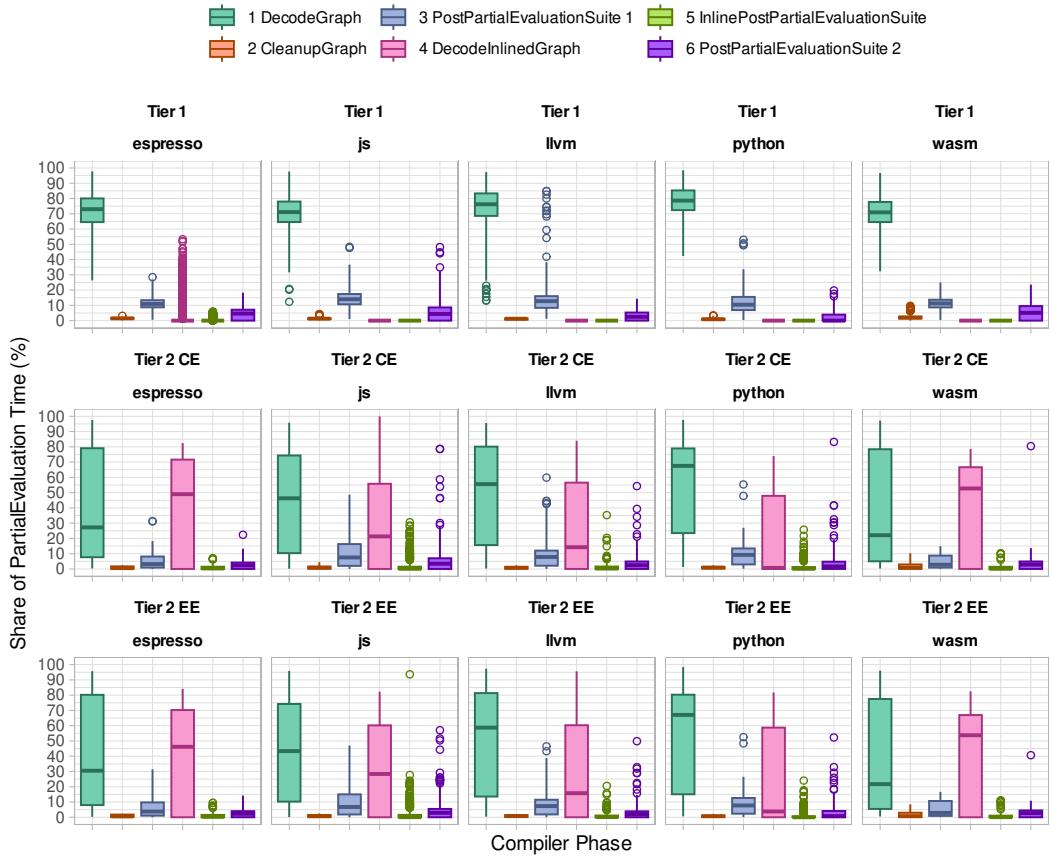

Figure 10 Compilation-time distribution of partial evaluation. Compiler phases are from left to right based on their index.

5 Optimization

5.1 Frame State Assignment – Optimizing Deletion Strategies

Graphs are a common way of implementing the intermediate representation of a compiler [39, 8, 7]. The design of these graphs is crucial because optimizations require an efficient way of traversing and manipulating the IR. The efficiency of these operations depends on the data structures used to represent nodes and edges in the graph.

GraalVM uses a directed graph that represents data flow and control flow in a single data structure [11, 12]. To model data flow, a node has *input edges*, pointing from the node using a value to the node defining this value. The reverse edges, so-called *usage edges*, which point in the opposite direction, are automatically maintained by the graph, so optimizations do not have to deal with maintaining them. However, in contrast to input edges, usage edges are not ordered and can only be accessed as an unordered set [11, 12]. Consequently, finding a specific usage of a node may require traversing the entire set. Unordered sets are a common way of reducing the memory footprint of the reverse-edge sets in JIT compilers³².

³²<https://chromium.googlesource.com/v8/v8/+refs/heads/main/src/compiler/node.h#181>,
<https://github.com/openjdk/jdk/blob/master/src/hotspot/share/opto/node.hpp#L319>

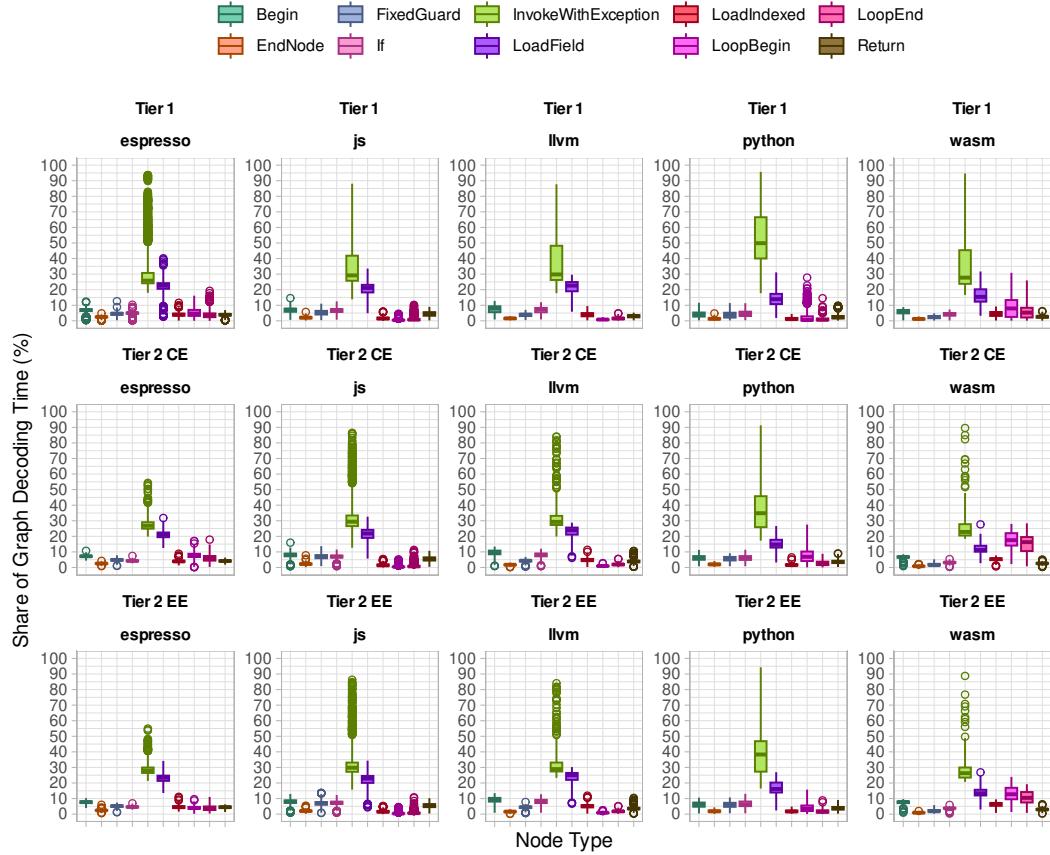

Figure 11 Compilation-time distribution of individual node types during graph decoding. Node types are from left to right in alphabetical order.

Usage edges are needed, for example, for deleting unused nodes in dead code elimination [29]. If a node is no longer used, its usage edges must be removed from all its inputs before the node can be deleted. As a result of deleting a usage of an input node, the input node itself can become unused, i.e., its usage set may become empty. This can lead to the transitive deletion of other nodes, which, in the worst case, requires several full traversals of potentially countless node usage sets.

For the frame-state-assignment phase of the GraalVM compiler, the outlier analysis in Section 4.5.1 showed that the deletion of unused frame-state nodes is responsible for a substantial part of the mid-tier time.

Normally, the traversal of usage sets during the deletion of frame-state nodes does not represent a problem, since the number of frame-state nodes is usually small. However, the graphs in which we identified outliers contained hundreds of frame-state nodes due to excessive inlining, resulting in slowdowns in the frame-state-assignment phase. Therefore, we updated the algorithm for deleting nodes. In the original implementation, every unused node was visited one after the other, and the usage sets of the node's inputs were updated immediately when deleting the node. This led to a lot of usage set traversals due to the transitive deletion of nodes.

Instead of updating the usage sets of nodes immediately, the updated algorithm tracks the usage counts of nodes in a separate map. The algorithm performs a depth-first traversal of the graph starting at the inputs of the deleted frame-state nodes, updates the usage counts

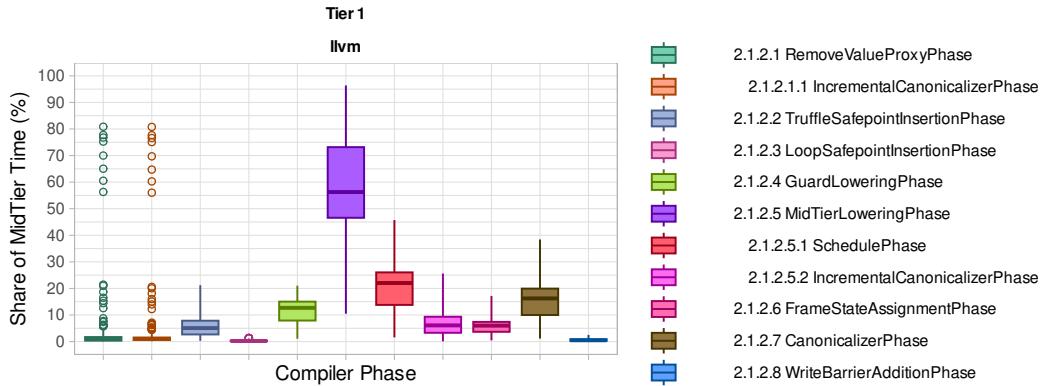

Figure 12 Compilation-time distribution of the mid tier in Tier-1 compilations after optimizing the frame-state-assignment phase. Compiler phases are from left to right based on their index.

in the map, and deletes unused nodes along the way. The traversal stops at nodes whose usage count in the map is non-zero. After the graph traversal, only nodes that are alive and have changed usage counts need to be updated. The pseudocode for the updated algorithm can be found in the appendix (Listing 3).

As a result of this optimized algorithm, the previous outliers no longer exist. We show the updated mid-tier compilation time of Tier-1 compilations in Figure 12. We also verified that the outliers no longer exist in Tier 2 (omitted from the paper). Due to the reduction of the time spent in the frame-state-assignment phase, new outliers in the *incremental canonicalizer phase* (2.1.2.1.1) arose that would be worth investigating, but are outside the scope of this paper. We confirmed that the new outliers were not caused by changes in the frame-state-assignment phase but were already present in the previous data set.

5.2 Graph Decoding – Constant-Fold Caches

Constant-folding is a crucial operation in compilers based on partial evaluation, because it allows these compilers to evaluate parts of the program at compilation time, and thus simplify the program [29, 1, 40]. When a partial-evaluation-based compiler identifies a constant in the program representation, many subsequent operations depending on that constant can also be replaced with constants. For example, a read operation from a field of a constant object (i.e., an object represented by a constant pointer), can be evaluated during compilation, and can be replaced with another constant that holds the value of the respective field.

Object-field reads and array reads on constant values are very common operations in interpreters, because the program representation is encoded in either ASTs or bytecode arrays [25], and the interpreter is partially evaluated for a given section of the program that is a constant value from the perspective of the compilation. Thus it is critical that constant-folding is executed very efficiently.

Reading a field from a constant object requires the compiler to (1) determine whether the field or an array location is guaranteed to remain constant after partial evaluation, and (2) to read the value from the respective offset in the program's memory. The first step usually relies on modifiers or annotations found in the source code of the interpreter. Both of these steps involve calls to the runtime environment, and rely on reflective metadata, which is usually expensive to obtain compared to a simple object-field read.

In the GraalVM compiler, the outlier analysis in Section 4.5.4 showed that the constant-folding of load-field nodes (which represent object-field reads in GraalIR) is responsible for a substantial part of the partial-evaluation time.

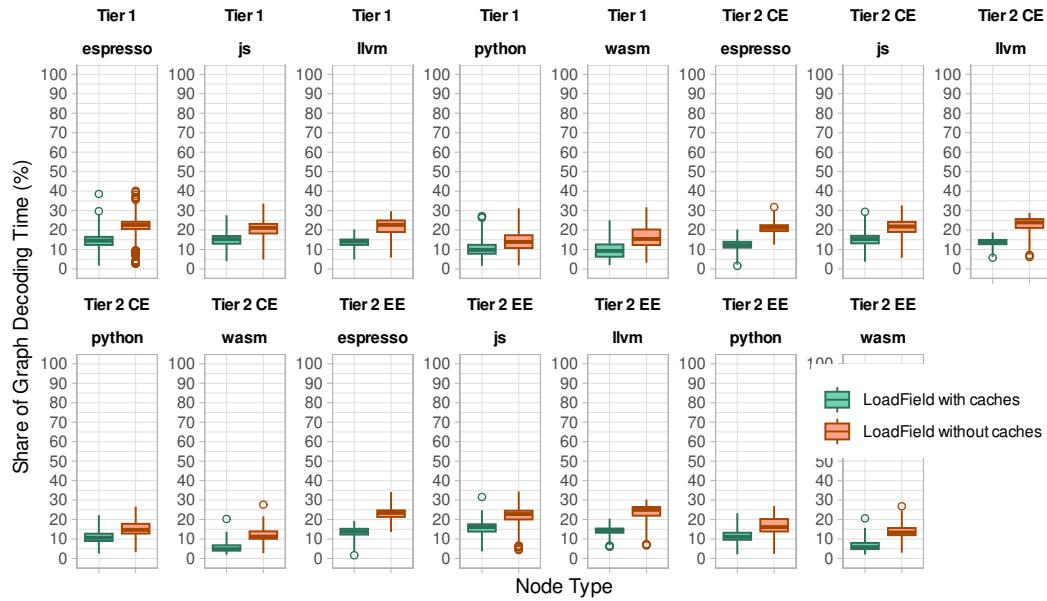

Figure 13 Comparison of time spent in load-field nodes during graph decoding before and after the introduction of caches. The time with caches is on the left in each plot, the time without caches on the right.

If the same constant occurs multiple times in an IR graph, it is represented by a single IR node to reduce memory footprint and compilation time [7, 8, 11, 12]. To maintain this graph property, the GraalVM compiler, before adding a new constant node to the graph, performs a graph traversal to look for equivalent nodes. This can be an expensive operation depending on the graph size.

In the current partial-evaluation implementation in the GraalVM compiler, all constant-folding attempts are independent. This means that the reflective metadata and value are loaded again and again regardless of whether this information was already retrieved by a previous constant-folding attempt. In addition, every constant-folding attempt allocates a new constant node that is discarded when the GraalVM compiler identifies an equivalent node in the graph. On average, the same constant field is read 8.5 times per compilation unit across all compiler tiers and editions. Therefore, to reduce the number of calls to the runtime environment as well as the number of allocated constant nodes and the number of graph traversals, we introduced a two-layer cache system in the constant-folding performed during partial evaluation.

As a result, the impact of constant-folding on partial evaluation was reduced, as shown in Figure 13. Overall, this optimization led to a compilation-time reduction between 2.25% (Python) and 6.88% (LLVM Runtime) in Tier 1, between 2.48% (Python) and 8.16% (WebAssembly) in Tier-2 CE, and between 4.49% (JavaScript) and 9.45% (Espresso) in Tier-2 EE.

6 Related Work

There is extensive research in the field of compilation-time optimization [22, 20, 30, 24, 2]. However, ICON, focusing on identifying outliers to find optimization opportunities in existing compilers, combines multiple aspects that we are not aware of being found together in any

sole research. It combines (1) iterative narrowing of scopes to analyze a problem with (2) focusing on outliers in extracted data to (3) improve compilation-time metrics. We, therefore, focus on related work in compiler optimization similar to ICON in at least one aspect.

Brown et al. [5], propose a data-driven methodology to identify the impact of compiler optimizations on security-oriented aspects of the generated machine code. They evaluate 20 benchmarks and analyze the availability of gadget sets used for code reuse attacks based on the enabled compiler optimizations in the GCC and Clang compilers. They perform a coarse-grained analysis based on optimization levels available in GCC and Clang, and a fine-grained analysis on individual optimizations in those compilers, similar to the narrowing of scopes in ICON. Furthermore, they use an outlier analysis to identify relevant compiler optimizations, similar to the outlier analysis defined in ICON.

Bryksin et al. [6], propose a method to identify code anomalies in order to find issues in compilers. They focus on source code fragments that are not typically found in a given programming language or uncharacteristic bytecode produced by a compiler. With anomaly detection algorithms, similar to the outlier detection in ICON, they identified several optimization opportunities in the Kotlin compiler.

Regarding compilation-time optimization, existing work can be categorized into approaches for phase selection and ordering [22, 30, 24, 2], automatic compiler optimization level selection [20], and automatic compiler heuristics or optimization tuning [14, 32]. Most existing approaches use machine learning and primarily focus on the common case instead of outliers.

6.1 ICON-like Approaches in Other Compilers

Based on online reports³³, compilation time is an important factor for many state-of-the-art compiler implementations. To improve these metrics, some compiler teams are actively working on improving their tooling to extract compilation-time metrics³⁴.

We surveyed the *V8*³⁵ JavaScript and WebAssembly compiler, the *Clang*³⁶ compiler in LLVM, the *GCC*³⁷ compiler, the Java *HotSpot* [23] compiler, and the C# *RyuJIT*³⁸ compiler in order to identify to which extent their capabilities overlap with the ideas proposed by ICON. Table 2 shows our findings from analyzing the documentation and source code of the compilers, as well as information provided by online forums and mailing lists. We tried to find out whether the compilers provide a way of extracting compilation-time metrics (column 1), whether they support the narrowing of extraction scopes (column 2), and whether they try to optimize compilation time based on outliers (column 3).

Based on the available compiler source code and the presence of compiler flags described in the online documentation, all surveyed compilers provide compilation-time metrics, although to varying degrees. To the best of our knowledge, HotSpot provides the compilation time

Table 2 Capabilities of compilation-time optimization of V8, Clang, GCC, HotSpot, RyuJIT, and GraalVM with ICON.

Compiler	Metrics extraction	Scope narrowing	Outlier analysis
V8	yes	no	no
CLANG	yes	yes	no
GCC	yes	yes	no
HOTSPOT	yes	no	no
RYUJIT	yes	no	no
GRAALVM WITH ICON	yes	yes	yes

across all compilations via the `-XX:+CITime` flag. V8 and RyuJIT report a fixed set of metrics for all compilation units via compiler flags (V8³⁹, RyuJIT⁴⁰). Clang⁴¹ and GCC⁴² provide detailed reports about time spent in individual optimizations via the `-ftime-report` flag.

Regarding scope narrowing, Clang allows passing a parameter to the `-ftime-report` compiler flag to differentiate whether the time is reported “per-pass” or “per-pass-run” to separate or combine individual pass executions. GCC supports narrowing via a separate compiler flag `-ftime-report-details`. As far as we know, none of the other compilers provide options to change the scope of extracted metrics.

To the best of our knowledge, the GraalVM compiler with our ICON enhancements is the only compiler using outliers to improve compilation time.

6.2 Synergy with Regression Testing

In addition to finding optimization opportunities in compilers, ICON is well suited to accompany compiler regression testing. While regression testing ensures that changes to the source code do not break existing compiler features and do not impair the correctness of the produced machine code [43], our approach ensures that changes to the source code do not lead to compilation-time regressions, additional memory allocation, or other aspects negatively impacting compilation. Therefore, in addition to ensuring the correctness of the output via regression testing, ICON ensures the efficiency of the compilation process and identifies any newly introduced defects. Both can execute the same tests, so no additional input programs are required to integrate ICON.

7 Conclusion

We presented ICON, a new data-driven approach to compilation-time optimization that splits high-level metrics into individual source program functions, compiler optimizations, or even into individual instruction in the compiler source code. By focusing on outliers in the extracted data, this approach can identify potential optimization opportunities in compiler implementations that are usually overlooked and provides a systematic approach to the analysis of compilation-time metrics.

⁴¹ <https://releases.llvm.org/12.0.0/tools/clang/docs/ClangCommandLineReference.html#cmdoption-clang1-ftime-report>

⁴² <https://gcc.gnu.org/onlinedocs/gcc/Developer-Options.html#index-ftime-report>

To demonstrate the effectiveness of our approach, we used ICON to extract a detailed view of the compilation time of the individual optimizations of the GraalVM compiler and performed a comprehensive outlier analysis on the resulting data with the goal of finding optimization potential. We found that most of the compilation time is spent in partial evaluation throughout all compiler tiers and editions, while the front end takes more time than the back end, especially in Tier-2 compilations.

The outlier analysis led to one language-agnostic and three language-specific outliers in compilation time. In the outlier analysis, the spatial component of the extraction-scope narrowing turned out to be useful at all levels. While the per-node analysis of partial evaluation helped us to identify an optimization opportunity in constant-folding, the per-phase analysis applied to the compiler mid tier, low tier and back end led to the detection of compiler defects in Python, JavaScript, and the GraalVM LLVM runtime, and helped us to develop an improved algorithm for the frame-state-assignment phase. Similarly, the temporal component was useful for analyzing Python, and we identified a single function as the compiler defect source.

Based on the identified optimization opportunities, we added additional caches to the constant-folding performed during partial evaluation and implemented a new deletion strategy for unused nodes in the frame-state-assignment phase. We reported the two remaining findings to the GraalVM compiler and language teams. The implemented optimizations improved compilation time in all languages between 2.25% (Python) and 9.45% (Espresso).

Abstract

Gradual typing has emerged as a promising typing discipline for reconciling static and dynamic typing, which have respective strengths and shortcomings. Thanks to its promises, gradual typing has gained tremendous momentum in both industry and academia. A main challenge in gradual typing is that, however, the performance of its programs can often be unpredictable, and adding or removing the type of a single parameter may lead to wild performance swings. Many approaches have been proposed to optimize gradual typing performance, but little work has been done to aid the understanding of the performance landscape of gradual typing and navigating the migration process (which adds type annotations to make programs more static) to avert performance slowdowns.

Motivated by this situation, this work develops a machine-learning-based approach to predict the performance of each possible way of adding type annotations to a program. On top of that, many supports for program migrations could be developed, such as finding the most performant neighbor of any given configuration. Our approach gauges runtime overheads of dynamic type checks inserted by gradual typing and uses that information to train a machine learning model, which is used to predict the running time of gradual programs. We have evaluated our approach on 12 Python benchmarks for both guarded and transient semantics. For guarded semantics, our evaluation results indicate that with only 40 training instances generated from each benchmark, the predicted times for all other instances differ on average by 4% from the measured times. For transient semantics, the time difference ratio is higher but the time difference is often within 0.1 seconds.

1 Introduction

Statically typed languages offer benefits such as early programming error detection, documentation, and better performance but can hinder program executions when they are incomplete or contain type errors. Dynamically-typed languages offer the benefits of fast prototyping and flexible usability but provide less program correctness guarantee. Traditionally, languages are either static or dynamic. In an effort to reconcile these typing disciplines, a typing discipline named *gradual typing* was developed and popularized in the last decade Siek and Taha [38],

21:2 Learning Gradual Typing Performance

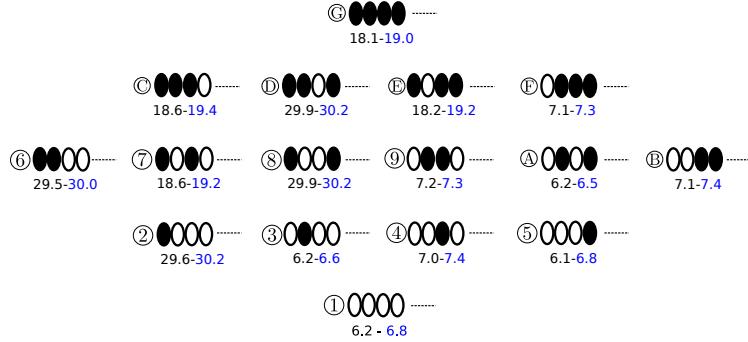

Figure 1 Part of the performance lattice for the Pascal benchmark. The lattice consists of 16 configurations, a combination of four parameters with each being typed or untyped. Each filled (unfilled) oval represents a typed (untyped) parameter. Each configuration shows only 4 ovals and omits the rest, which is the same across the 16 configurations. A circled number or letter is attached to each configuration for easy reference in the paper. Each configuration is associated with two times, separated by a ‘-’. The first time is the measured time of the configuration and the second (in blue) is the predicted time by our machine learning algorithm. All times are in seconds in the paper.

Siek and Vachharajani [39], Garcia and Cimini [13], Tobin-Hochstadt and Felleisen [42], Tobin-Hochstadt et al. [43], Campora et al. [6], Castagna et al. [9], Migeed and Palsberg [22], Phipps-Costin et al. [31], Greenman and Felleisen [14].

The main idea of gradual typing is that within a single program, parts of it may be statically typed (by giving type annotations to parameters in that part) and parts of it may be dynamically typed (by leaving out type annotations to parameters or explicitly giving them the dynamic type, written as `dyn`). Ideally, in gradual typing, prototyping and initial development is done with the dynamic aspect of the language, and programs are migrated to static aspect when performance and correctness becomes critical.

The goal of type migration is to add type annotations to parameters with dynamic types of a program. A commonly used notion in type migration is *configurations* Greenman et al. [15]. For any program, a configuration specifies which subset of all the parameters are typed. For example, in the fully dynamic configuration, this subset is empty, and in the fully static configuration, this subset includes all parameters. For a program with n parameters, there can be up to 2^n configurations since each parameter can be typed or untyped. We can organize all the configurations into a lattice such that the set of typed parameters in the join of two configurations is a union of those of the two configurations. To illustrate, Figure 1 presents a part of the lattice for the Pascal benchmark in Python.

1.1 Performance Problem in Type Migration

There are two issues related to gradual type migration:

- (1) finding parameters where type annotations could be added and
- (2) understanding performance changes and maintaining good (acceptable) performance as type annotations are added.

For issue 1, a lot of work has been done to automatically adding type annotations to dynamically-typed programs, including static approaches Castagna et al. [9], Kristensen and Møller [19], Campora and Chen [7], Rastogi et al. [34], Chandra et al. [10], Siek and Vachharajani [39], dynamic approaches Miyazaki et al. [24], Cristiani and Thiemann [11], and machine learning based approaches Mir et al. [23], Peng et al. [30], Pradel et al. [33],

Allamanis et al. [3]. Several approaches have also been developed to find best migrations in the sense of adding type annotations to as many parameters as possible Campora et al. [6], Migeed and Palsberg [22], Phipps-Costin et al. [31]. Issue 2, however, has received less attention.

While it is tempting to integrate all the type annotations suggested by a type migration tool Castagna et al. [9], Kristensen and Møller [19], Campora and Chen [7], Rastogi et al. [34], Chandra et al. [10], Siek and Vachharajani [39], Mir et al. [23], Peng et al. [30], Pradel et al. [33], Allamanis et al. [3], doing so may turn the original configuration into a new one that degrades performance significantly. The slowdown can be as high as more than 100 times Takikawa et al. [41], due to intricate type interactions. This is the case even when the type annotations for all the parameters in a single project are inferred. For example, in the spectral norm benchmark, the runtime for the fully typed configuration is about 2 times that of a configuration that has one fewer function typed Campora et al. [8]. The reason is that even all parameters in a project are typed, the libraries and third-party code used by the project may not be typed.

In general, after migrating from configuration K_s to K_e , manually or with the aid of type migration tools, the developer may face a few performance related questions. In particular, if the performance at K_e is not satisfactory, then the user will have to explore the performance of the neighbors of K_e to find a configuration that can restore the performance at K_s or whose performance is the best among all neighbors.

To illustrate, consider the performance lattice for the Pascal benchmark in Figure 1. The Pascal program has 19 parameters and thus 2^{19} configurations, and we present a part of the lattice in the figure. Assume the user is currently at configuration ① and a migration tool infers types for the four parameters, which corresponds to configuration ⑥. However, noting that the performance at ⑥ is about 3 times slower than that at ①, the user will explore the performance of neighbors and find one with good performance.

The problem is that there is no obvious strategy Greenman et al. [15], Takikawa et al. [41] that the user could employ to quickly find desired configurations. For example, a strategy like breadth-first-search will not find ⑥, the configuration that both has good performance and has largest number of parameters being typed, without trying ②, ③, and ④. Similarly, a strategy like depth-first-search will not find any configuration that restores performance until it goes back to the original configuration ①. This problem will become worse in practice due to three reasons. First, type migration tools may suggest adding types to many more parameters, which quickly enlarges the search space. Second, as the program becomes bigger, it takes more time to measure the performance of each configuration. Also, it takes more time to move from one configuration to another as more type changes are involved. Third, since each program has its own structure and type of interactions, as witnessed by very diverse performance lattices in different programs Takikawa et al. [41], Greenman et al. [16], Campora et al. [8], no single searching strategy works well for all programs.

The biggest problem is probably the uncertainty associated with the exploration process. If the user has not found a configuration with good performance following some strategy, should the user stick to the strategy in hoping that the performance will finally improve or change the strategy in fearing that performant configurations are in other neighborhoods.

1.2 A Machine Learning Based Solution

In this paper, we propose and develop `LearnPerf`, a machine learning based solution for this problem. For each program, we train a model from the running time for a very limited number (usually 40) of configurations. We then use this model to predict the execution times of other configurations. To give a sense of how the predicted times of `LearnPerf` look like, we present them in Figure 1 in blue.

Our prediction result is pretty accurate, with the *difference ratio* (defined as $|\text{predicted time} - \text{measured time}|/\text{measured time}$) often within 4%. On top of the prediction result, we can develop a series of migration support under different scenarios. We list some of them below.

1. `LearnPerf` is able to predict the performance for a given configuration. Assume the developer wants to migrate the current configuration to a new one, this information can inform how performance looks like at the new configuration.
2. `LearnPerf` is able to classify the performance of adjacent configurations. For a certain number of configurations around the current one, we can classify them according to performance speedup/slowdown scales. Takikawa et al. [41] introduced the notion 2-deliverable, which includes all configurations whose performance degrades by less than 2 times that of the original configuration, and 2-5 usable, which includes all configurations that slows down the original configuration by 2-5 times. With the help of `LearnPerf`, we can highlight configurations that are 2-deliverable, 2-5 usable, etc.
3. For each configuration, `LearnPerf` is able to find the most performant configurations within its neighborhood. If the user is not satisfied with the performance of the current configuration, this capability can suggest an alternating configuration with good performance.

Note that this work studies the performance aspect of type migration only and is not intended to develop a new type inference algorithm or machine learning algorithm to automatically add type annotations. As mentioned earlier, there has been a long line of research of adding type annotations but little work has been done for the performance aspect except for two papers Campora et al. [8], Greenman et al. [15]. Many approaches Feltey et al. [12], Ortin et al. [28], Moy et al. [25], Kuhlenschmidt et al. [20], Vitousek et al. [46] have investigated performance optimization of gradual typing. Our work is orthogonal to these approaches and we discuss the relation with them in Section 6.

To illustrate the usefulness of our migration support, assume the user was at configuration ① and has just migrated to ⑥ and observed that the performance at ⑥ is not satisfactory. `LearnPerf` can help in this case. For example, there are four neighbors of ⑥, ⑦ through ⑩. `LearnPerf` predicts that their running times are 19.4, 30.2, 19.2, and 7.3 seconds, respectively. Based on the predicted times, `LearnPerf` suggests the user to migrate to ⑩, rather than ⑥. We can observe that ⑩ slows down ① by only 15% while ⑥ slows down by 3 times.

Overall, `LearnPerf` finds ⑩ that reconciles both performance and static migration. It seems undesirable to migrate to ⑩ and not ⑥ because ⑥ adds a type annotation to one more parameter. In practice, this problem can often be solved by migrating a few parameters in unison in later migrations.

1.3 Workflow and Contributions of This Work

Figure 2 presents the workflow of `LearnPerf`. Starting from any “original program”, assume the user added some type annotations, manually or with the help of type migration tools. This will lead to a new, more precise program that has more type annotations than the original program. Note, that the new program may be partially typed or fully typed. As discussed earlier, both partial and fully typed programs may experience significant performance degradation. From the new program, we create 40 random training samples. We then extract relevant feature vectors that characterizes runtime performance as well as the running time for each generated configuration. This information is then input into `LearnPerf` for the purpose of training our model.

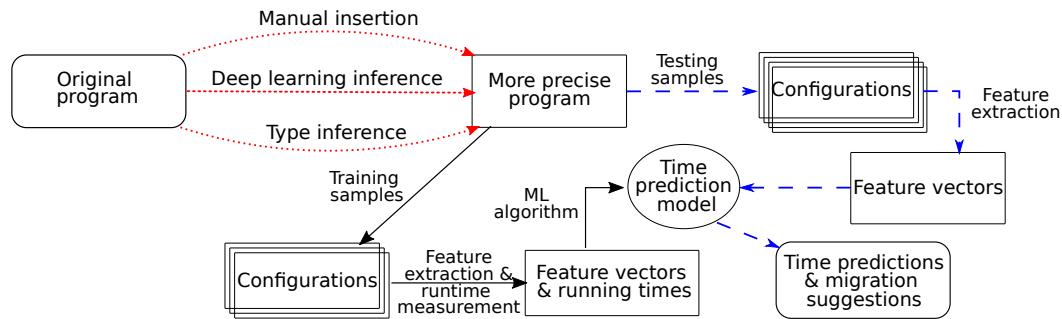

Figure 2 Workflow of LearnPerf. Solid arrows denote information flow in training phase and dashed, blue arrows denote that in prediction phase. Dotted, red arrows denote type annotation additions, and they are not a part of this work.

Once we have the trained model, we can support scenarios 1 through 3 by generating appropriate configurations and predicting their running times. Section 5 will sketch the main steps to support scenarios 2 and present our evaluation results.

In the above, the training will not start until the user initiates it. In practice, however, our approach will actively invoke a deep learning model Mir et al. [23], Peng et al. [30], Pradel et al. [33], Allamanis et al. [3] to generate type annotations. As a result, the performance prediction model could be ready before the programmer starts the migration process and needs migration support. We applied this idea to three large datasets for our evaluation (Section 5).

Overall, this paper makes the following contributions:

1. We develop a machine-learning based approach that can help understand the performance landscape of different configurations of a gradually-typed program. On top of that, many migration supports can be developed.
2. We explore different features to represent program run times and find out that overheads of casts inserted by gradual typing are simple yet representative features.
3. We implement our approach and evaluate its performance on twelve benchmarks, including nine benchmarks that are frequently used in gradual typing research and three larger benchmarks that each have more than 1000 LOC. We observe that with only 40 training instances, our predicted times differ from measured times by 4% only for guarded semantics. For transient semantics, the difference between the predicted time and measured time is often within 0.1 seconds.

The rest of the paper is organized as follows. In Section 2, we discuss the background of gradual typing. In Sections 3 and 4, we present our exploration of searching for appropriate machine learning model and representative features for precisely estimating execution times of gradual programs. In Section 5, we present the evaluation results, as well as implementation details and benchmarks used. We discuss related work in Section 6 and conclude in Section 7.

2 Background

This section covers the background of gradual typing, with a focus on cast insertions and their overheads.

In gradual typing, a parameter may be given a static type, a dynamic type (often written as `Dyn` or is omitted) signifying that the type is not known statically, or a mix of static and dynamic types. Static type checking is applied to program parts that use parameters with static types, and dynamic type checking is used for other program parts.

21:6 Learning Gradual Typing Performance

```

def myreduce(f, lst, init):
    result = init
    for i in range(len(lst)):
        result = f(result, lst[i])
    return result

def wider(cw:Int, ci>List(Int))>Int:
    return max(cw, len(ci))

myreduce(wider, [[1], [], [4,5]], 0)

```

```

def myreduce(f, lst, init):
    result = init
    for i in range(len(lst)):
        result = (f : Dyn => Dyn -> Dyn -> Dyn)(result, lst[i])
    return result

def wider(cw, ci):
    return max(cw, len(ci)) : Dyn => Int

myreduce(wider: Int -> List(Int) -> Int => Dyn,
        [[1], [], [4,5]] : List(List(Int)) => Dyn,
        0 : Int => Dyn)

```

 **Figure 3** A partially-typed version of `myreduce` (left) and its cast-inserted program (right).

For example, Figure 3 (left) presents a program snippet written in a hypothetical gradual language in Python type hint syntax Vitousek et al. [45]. The function `myreduce` takes in a binary function, a list, and an initial value and reduces the list to a single value. In this program, static type annotations are given to the parameters, and the return of `wider`. All other parameters have dynamic types. A static type error will be detected if we pass a string value as the first argument to `wider` because the first parameter has a type annotation `Int`. In contrast, no such error will be detected if we pass a string value as the first argument to `myreduce`.

Gradually-typed languages are often obtained by adding static type checking to underlie dynamic languages, such as Typed Clojure for Clojure, Typed Racket for Racket, and Reticulated Python Vitousek et al. [45] for Python. As such, a common implementation strategy of gradual typing is to translate its programs into programs in the underlying language and insert necessary runtime type checks (often called casts) during the translation.

For example, when executed by a gradual typing implementation for Python, the program in Figure 3 (left) is translated to the program in Figure 3 (right), which can be executed on any Python interpreter. Comparing programs in Figure 3 left and right, we observe two important differences. First, the program on the right does not have type annotations. This is because the interpreter for the underlying, dynamic language often does not make use of type annotations so they are erased during translation. Second, the program on the right has extra constructs in the form of `expr : src_type => trg_type`, which are often called casts. Such casts are inserted when the static type checker determines that `expr` has the type `src_type` but is used in a context where a value of `trg_type` is required.

As runtime type checks, these casts incur runtime overheads, and different casts lead to very different overheads. For example, the cast `x : Dyn => Int` can be performed where it appears as we can always verify if `x` is indeed an integer and is thus very lightweight. In contrast, the cast `g : Dyn => Int -> Bool` can not be verified where it appears because, for example, we do not know how `g` will be used and what arguments will be passed to it. As such, a proxy will be created for `g` such that the invocation of `g` will be handled by the proxy, which inserts a cast to check that the argument to `g` is `Int` and another cast to check that the return value of `g` is `Bool`. Such casts are more involved and lead to more significant overheads. Casts over data structures and objects are similarly heavyweight.

It is not hard to envision that adding or removing the type annotation for a single parameter in gradual typing may yield significant performance swings Takikawa et al. [41], Greenman et al. [16]. One might consider this a reason to abandon gradual language designs that enforce type invariants at runtime, but a study by Tunnell Wilson et al. [44] shows that programmers often expected the behavior of programs to emulate those done by gradual typing. This work in this paper enables programmers to enjoy the benefits of gradual typing while staying informed about the performance landscape as they migrate programs toward more static.

■ **Table 1** Deep learning model performance on unseen benchmarks.

Unseen Benchmark	# training	# testing	MAE	MSE	<i>DR</i>
Meteor	105945	1024	5.26	28.09	56.84%
Zebrafy	103969	3000	149.37	22350.18	86.96%
Pascal	101785	5184	22.82	653.85	273.42%
Chaos	100969	6000	25.67	784.96	35.57%
Richard	100969	6000	23.73	766.28	36.05%
Sieve	91608	15361	53.88	2933.99	1655.90%

Raytrace	73065	33904	6.49	46.29	110.17%

3 Feature Engineering

The two most important questions in machine learning are what kinds of models to train and what features will be used for representing programs. In this section and next, we present our exploration of searching for a suitable model and simple yet representative features.

3.1 First Attempt: Global Model with Deep Learning

Ideally, we train a *global* model that can be used to predict the runtime of different configurations for all user programs. Such a model needs to be trained only once by us (the model developer) and can be distributed to users (developers who migrate gradual programs) for use.

Motivated by recent successes of deep learning models for predicting types Mir et al. [23], Peng et al. [30], Pradel et al. [33], Allamanis et al. [3], our first attempt is to exploit deep learning to train a global model. For a given set of configurations for training and a set for testing, this process consists of several steps. The main challenge here is that the training instances may have different lengths. To solve this issue, we leverage source code embeddings that convert each configuration into an embedding that has the same length. Specifically, we use UniXcoder Guo et al. [17] to convert each configuration into a 4 * 768 float matrix. These embeddings, together with runtimes of corresponding configurations, are fed into a multi-layer perception network Popescu et al. [32] to train a global model. Based on the trained model, we can predict the runtime for each configuration in the test set.

To test the performance of this idea, we have developed a prototype and conducted experiments in two settings. In the first setting, we collected all configurations from nine benchmarks (listed in Table 1), with a total of 106,969 configurations (Section 5.1 will give more details about our evaluation benchmarks). We randomly choose 80% of them for training, 10% for cross-validation, and 10% for testing. In the second setting, we chose one benchmark for testing and used configurations from all other benchmarks for training. The main difference between these two settings is that in the first setting some testing configurations and training configurations may come from the same benchmark.

To measure the performance of this exploration and later ones in this paper, we use two of the most popular metrics for a regression problem, mean absolute error (*MAE*) and mean square error (*MSE*). In addition, to capture the accuracy or error ratio more intuitively, we used another metric called difference ratio, shortened to *DR*. The definitions of these three metrics are given below, where t_i and \hat{t}_i denote the measured and predicted running times of

the configuration i , respectively, and D denotes the testing set of instances. For example, if the measured and predicted times for a configuration is 7.9s and 8.1s, respectively, then the difference ratio for this configuration is 2.53%. We will use these notations throughout the paper.

$$MAE = \frac{\sum_{i=1}^D |t_i - \hat{t}_i|}{|D|} \quad MSE = \frac{\sum_{i=1}^D (t_i - \hat{t}_i)^2}{|D|} \quad DR = \frac{\sum_{i \in D} \frac{|t_i - \hat{t}_i|}{t_i}}{|D|}$$

The DR for the first setting is 147.58%. The details of the results for the second setting is given in Table 1. The results show that the global model trained with deep learning performs poorly. There are a few possible reasons. First, as discussed in Section 2, a gradual program is often translated to a base program in the untyped, underlying language with casts inserted. As such, the running time of a configuration roughly includes the time to execute the base program and the overhead due to casts. To be able to precisely predict the running time, we need to be able to do that for both parts. However, predicting the running time of a general program is still an open problem Matsunaga and Fortes [21]. Second, the overhead due to casts can vary significantly across different programs as it depends on program structures, such as whether casts are in loops, whether multiple casts are applied to single values, etc. Third, as discussed in Section 2, two configurations that differ by whether a single parameter is typed or not may have very different runtimes. This exhibits similar phenomena as in molecular property prediction where minor changes in molecular structures lead to significant changes of properties Stumpfe and Bajorath [40]. Earlier work Xia et al. [50] has demonstrated that deep models often do not perform well for such tasks.

For this reason, we decide to train an individual, project-specific model for each project in this work. Having decided which model to train, we next explore different feature representations to find representative features.

3.2 Second Attempt: Individual Models with Bit Strings

The problem of predicting gradual typing performance bears some similarity to performance prediction for highly-configurable software systems Kolesnikov et al. [18]. A highly-configurable program usually contains a large number of configuration options (for example, Linux has about 13,000 such options) for customizing the functional and non-functional features of the program. For instance, Linux can be configured to run on a diverse set of devices, ranging from embedding devices to servers. Each configuration option may be set or unset, corresponding to enabling or disabling associated features, which often leads to the inclusion or exclusion of certain pieces of code into the generated program after customization. As such, different configurations of the same configurable program will lead to different performances.

Understanding the performance landscape of configurable software systems is an important research problem, particularly as generating all possible programs and measuring their performance is infeasible due to the exponential complexity (the number of different configurations that can be generated is exponential in the number of configuration options). A prevalent solution to this problem is building a *performance-influence* model for each configurable software system. This can be achieved by generating a few samples, measuring the performance of these samples, and building a model from them. With the *performance-influence* model, predicting the performance of a certain configuration is instantaneous, without having to generate the configuration and measure the performance.

■ **Table 2** Python benchmark Performance (Bit strings).

Benchmark	# training	# testing	MAE	MSE	<i>DR</i>
Monte Carlo	40	344	0.53 ± 0.00	0.45 ± 0.00	35.30%

Pascal	2592	2592	3.81 ± 0.00	5.09 ± 0.00	20.45%
Chaos	3000	3000	1.72 ± 0.01	2.13 ± 0.00	3.41%
Richard	3000	3000	8.86 ± 0.01	13.05 ± 0.02	36.78%
BenchFirst	3000	3000	28.85 ± 3.05	36.58 ± 3.90	11.88%
Sieve	7680	7680	0.10 ± 0.00	0.13 ± 0.00	1.32%
Nbody	8192	8192	2.70 ± 0.00	3.58 ± 0.00	23.64%
Scimark	12544	12544	1.75 ± 0.00	2.42 ± 0.00	12.36%
Raytrace	16952	16952	2.81 ± 0.00	3.19 ± 0.00	18.84%

In gradual typing, each parameter can be typed or untyped, corresponding to enabling or disabling a configuration option. Due to this similarity, we started our exploration by using bit-string as features for machine learning. Specifically, we treat each parameter as a binary feature and use 1 to denote that the parameter is typed and 0 to denote it is untyped. Feature values for all parameters are concatenated together to form a bit-string, which forms the feature vector in this exploration.

We developed a prototype implementing this idea and tested its performance on 12 Python benchmarks (we will show details about them in Section 5.1). We present the result in Table 2. In the upper part of Table 2, we present the results with bit-strings as features when each individual model is trained with 40 configurations. We can observe that the average difference ratio (*DR*) is quite high for several benchmarks. For example, *DR* is around 92% for Zebrafy and 43% for Richard. We may think of increasing the number of training instances to boost the performance. Surprisingly, the performance does not increase significantly as we remarkably increase the number of training instances, as can be seen from the bottom part of Table 2. For example, as we increased the training instances from 40 to 2000 (that is we used 50% of instances for training) for Zebrafy, the average *DR* is still around 87%. Similarly, the average *DR* is about 37% for Nbody as we use 50% of all instances for training.

Another issue is that as we are training an individual model for each project, using too many training instances needs a very long preparation time. To solve this issue, we choose to generate a limited amount of configurations but extract highly effective features.

21:10 Learning Gradual Typing Performance

```

def myreduce(f:Function([Int,List(Int)],Int),
            lst>List(List(Int)), init:Int):
    result = init
    for i in range(len(lst)):
        result = f(result,lst[i])
    return result

def wider(cw:Int, ci>List(Int)) -> Int:
    return max(cw, len(ci))

myreduce(wider, [[1], [], [4,5]], 0)

```

```

def myreduce(f, lst, init):
    result = init
    for i in range(len(lst)):
        result = f(result : Dyn => Int,
                  lst[i]) : Int => Dyn
    return result

def wider(cw, ci):
    return max(cw, len(ci)) : Dyn => Int

myreduce(wider, [[1], [], [4,5]], 0)

```

Figure 4 The fully-typed version of `myreduce` (left) and its cast-inserted translation (right).

4 Third and Successful Attempt: Gauging Cast Overheads

The main reason that bit strings do not work well is that bits only represent whether parameters are typed or not while the types of parameters interact in an intricate way. This makes bit strings a poor candidate for capturing inserted casts, which are the main causes for performance overheads. For example, if we compare the programs in Figures 3 and 4, we can observe that while the program in Figure 4 (left) has strictly more type annotations than that in Figure 3, no such relation appears for the casts in the translated programs. In particular, these programs share only one common cast (the cast for the return value in `wider`), and all other casts are different. The running times of these two versions of `myreduce` are very different: the running time of the partially-typed version (Figure 3) is about 16 times that of the fully-typed version (Figure 4). In practice, removing or adding the type for a single parameter may lead to a completely different cast being inserted.

Thus, instead of using bit strings, we will next explore the inserted casts of the translated programs by gauging cast overheads. Our main idea is to give symbolic overheads to casts and let machine learning algorithm figure out the real overhead of each cast. To give a more formal account of our approach, we present the type syntax used for the rest of this section below.

$$\begin{array}{ll} \text{Base types} & U ::= \text{Bool} \mid \text{Int} \mid \text{Unit} \\ \text{Gradual types} & G ::= U \mid G \rightarrow G \mid \text{Dyn} \mid [G] \end{array}$$

Our type definition includes base types, ranged over by U , and gradual types, ranged over by G . Our base types include `Int`, `Bool`, and `Unit`, but they can be extended easily. In gradual types, we consider two type constructors: function types and list types. Again, they can be extended easily.

In the rest of this section, we first discuss how to gauge the overhead for individual casts (Sections 4.1 and 4.2) and then the overhead for a whole program (Section 4.3). Finally, we assess the effectiveness of cast overheads (Section 4.4).

4.1 Overheads for Individual Casts

Casts involving base types. Our first observation of gauging cast overheads is that casts have very different runtime overheads, as we discussed in Section 2. We first deal with casts that involve base types. For a cast of the form $U \Rightarrow \text{Dyn}$, it can be checked where it appears. We assign the symbolic overhead U^i to it. Similarly, for the cast $\text{Dyn} \Rightarrow U$, we assign the symbolic overhead U^p .

Casts involving function types. Next, we investigate overheads of casts that involve function types. In general, as discussed in Section 2, a function cast can not be verified where it appears. Instead, for a cast of the form $f: G_1 \rightarrow G_2 \Rightarrow G_3 \rightarrow G_4$, a proxy will be created to

wrap f . In place where f is called, the call is handled by the wrapper, which first casts the argument from G_3 to G_1 , calls f with the cast argument, and casts the return value of f from G_2 to G_4 . As such, a function cast induces two kinds of overheads: (1) the overhead that creates the proxy and (2) the overhead that casts the arguments and returned values. We refer to these two kinds of overheads as *creation overhead* and *invocation overhead*, respectively. The creation overhead should be similar across different proxy wrappers because type differences in casts do not cause the creation behavior to change much. As such, we assign F^c to represent a proxy creation overhead.

One challenge with invocation overheads is that they are incurred when the cast functions are invoked, not where the function casts appear. However, it is unclear when cast functions are invoked by looking at the translated program (neither with some standard static analysis) because cast functions may be assigned to other variables, stored in data structures, and passed over to other functions, and call sites can be very distant from where proxies are created. Our solution to this problem is to gauge the invocation overhead for each cast and directly add it to its creation overhead. This is very simple to implement: no complex alias analysis is needed.

Interestingly, this approach works well for predicting runtimes of configurations. Intuitively, the function cast created at the same program location will have the same invocation sites across different configurations since two configurations only differ by type annotations. Thus, if two casts cast the same function and have the same invocation overhead across two configurations, then they induce the same cast overheads. Of course, if the arguments to the cast functions in different configurations are cast differently, then the invocation takes different times to complete. However, such differences should be reflected through overhead differences of casts on the argument. Similarly, if the function cast in the first configuration has larger invocation overhead than that in the second configuration, then the cast function in the first configuration has more runtime overheads at invocation sites. We leave it to the machine learning algorithm that we use to train our model to figure out the relation between symbolic difference and the runtime difference for different configurations.

Another challenge in gauging invocation overheads is that unlike creation overheads that are similar across different function casts, invocation overheads can vary significantly, based on the types involved. For example, the cast $f1 : \text{Int} \rightarrow \text{Int} \Rightarrow \text{Dyn} \rightarrow \text{Dyn}$ should have a much smaller invocation overhead than $f2 : [\text{Int}] \rightarrow \text{Int} \Rightarrow \text{Dyn} \rightarrow \text{Dyn}$ because the cast for the argument for $f1$ is $\text{Dyn} \Rightarrow \text{Int}$ and that for $f2$ is $\text{Dyn} \Rightarrow [\text{Int}]$. As we have seen earlier, the cast $\text{Dyn} \Rightarrow \text{Int}$ is very lightweight while the cast $\text{Dyn} \Rightarrow [\text{Int}]$ involves the creation of another proxy over the argument (We will discuss casts involve lists later in this subsection), which will be treated as a list. Therefore, a plausible idea to accurately gauge invocation overheads is to assign different symbols for denoting different invocation overheads to different casts, based on their argument types and return types. The problem with this idea is that, however, we need to introduce a lot of different symbols for invocation overheads because within a program we could have many casts involving function types with different arities and different argument and return types. As we wanted to train our model with as few instances as possible, having too many symbols will negatively affect machine learning performance.

Our solution to this challenge is to break invocation overheads down and represent them with symbols we have already introduced. Our main insight is that an invocation overhead is originated from creating further casts at runtime. Thus, an invocation overhead can be approximated as a sum of all the creation overheads of the argument types and the return type. For example, for $f3 : (\text{Int} \rightarrow \text{Bool}) \rightarrow \text{Dyn} \Rightarrow \text{Dyn} \rightarrow \text{Int}$, the invocation overhead is creating a new function proxy for the argument to $f3$, which we have already introduced a symbol F^c , and

another cast for the $\text{Dyn} \Rightarrow \text{Int}$, which we used U^p to represent the overhead. Since the created function cast for the argument also introduces invocation overhead, we recursively apply this idea to the argument cast $\text{Dyn} \Rightarrow \text{Int} \rightarrow \text{Bool}$ and calculate its invocation overhead as $U^i + U^p$. Overall, the invocation overhead for the function cast $f3 : (\text{Int} \rightarrow \text{Bool}) \rightarrow \text{Dyn} \Rightarrow \text{Dyn} \rightarrow \text{Int}$ is $F^c + 2 \cdot U^p + U^i$. We give an algorithm for calculating cast overheads in Figure 5.

Casts involving list types. A cast involving list types, such as $l : \text{Dyn} \Rightarrow [\text{Bool}]$, also can not be verified where it appears because this cast ensures that future write accesses to l should add elements of type Bool only and future read accesses should get elements of Bool type. As such, similar to casts on function types, a proxy will be created for l and the proxy will make sure accesses to l have expected types. Therefore, the overhead of a list cast includes the creation overhead and access overhead. For the creation overhead, we use the symbol L^c to denote it.

For gauging access overheads, we face a challenge of locating where lists are accessed in the program, some of what we had for gauging invocation overheads for function casts. We adapt the solution there by gauging access overheads and add them to list creation overheads. For gauging access overheads themselves, the main insight is that list accessing can often be reduced to function calls Siek et al. [37], Vitousek et al. [45]. For example, for a list of type $[\text{Bool}]$, the function for ensuring that the element read from the list is Bool has the type $\text{Int} \rightarrow \text{Bool}$, where Int is the type of the parameter (list index) and Bool is the return type. The function for ensuring that the element added to the list is Bool has the type $\text{Int} \rightarrow \text{Bool} \rightarrow \text{Unit}$, where Int is the index type, Bool is the type of the element to be added to the list, and Unit is the return type of the function.

Based on this idea, the read access to the list l with the cast $l : \text{Dyn} \Rightarrow [\text{Bool}]$ can be reduced to the function cast $\text{Int} \rightarrow \text{Dyn} \Rightarrow \text{Int} \rightarrow \text{Bool}$, and the write access can be reduced to the cast $\text{Int} \rightarrow \text{Dyn} \rightarrow \text{Unit} \Rightarrow \text{Int} \rightarrow \text{Bool} \rightarrow \text{Unit}$. Thus, the access cost is approximated to be the cost of these two function casts. In practice, other operations may be performed on a list, such as insertion, extension, popping, and obtaining the length. However, read and write accesses are good representatives of access overheads because they are used frequently while others may not need function casts. Moreover, as we did in gauging invocation overheads, we only need to figure out the symbolic difference of list casts for the same list across different configurations, and let the machine learning algorithm scale that difference to appropriate runtime differences.

4.2 An Algorithm for Gauging Individual Casts' Overheads

We present an algorithm for gauging cast overheads in Figure 5. The algorithm is more general than our description in Section 4. For example, the algorithm deals with function casts that have multiple parameters. The algorithm is defined using the idea of pattern matching, and we assume that the most specific matching rule is used to handle the computation.

The main entry of the algorithm is the function $overHd$, which consists of eight cases. In the first case, the two types being cast are the same. Standard gradual typing implementations simply drop such casts, and so we assign 0 as its overhead. Cases two and three deal with casts between Dyn and function types, and we extend Dyn into a function type with the same arity as the function on the other side and delegate the computation to case eight of $overHd$. Cases four and five deal with casts between two function types that have different number of parameters. We assume that corresponding parameter types (such as G_1 and G'_1) and return types are consistent Siek and Taha [38]. We extend the type with fewer parameter types by padding it with DyNs . Cases six and seven deal with casts between Dyn and list types and are

$$\begin{aligned}
& \text{overHd}(G \Rightarrow G) = 0 \\
& \text{overHd}(\text{dyn} \Rightarrow G_1 \rightarrow \dots \rightarrow G_r) = \text{overHd}(\text{dyn} \rightarrow \dots \rightarrow \text{dyn} \Rightarrow G_1 \rightarrow \dots \rightarrow G_r) \\
& \text{overHd}(G_1 \rightarrow \dots \rightarrow G_r \Rightarrow \text{dyn}) = \text{overHd}(G_1 \rightarrow \dots \rightarrow G_r \Rightarrow \text{dyn} \rightarrow \dots \rightarrow \text{dyn}) \\
& \text{overHd}(G_1 \rightarrow \dots \rightarrow G_i \rightarrow \text{dyn} \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_{i+j} \rightarrow G'_r) \\
& \quad = \text{overHd}(G_1 \rightarrow \dots \rightarrow G_i \rightarrow \text{dyn} \rightarrow \dots \rightarrow \text{dyn} \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_{i+j} \rightarrow G'_r) \\
& \text{overHd}(G_1 \rightarrow \dots \rightarrow G_{i+j} \rightarrow G_r \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_i \rightarrow \text{dyn}) \\
& \quad = \text{overHd}(G_1 \rightarrow \dots \rightarrow G_{i+j} \rightarrow G_r \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_i \rightarrow \text{dyn} \rightarrow \dots \rightarrow \text{dyn}) \\
& \text{overHd}([G] \Rightarrow \text{dyn}) = \text{overHd}([G] \Rightarrow [\text{dyn}]) \\
& \text{overHd}(\text{dyn} \Rightarrow [G]) = \text{overHd}([\text{dyn}] \Rightarrow [G]) \\
& \text{overHd}(G_1 \Rightarrow G_2) = \text{createOH}(G_1 \Rightarrow G_2) + \text{callOH}(G_1 \Rightarrow G_2) \\
& \text{createOH}(\text{dyn} \Rightarrow U) = U^p \\
& \text{createOH}(U \Rightarrow \text{dyn}) = U^i \\
& \text{createOH}(G_1 \rightarrow \dots \rightarrow G_r \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_r) = F^c \\
& \text{createOH}([G_1] \Rightarrow [G_2]) = L^c \\
& \text{callOH}(\text{dyn} \Rightarrow U) = 0 \\
& \text{callOH}(U \Rightarrow \text{dyn}) = 0 \\
& \text{callOH}(G_1 \rightarrow \dots \rightarrow G_n \rightarrow G_r \Rightarrow G'_1 \rightarrow \dots \rightarrow G'_n \rightarrow G'_r) \\
& \quad = \sum_1^n \text{overHd}(G'_i \Rightarrow G_i) + \text{overHd}(G_r \Rightarrow G'_r) \\
& \text{callOH}([G_1] \Rightarrow [G_2]) \\
& \quad = \text{overHd}(\text{int} \rightarrow G_1 \Rightarrow \text{int} \rightarrow G_2) + \text{overHd}(\text{int} \rightarrow G_1 \rightarrow \text{unit} \Rightarrow \text{int} \rightarrow G_2 \rightarrow \text{unit})
\end{aligned}$$

 **Figure 5** An overhead gauging algorithm.

similarly delegated to case eight. Case eight deals with all cases not matched by earlier cases. It says that the overhead is an addition of the creation overhead, returned from *createOH*, and the call overhead, returned from *callOH*.

The definition of *createOH* is straightforward: it assigns a corresponding symbolic overhead to each kind of cast. The function *callOH* implements the idea of invocation overheads and access overheads discussed in Section 4. For casts involving base types, the call overhead is 0 because they can not be invoked or no elements may be accessed from them. The call overhead for a function cast is the overhead of casting all parameter types plus that of casting the return type. The call overhead for a list cast is the total overhead of read access and write access.

The following example illustrates the calculation process for gauging the overhead for the cast *dyn* \Rightarrow [*Bool*].

$$\begin{aligned}
& \text{overHd}(\text{dyn} \Rightarrow [\text{Bool}]) \\
& = \text{overHd}([\text{dyn}] \Rightarrow [\text{Bool}]) \\
& = \text{createOH}([\text{dyn}] \Rightarrow [\text{Bool}]) + \text{callOH}([\text{dyn}] \Rightarrow [\text{Bool}]) \\
& = L^c + \text{callOH}([\text{dyn}] \Rightarrow [\text{Bool}]) \\
& = L^c + \text{overHd}(\text{int} \rightarrow \text{dyn} \Rightarrow \text{int} \rightarrow \text{Bool}) + \text{overHd}(\text{int} \rightarrow \text{dyn} \rightarrow \text{unit} \Rightarrow \text{int} \rightarrow \text{Bool} \rightarrow \text{unit}) \\
& = L^c + F^c + \text{overHd}(\text{int} \Rightarrow \text{int}) + \text{overHd}(\text{dyn} \Rightarrow \text{Bool}) + \text{overHd}(\text{int} \rightarrow \text{dyn} \rightarrow \text{unit} \Rightarrow \text{int} \rightarrow \text{Bool} \rightarrow \text{unit}) \\
& = L^c + F^c + 0 + U^p + F^c + \text{overHd}(\text{int} \Rightarrow \text{int}) + \text{overHd}(\text{Bool} \Rightarrow \text{dyn}) + \text{overHd}(\text{unit} \Rightarrow \text{unit}) \\
& = L^c + F^c + 0 + U^p + F^c + U^i \\
& = L^c + 2 \cdot F^c + U^p + U^i
\end{aligned}$$

Due to the limited space, the algorithm in Figure 5 deals with base types, function types, and list types only. Our implementation supports many more types, including dictionary types, tuples, objects, records, and several others, with the same idea.

4.3 Representing Overheads for a Program

Without the loss of generality, we assume that a program consists of a few functions and top-level statements. When the program is translated, casts are inserted into function definitions and top-level statements. To extract the feature vector for a program, we repeat the following for each function. For each cast inserted in the function, we use Figure 5 to calculate the overhead. We then sum the overheads for all casts together. If a cast appears in a loop, then we automatically instrument the loop, obtain the number of times the loop is executed, and multiply the cast overhead by that number. For example, if a function has two casts that are outside of loops and have the overheads $F^c + U^p$ and $L^c + F^c + U^p + U^i$, then the total overhead for that function is $L^c + 2 \cdot F^c + 2 \cdot U^p + U^i$. The feature vector for that function is the coefficients of all overhead symbols, represented as 1, 2, 2, 1 in this case. The machine learning algorithm will turn these coefficients into runtime predictions.

Similarly, for the casts inserted in top-level statements, we calculate the overhead of each cast and sum them together.

Finally, we concatenate representations for all functions and top-level statements, forming a list of coefficients. This list will be the feature representation of the whole program.

4.4 Assessing Feature Effectiveness

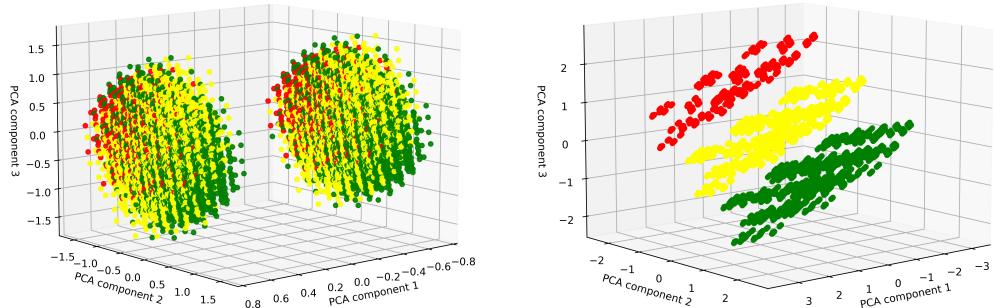

Figure 6 3D PCA analysis for Nbody using bit strings (left) and cast overheads (right). Both figures are generated with elevation of 10.0 and use azimuth angle 50.

Our approach `LearnPerf` is developed using cast overheads as features. For all the benchmarks we used to evaluate the performance, the DR is always less than 4% except for one benchmark whose DR is 5.3% (We will present the results in more detail in Section 5). In general, this means that our predicted time is in average within 4% of difference compared to the real measured time. We view this as a significant improvement over the performance of bit-string based solution, where DR is often higher than 30% and can be as high as 90%.

We have performed a PCA analysis Abdi and Williams [1] to understand the effectiveness of both bit strings and cast overheads. Figure 6 presents the analysis results for Nbody. In the figure, axes represent values of PCA components and colored circles represent configurations. In particular, configurations with similar running times get the same color. The running times of Nbody are roughly in three groups: those less than 7.5s (seconds), between 12.5s and 15s, and more than 20s (see Figure 7 for more details). From Figure 6, we can observe that bit strings fail to separate configurations while cast overheads successfully separate configurations according to their runtimes. Intuitively, clear separations of configurations according to their runtimes mean fewer prediction errors. This shows the usefulness of using cast overheads as features.

Table 3 Python benchmarks used for performance evaluation. The last column gives the number of configurations generated for the corresponding benchmark.

Benchmark	LOC	# of functions	# of pars	# of typed pars	# of configurations
Monte Carlo	90	4	9	9	385
Meteor	238	8	26	14	1024
CPU	2824	32	39	23	2897
Zebrafy	1578	28	72	38	4000
Pascal	70	7	19	15	5184
chaos	271	22	42	29	6000
Richard	455	21	94	67	6000
BenchFirst	1017	27	76	54	6000
Sieve	56	9	22	21	15361
Nbody	195	4	21	18	16384
Scimark	65	5	22	17	25088
Raytrace	254	37	67	38	33904

5 Performance Evaluation

We have implemented `LearnPerf` in Python. The main components are type addition, feature extraction, model training. Some of evaluated benchmarks are adopted from earlier work in gradual typing Campora et al. [8], Vitousek et al. [45], which already have type information. For other benchmarks, we use HiTyper (Peng et al. [30]), a state-of-the-art deep learning approach, to infer types that may be added. One issue with HiTyper is that some inferred types are erroneous, as noted by Yee and Guha Yee and Guha [51]. We remove a type annotation whenever adding it causes static type conflicts. We generate a new, more precisely typed program after merging the type annotations from HiTyper into the original program. From the new program, we generate a desired number of configurations for each benchmark (Table 5).

We implemented feature extractions on top of Reticulated Python (Vitousek et al. [45, 47, 46]). To test the generality of our approach, we have implemented feature extractions for both the guarded semantics Vitousek et al. [45] and transient semantics (Vitousek et al. [47]). Since these two semantics lead to different translated programs, we have different feature extraction codes. However, both implementations are based on the idea of gauging cast overheads, discussed in Section 4. Our feature extraction, which totals about 1,850 lines of code, supports the most commonly used Python types, including lists, functions, dictionary types, tuples, iterables, objects, classes, and many others.

The model training component is implemented on top of the scikit-learn Pedregosa et al. [29] package, a frequently used machine learning Library in Python. We use scikit-learn’s various models, its training-testing data split package, and its metrics package. This component includes less than 200 LOC.

5.1 Benchmarks

To evaluate the performance of `LearnPerf`, we adopted nine benchmarks that were commonly used in gradual typing research in Python (Vitousek et al. [47, 46], Campora et al. [8]. These programs are relatively small, often below 500 LOC. In addition, we adopted three large benchmarks, including Zebrafy (a Python program for creating PDF files) and CPU

Benchmark and BenchFirst (two performance bench-marking programs). For each benchmark, we present the name, lines of code, number of functions, number of parameters, number of parameters that are typed originally or with the help of HiTyper, and total number of configurations we generated for evaluating our performance in Table 3.

The number of configurations generated for each benchmark is mainly determined by two factors: the number of parameters in the benchmark and the time required to run each configuration. For example, each configuration in Zebrafy, CPU Benchmark, and BenchFirst takes more than 100 seconds to finish. As a result, we generate about only 4000 configurations for such benchmarks.

The configurations for each benchmark for evaluating performance are generated follow the insights from Greenman et al. [16] to ensure that they are representative. We can imagine that all configurations from a benchmark be organized into a lattice based on the parameters that are typed. The lattice includes 2^n configurations if n parameters are typed. All configurations in the same row of the lattice assign types to the same number of parameters. For example, the bottom-most row assigns types to zero parameters, and the row above assign types to only one parameters, and the row above that assign types to two parameters, and so on.

In our experiments, we generated configurations such that every row of the lattice is covered. Moreover, we try to maintain same proportion of generated configurations over all configurations in a row across all rows. However, for middle rows, the percentage is smaller because there are too many configurations in them. For example, the middle row has $C_n^{\frac{n}{2}}$ configurations. Once these configurations are generated, we randomly split them so that 40 are used for training and the remaining are used for testing. Note, we repeated 5 times for the training/testing process.

The running times in this paper are measured on a machine equipped with Intel(R) Core(TM) i9-9900K CPU @ 3.60GHz, 8 Core(s), and 16GB RAM. Each measured time is an average of 10 runs.

Figure 7 gives an idea of how execution times look as a certain number of parameters are typed. The figure shows that while the running times of some benchmarks are clustered, others are scattered. We believe that these benchmarks serve the evaluation purpose well.

Our evaluation focus on Scenarios 1 and 3 only. The result for Scenario 2 is similar to that for Scenario 3, and we omit it in the paper.

5.2 Supporting Scenario 1

To simulate the real development scenario, we randomly selected 40 instances from all generated configurations as training instances, and we use linear regression to train a time prediction model. Compared to standard machine learning applications, our approach uses significantly fewer data instances for training.

To ensure that the model correctly learns patterns from the data and doesn't pick up too much noise, we used k-fold cross-validation technique. As is standard in machine learning practice, our results are averaged over all k trials to get the overall performance of the model. We set k to 5 in our evaluation. Experiments were run on the same machine we used for generating benchmark's configurations.

Table 4 describes the performance of `LearnPerf` on all evaluated benchmarks. Columns three through five of the table show that even when the model is trained with only 40 instances, our prediction result is very accurate, with DR (defined in Section 3.2) less than 3% for nine benchmarks, between 3% and 4% for two benchmarks, and is 5.26% for one benchmark. Intuitively, this means that our predicted times are very close to measured times.

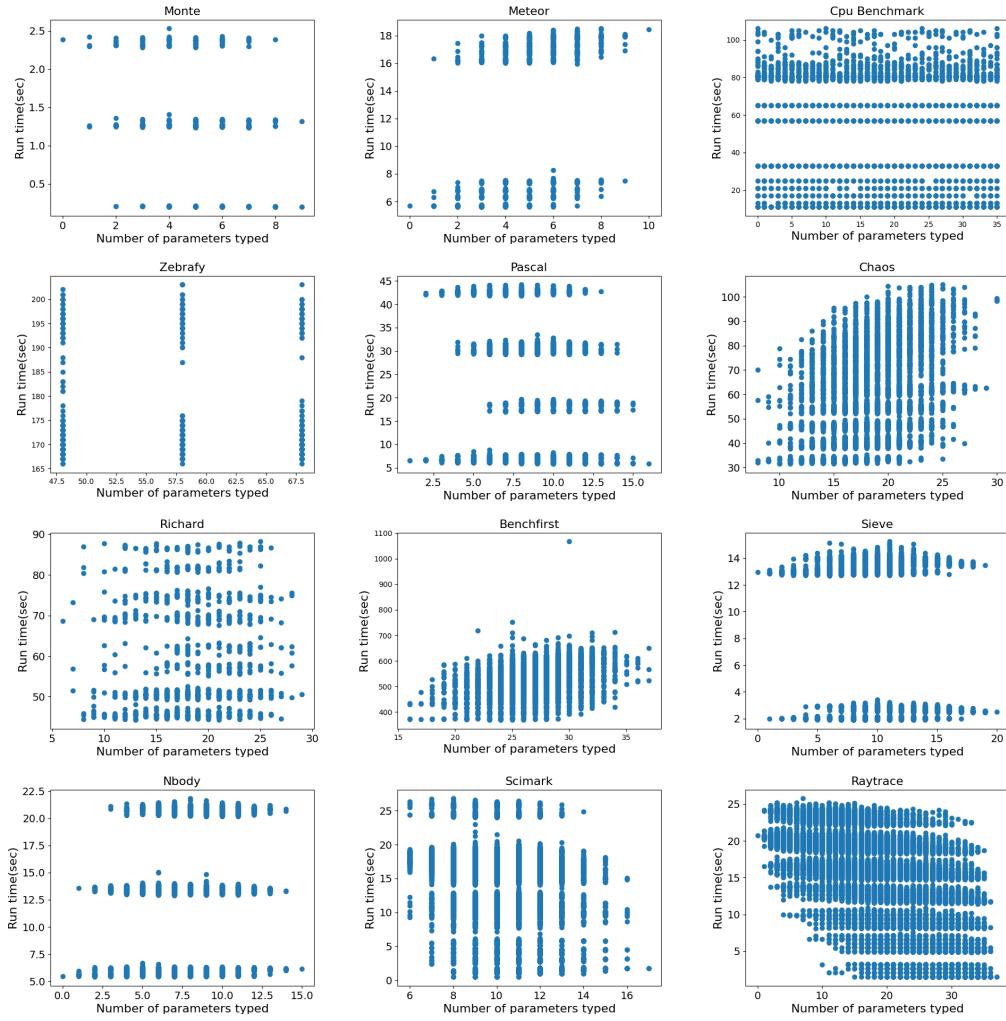

Figure 7 Benchmark's configurations description: Run Time vs Number of parameters typed for each benchmark.

Columns six and seven of Table 4 present the ratios of configurations whose *DR* are less and greater than 10%, respectively. The result shows that there are fewer configurations that have large difference ratios.

Figure 8 presents a closer investigation of the evaluation result. Specifically, we divide each benchmark into five groups in terms of their measured running time of different configurations of the benchmark. Next, we predict the performance (running time) and measure the *DR* of all configurations within each group. For every group, green represents a *DR* of less than 5%, cyan represents 5 to 10%, blue represents 10 to 15%, violet represents 15 to 20%, and red represents more than 20% of *DR*. The figure reveals that, in general, the configurations that have smaller running times tend to experience higher *DRs*. There are two potential reasons behind this. First, a small variance in predicted time for such configurations can lead to a higher *DR*. Second, even averaged over ten runs, each measured time includes a small randomness due to computer execution dynamics, and the randomness in such configurations has a more conspicuous impact.

Table 4 The performance of `LearnPerf` on evaluated benchmarks. The model for each benchmark is trained with forty randomly selected configurations. The second column gives the number of testing instances (configurations). Columns three through five gives the average performance of all testing instances. Columns six and seven give the ratios of instances whose *DR* are less than and greater than 10%, respectively.

Benchmark	# testing	MAE	MSE	<i>DR</i>	<10%	>10%
Monte Carlo	344	0.05 ± 0.01	0.07 ± 0.01	3.597%	93.77%	6.23%
Meteor	984	0.32 ± 0.01	0.39 ± 0.02	2.70 %	97.35%	2.65%
CPU	2857	1.56 ± 0.01	2.07 ± 0.08	1.91%	99.80%	0.2%
Zebrafy	3960	2.70 ± 0.00	3.63 ± 0.00	1.57%	92.88%	7.12%
Pascal	5144	0.37 ± 0.03	0.460 ± 0.04	2.10%	95.55%	4.45
Chaos	5960	2.37 ± 0.07	2.92 ± 0.09	3.56%	97.09%	2.91%
Richard	5960	0.55 ± 0.00	0.71 ± 0.00	0.91%	100%	0.0%
BenchFirst	5960	17.12 ± 0.03	25.06 ± 0.7	5.26%	86.04%	13.96%
Sieve	15321	0.17 ± 0.01	0.23 ± 0.01	2.18%	89.06%	10.94%
Nbody	16344	0.21 ± 0.01	0.25 ± 0.01	1.84%	99.86%	0.14%
Scimark	25048	0.14 ± 0.04	0.193 ± 0.05	0.97%	98.92%	1.08%
Raytrace	33864	0.26 ± 0.06	0.330 ± 0.09	1.73%	94.46%	5.54%

5.3 Supporting Scenario 3

Scenario 3 aims to find the neighbor with best performance for any given configuration. This is particularly helpful when the current configuration has poor performance and the user wants to find a neighbor with good performance. We can imagine that there are two lattices with the current configuration. One grows up, adding more type annotations to current configuration, and one grows down, removing type annotations from the current configuration. We then use the idea of these two method to choose neighbors. However, here we consider configurations that add/remove up to seven parameters. To evaluate how well `LearnPerf` can support this scenario, we randomly choose a certain number of configurations, and find the most performant neighbor of it using our model.
